Historically, there has been little agreement on a precise definition of the term “failure to thrive” (FTT). It has been defined in several ways, including by weight centile, by weight-for-height and by growth faltering over time (Benoit, 2000). Traditionally, FTT was divided into two subgroups: organic and non-organic, the latter term carrying connotations of psychosocial causation, such as parental neglect, abuse or poor management of feeding. However, more recently the assumption of a clear-cut distinction between organic and non-organic FTT has been called into question (Boddy & Skuse, 1994; Chatoor & Ganiban, 2004). Absence of a physical explanation does not mean that poor parenting is necessarily the cause. However, attributing growth delay to parental neglect may be unhelpful (Skuse, 1985), and in some cases may have harmful consequences. Furthermore, many children with non-organic FTT turn out later to have undiagnosed illnesses or impairments in oral–motor skills. One population survey (Reilly, Skuse, Wolke, & Stevenson, 1999) found oral–motor dysfunction in 35% of children with non-organic FTT, suggesting that assumptions about parental causes may often be unwarranted. Finally, as discussed in relation to other early behavior problems, FTT is now thought likely to have multifactorial causes, where factors such as temperament, developmental delay and poor feeding skills interact with parental stress and poor management of feeding. In a UK population survey of growth delay (Skuse, Reilly, & Wolke, 1994), a prevalence rate of 3–4% was found. However, it was also noted that there was considerable variation between ethnic groups, with higher rates among South Asian and lower rates in African groups. We should be cautious about assuming that these are related to cultural differences in early feeding patterns; it is also possible that norms are inadequate for defining growth faltering in minority groups.

Food Refusal
Food refusal is a general term for a range of feeding problems, broader than DSM “Feeding disorder of infancy and early childhood,” as it focuses on child behavior rather than requiring growth failure. It includes children of normal weight who consistently or selectively refuse to eat. Selective refusal may be unpredictable, or may be specific to certain foods or situations (Chatoor & Ganiban, 2004; Douglas, 2002). In toddlers, it may be linked to other behavioral problems, or may be limited to feeding contexts. It may be related to long-standing early feeding problems or arise anew in the “terrible twos.” Again, causes are likely to be multifactorial, including combinations of temperament, family stress and poor parenting skills, as for other oppositional problems. In many cases, there may be more specific contributing factors related to food, including feeding experiences, parental anxiety about food and body shape or prior health problems that might initiate the feeding problem (e.g., pain or anxiety about vomiting or reflux), which may then be unwittingly reinforced by parental reactions (Douglas, 2002; Stein & Barnes, 2002).

Treatment
General Principles for Selecting Treatments
From earlier discussions of multiple interacting factors that contribute to behavioral problems in the 0–5 period, it will be clear that intervention requires assessment of the presenting problems in the context of family and caregiver influences, as well as the child’s development and physical health. Thus, factors such as fussy temperament, parental inconsistency, stress of poverty, early illness and oral–motor delay may all combine to produce toddler eating problems. Knowing the causes of a problem can be helpful for understanding and selecting treatment; however, at the same time it is vital that clinicians use, wherever possible, interventions that have a strong evidence-base, and that they keep up to date with this knowledge as new trials and systematic reviews appear. Thus, knowing that oral–motor dysfunction is contributing to a long-standing eating problem in a toddler born very prematurely is helpful in making sense of a problem, and for reducing parental blame and guilt; however, arguably it is not useful information for treatment if there is no evidence of effectiveness of available speech therapy for oral–motor delay. However, there is better evidence about the effectiveness of parenting interventions for food refusal and other mealtime behavior problems (Kerwin, 1999; Turner, Sanders, & Wall, 1994). Parent management difficulties are only one of several causal factors contributing to early eating, sleep, oppositional or attentional problems, but parenting intervention might nevertheless be the treatment of choice. In this age group, it is developmentally appropriate and has the strongest evidence-base from randomized trials. This is the case even for preschool ADHD, where there is a clear genetic contribution to etiology.

Given these considerations, this section focuses on common principles behind evidence-based approaches, particularly...
CHAPTER 53

parent management of toddler behavior problems, as well as including specific guidance for clinicians. We concentrate on interventions with an evidence-base from high-quality systematic reviews, such as those published by the Cochrane Collaboration, and randomized controlled trials (RCTs). Some of these cover a wide age range but, where possible, we have sought effectiveness data applicable to the 0–5 age group. Readers are referred to other chapters for fuller details on particular problems and interventions.

Overview of Evidence

We begin with a brief overview of evidence on intervention effectiveness. A systematic review of interventions for early conduct problems age 3–8 (Barlow & Stewart-Brown, 2000) concluded that behaviorally based parent-training is effective. Several recent trials that comprise entirely, or high proportions of, preschoolers reach similar conclusions (Gardner, Burton, & Klimes, 2006; Hutchings, Bywater, Daley et al., 2007; Sanders, Markie-Dadds, Tully, & Bor, 2000; Scott, Spender, Doolan, Jacobs, & Aspland, 2001; Webster-Stratton, 1998a), suggesting that interventions are translatable across countries and varied service settings. Some programs appear to be equally effective across ethnic groups; a secondary analysis of 630 preschoolers in trials of the Webster-Stratton preventive parenting program found no differences by ethnicity on any parent or child outcome measures, or on parent engagement and satisfaction (Reid, Webster-Stratton, & Beauchaine, 2001).

For sleeping problems, systematic reviews suggest that behavioral parent management of settling and night-waking problems is effective (Mindell, 1999; Ramchandani, Wiggs, Webb, & Stores, 2000). For toddler and preschool eating problems, evidence from two very small RCTs and several case series leads to the tentative conclusion that parent management approaches may be effective (Turner, Sanders, & Wall, 1994). Kerwin’s (1999) review reached a similar conclusion for severe infant feeding problems. The picture is much less clear for early emotional disorders, as very few treatment trials include children under 5.

Medication is controversial in this age group, and practice varies between USA and Europe. For ADHD, stimulant medication is not licensed for preschoolers because of worries about safety, and parenting interventions have been found to be as effective in this age group as stimulant drugs are in older children (Sonuga-Barke, Daley, Thompson, Laver-Bradbury, & Weeks, 2001). Nevertheless, one trial claimed methylphenidate may be effective in preschoolers (Greenhill, Kollins, Abikoff et al., 2006), although it should be noted that the trial only included children for whom parent-training approaches were not effective, and there was quite a high rate of side effects. Tricyclic antidepressants are not recommended in prepubertal children (Hazell, O’Connell, Heathcote, & Henry, 2002), and there are considerable doubts about the effectiveness of selective serotonin reuptake inhibitors (SSRIs) in children of all ages (Whittington, Kendall, Fonagy et al., 2004).

Interventions for Disruptive Behavior Problems

We begin with principles of parenting interventions for early oppositional and attentional problems, while noting that these broad principles are also applicable to toddler eating and sleeping problems, particularly given the frequent comorbidity and common causes for these problems. Specific interventions for feeding problems follow. (For fuller details on parenting interventions see chapter 64. For useful detailed guides to carrying out parenting interventions in young children see Sutton, 1999; Webster-Stratton, 1992; Webster-Stratton & Herbert, 1994.)

Intervention begins with broad assessment of the child’s health, development and temperament, the overall family and caregiving setting, and a detailed evaluation of the frequency, duration and situational determinants of the presenting problems. In particular, assessment should focus on parenting strategies and other situational factors that may be triggering or maintaining the problem on a day-to-day basis. Equally important is examination of parenting strengths and competencies that can be built on in treatment. What are the positive features of the relationship between child and parents? Under what conditions does the problem fail to occur, or how have parents succeeded in preventing or alleviating it? Parenting strategies are best assessed through a combination of parent diary records, direct observation of parent–child interaction and careful interviewing. Observational methods are particularly useful for preschoolers (see chapter 19), who tend to be less reactive to being observed. There is increasing evidence that learning and putting into practice new parenting skills, carefully tailored to the child’s needs, is a critical intervening mechanism (Rutter, 2003) underlying successful interventions for early conduct problems (Forgatch & DeGarmo, 1999; Gardner, Burton, & Klimes, 2006; Gardner, Shaw, Dishion et al., 2007; Hutchings, Lane, & Gardner, 2004). Hence, this parenting assessment information is central to planning the main active ingredients of the intervention. Providing systematic sensitive feedback to parents about the findings of assessment may be helpful for several reasons (Dishion & Kavanagh, 2003; Shaw, Dishion, Gardnet et al., 2006), including to motivate parents’ engagement with challenging interventions; to reach a shared formulation and plan for treatment (rather than one that is imposed by the clinician); and to aid later skills coaching.

Although enhancing parenting skills is a key part of intervention for behavior problems, it is important to help the parents understand that they are not necessarily the main cause of the problem, rather that they are the best solution. Helping parents understand how the child’s temperament and development (e.g., language or cognitive impairment; see chapters 47 and 49) contribute to parenting and conflict can be very helpful in formulating a problem, and preparing the ground for skills-based work. A preschool ADHD intervention provides an excellent example of this approach (Sonuga-Barke, Daley, Thompson et al., 2001; Thompson, Weeks, & Laver-Bradbury, 1999). The first part of the intervention involves helping parents to understand and empathize with the individual temperamental characteristics of the child with ADHD,
and considering how some of the parents’ expectations and skills may need to be adapted to fit better with the child. Following this, parents work on setting new expectations and limits, and practice strategies to manage the child and change symptomatic behavior. As the majority of children with ADHD show comorbid conduct problems, such approaches are also applicable to changing oppositional behavior (Sonuga-Barke, Thompson et al., 2001).

Following assessment, intervention focuses on applying cognitive–behavioral parenting principles in an individualized manner to the child and family. An example of a well-specified effective parenting intervention is Webster-Stratton’s (1998a,b; Webster-Stratton & Herbert, 1994) “Incredible Years” program (see chapter 64), which employs a collaborative approach, building on parents’ strengths and expertise. Principles covered include parent–child play, praise, incentives, limit-setting, problem-solving and discipline. Video clips are used to encourage problem-solving around strategies to manage their child, and to illustrate their varying effects on child behavior. Role plays and homework are used to find solutions and practice parenting skills. In each session, homework successes and problems are discussed, and used as further problem-solving examples. Although this program is designed to be delivered to groups of parents, these principles are equally important in individual work with families of young children. Similar effective programs, aimed particularly at 2- to 5-year-olds, and designed to be carried out in a home or clinic setting with individual families, include Sanders, Markie-Dadds, Tully et al.’s (2000) Triple-P program, and Forgatch and DeGarmo’s (1999) Parent Management Training.

When advising parents about disruptive behavior, it is helpful to encourage them to observe and record their child’s behavior, the situations that trigger it, and their reactions and attempts at managing the behavior. It is important to help parents build a warm cooperative relationship with the child, especially if this appears to be lacking, by advising a regular daily joint play session, say 5–10 min, using an age-appropriate calm activity. Co-operative play should be encouraged and rewarded. Meanwhile, it is important for parents to explain simple ground rules to the child (behavior that is expected or prohibited, in key situations), and then to reward the child using praise, and token rewards (e.g., sticker or star charts) for behaving well, especially in situations that commonly lead to troublesome behavior. Planning ahead for how to deal with the most difficult situations is an important element. It is possible to plan to ignore milder problem behaviors, and use mild consequences for more severe problems (e.g., aggression, repeated defiance about important issues), such as time out (for 2–3 min at age 2–5) or brief immediate withdrawal of enjoyable activities. For milder problems, a Cochrane review suggests that self-help materials can improve disruptive problem behavior (Montgomery, Bjornstad, & Dennis, 2006). For example, books explaining evidence-based principles for managing early behavior problems (e.g., Sanders, 2004; Webster-Stratton, 1992) can be useful for parents, or for clinicians to work through with parents.

Non-attendance is a common problem in treatment services, and it behoves clinicians to find ways to overcome barriers to engagement, especially for distressed and disadvantaged families. Webster-Stratton (1998a,b) achieves this by offering flexible timing of intervention, transport and child care, which are particularly important for families with preschoolers. Other strategies include home-visiting, or using community locations, such as primary healthcare clinics (Stewart-Brown, Patterson, Mockford et al., 2004; Turner & Sanders, 2006). Others have developed specific strategies to enhance parent motivation (Dishion & Kavanaugh, 2003; Dishion, Shaw, Connell et al. (in press)). It is undoubtedly challenging to be flexible to parents’ needs when working in a clinic setting; without attention to these issues, attendance rates may remain low and the most troubled children may be unable to access services.

Interventions for Emotional Problems
There is a good deal of evidence from systematic reviews and randomized trials (Ollendick & King, 1998) to support the use of cognitive–behavioral interventions for anxiety and depression in school-age children, but few treatment trials include children under 5 years. However, there is some evidence from single-case studies and small trials (Ollendick & King, 1998) that the same techniques may be applied to 3- to 5-year-olds, provided the intervention is carefully matched to the children’s developmental level. There is also important evidence emerging about cognitive–behavioral interventions from studies aimed primarily at helping preschool conduct problems, namely Webster-Stratton and Hammond’s (1997) child-focused “Dinosaur” program. They find that cognitive–behavioral techniques, delivered using developmentally appropriate games and puppets, to groups of preschoolers, can reduce comorbid emotional symptoms as well as disruptive problems. Parental involvement in cognitive–behavioral interventions is useful in older children, especially where parents are very anxious, and may well prove to be helpful with younger children, pending further empirical validation (Barrett, Dadds, & Rapee, 1996). Chapter 63 describes detailed principles of cognitive–behavioral interventions for anxiety. These intervention principles can be adapted for the developmental level of preschoolers (Hirshfeld-Becker & Biederman, 2002); for example, using pictures to help with discussions about emotions, and by a greater focus on behavioral strategies, such as graded exposure and modeling to deal with phobias.

Interventions for Feeding Problems
Colic
A systematic review by Garrison and Christakis (2000) found 22 randomized trials of interventions for colic. Most trials were of poor quality, and the reviewers concluded that there was little clear evidence for efficacy of the various interventions tested. Medication did not appear to be effective; nor did infant carrying (although this has been found to be effective for other, less persistent forms of crying). There was slightly more promising support for helping parents to manage crying by
CHAPTER 53

reducing stimulation or improving communication skills, and some support for dietary interventions, including four small trials of hypoallergenic diets. Lactase was not effective. Because of methodological weaknesses, these results need to be treated with a great deal of caution, as putting infants on restricted diets, although potentially beneficial, could cause harm to the infant and unnecessary stress to the family. A recent trial of 600 neonates tested whether persistent crying could be prevented with behavioral interventions (St. James-Roberts & Gillham, 2001). Only modest effects on sleeping and crying were found, representing an increase of 10% in the number of babies sleeping through the night. Given the evidence from many trials suggesting that most interventions are ineffective for colic, including parental management strategies (e.g., carrying) and dietary change, advice needs to be based on reassurance and information, coupled with acknowledgment and management of parents’ understandably high levels of stress. Parents can be advised that there are no significant long-term consequences of early colic, that it normally peaks around 6 weeks and stops at 3–4 months (Stifter & Wiggins, 2004; St. James-Roberts, 2004), and that the child is not ill, nor necessarily in pain.

Failure to Thrive
Intervention should aim to assess the contribution of parent management and child feeding skills to mealtine and food intake problems, in order to reduce tense cycles of coercive interaction that often prevail (Skuse, 1985). Direct observations of mealtine interaction (see chapter 19), ideally at home, may be particularly useful for analyzing factors that contribute to maintaining conflict over food. There is some evidence for effectiveness of parent-focused interventions from a small number of trials. Wright, Callum, Birks, and Jarvis’ (1998) RCT of a primary care-based, health visitor-led multidisciplinary intervention for under-twos, involving dietary advice and some parent-management work, found positive effects on growth 1 year later compared to usual health visitor care. Black, Dubowitz, Hutcheson et al. (1995) found more mixed effects for a combined intervention involving clinic-based dietary advice and home-based parenting skills. For under-twos with non-organic FTT from low-income families, there were no effects on growth; rather, both intervention and control group children improved over the trial period. However, beneficial intervention effects were found in the quality of the home environment and on child language development, suggesting that such interventions may alleviate some of the concomitant psychosocial problems found with FTT.

Food Refusal
Careful assessment is needed to establish whether food refusal is linked to weight loss, and to reveal the situations in which it occurs, and in toddlers whether it is linked to other oppositional behaviors. In the latter case, feeding problems need to be assessed and managed in the context of other toddler non-compliant behaviors. If assessment reveals that parents are very anxious about food intake, then this may be a factor contributing to mealtine conflict (Stein & Barnes, 2002). Where appropriate, reassuring parents about physical health and growth of the child is important, coupled with advice on strategies for setting reasonable limits on the child and for reducing mealtine conflict (Douglas, 2002; Turner, Sanders, & Wall, 1994).

There is modest evidence of effectiveness of interventions for food refusal. No Cochrane or other rigorous systematic review was found. We can draw tentative conclusions from a narrative review by Kerwin (1999), which found two very small RCTs (Turner, Sanders, & Wall, 1994) and 27 single-case designs with quantitative outcome measurement, suggesting that behavioral parent management interventions may be effective. Searching did not reveal further RCTs since 1999. When dealing with food refusal and other problem behavior at mealtine in 2– to 5-year-olds, clinicians need to adapt the broad principles outlined for disruptive behavior. Additionally, it is important with mealtine problems to plan how to help eating to become a positive experience and how to reduce stress and conflict over food, particularly by taking a graduated approach to changing the specific problem. Douglas (2002) provided very helpful advice to clinicians. For example, to help food refusal and fussy eating, parents should cease force-feeding and angry responses, and instead take small steps to introduce new habits. It is important to switch to providing praise and attention for eating, and to reduce parents’ natural response, which is to attend to a child when they refuse to eat. Where child anxiety appears to be factor, modeling pleasure in eating and even playing with food can be helpful in establishing enjoyment and reducing anxiety around meals. This may be particularly difficult for parents who feel very anxious around food and its mess, and they may need a good deal of support and encouragement to change (see chapter 27).

Conclusions
It will be apparent that the state of knowledge about preschool behavior problems is quite uneven. A good deal is known about preschool disruptive behavior, and about effective preventive and treatment interventions for this age group. This is particularly true for oppositional problems, and somewhat less so for ADHD. There is a growing literature on how interventions for early disruptive behavior that have been tested in specialized settings (i.e., “efficacy” trials) can be translated to other settings and cultures, and how they might be disseminated on a wider scale. In contrast, little is known about preschool emotional problems, with poor agreement on classification and little evidence about causes and treatment. To some extent, the same applies to childhood emotional disorders in general. This area should be a priority for future basic and treatment research, especially if it can be confirmed that these problems are stable and significant from an early age. Feeding problems have a longer history of treatment research, much of it from pediatric multidisciplinary teams, but work in this area is still hampered by lack of an agreed classification. Furthermore, understanding diagnosis and causes is complicated by great clinical variability in children who may have
accompanying disabilities and developmental delays, combined with psychogenic feeding problems. At the younger end of the 0–5 range, in the specialty known as infant psychiatry, diagnosis is much more controversial and there is a need to establish validity or otherwise of categories and, eventually, effectiveness of treatments that follow from diagnosis. To further understand causal mechanisms, and to delineate the active ingredients of interventions in this age group, work is needed on intervention mechanisms, including gene–environment interactions (Caspi, Mofitt et al., 2002), to address questions about whether interventions operate in different or similar ways in early childhood compared to older ages.

conduct problems: A longitudinal observational study. Social Development, 12, 361–379.

Sleep problems occur frequently in children and adolescents – particularly among youth with behavioral and/or emotional disorders. Moreover, difficulties related to sleep often overlap with psychiatric problems, making sleep an important domain of symptoms relevant to the diagnosis and treatment of psychopathology. For example, sleep difficulties are a common symptom of depression and improving sleep can contribute positively to the management of mood disorders (Dahl, 1996a,b). A second example is illustrated by the way sleep deprivation can create irritability and difficulties with focused attention that mimic or exacerbate symptoms of attention deficit/hyperactivity disorder (ADHD) and improvements in sleep can have a positive impact on attentional functioning (Chervin, Archbold, Dillon et al., 2002; Dahl, Pelham, & Wierson, 1991). Thus, not only is a knowledge about the assessment, diagnosis and treatment of sleep problems in youth an important clinical domain, but acquiring a solid knowledge of sleep – including its development and disorders – provides a critical foundation of expertise relevant to understanding (and effectively intervening in) a broad range of clinical problems in child and adolescent psychiatry.

At a pragmatic level, pediatric sleep problems in children range from highly specific disorders such as narcolepsy where the pathophysiology involves alterations in specific neural systems underpinning sleep–wake regulation to simple behavioral difficulties such as bedtime resistance and late erratic schedules (for estimates of prevalence rates see Table 54.1). However, it is important to recognize that even simple and seemingly minor behavioral sleep problems can become a source of major distress and conflict in children and their families, and these can have serious health consequences. There is increasing evidence that sleep has an important role in basic aspects of learning and memory consolidation as well as impacting on the regulation of behavior and emotions. Therefore, inadequate or disturbed sleep in childhood and adolescence may have long-term consequences on learning and the development of self-regulation that have major clinical implications for child and adolescent psychiatry – crucial questions at the forefront of current research.

For the clinician wanting to provide effective prevention, diagnosis and treatment of sleep problems or appropriate referral for the evaluation of more serious disorders, knowledge and clinical skills are needed in four areas:

1. Understanding normal sleep physiology and the normal development of sleep patterns in children and adolescents.
2. Knowledge of common sleep disorders, including aspects of the etiology, pathophysiology and differential diagnoses for common symptoms.
3. Clinical skills and knowledge relevant to assessing sleep habits and symptoms and diagnosing sleep disorders.
4. Knowledge of the relevant treatment principles – particularly behavioral interventions.

Accordingly, in this chapter we provide an overview of sleep physiology, organization and function, including emerging findings on the role of sleep in learning and regulatory control in the developing brain, and discuss five key examples of sleep disorders in youth, including assessment, diagnosis and approach to treatment.

Physiology, Organization and the Function of Sleep during Human Development

Beginning in infancy, the brain cycles through stages of neural activity/behavioral states which correspond to periods of wakefulness and different stages of sleep. Sleep is divided into two major categories: rapid eye movement (REM) sleep and non-REM (NREM) sleep. REM sleep is characterized by high levels of desynchronized cortical electroencephalogram (EEG) activity (mixed frequencies, relatively low voltage), absence of muscle tone, irregular heart rate and respiratory patterns, and episodic bursts of phasic eye movements. NREM sleep is characterized by low-frequency, high-voltage EEG activity, low muscle tone and absence of eye movements. NREM sleep is subdivided into four stages: stage 1 occurs at transitions of sleep and wakefulness; stage 2 is characterized by frequent bursts of rhythmic EEG activity, called sleep spindles, and high-voltage slow spikes, called K-complexes; stages 3 and 4 (also called slow wave sleep [SWS] or delta sleep), represent the deepest stages of sleep and are comprised largely of high-voltage EEG activity in the slowest (delta) frequency range.

Two independent regulatory processes appear to interact in regulating the timing, intensity and duration of sleep: a homeostatic sleep process and a circadian sleep process (Borbély, 1982; Borbély & Achermann, 2005). The first, often called...

“Process S,” represents a sleep–wake dependent homeostatic component of sleep that increases as a function of previous wakefulness and gradually decreases over the course of a sleep period. Process S has been associated with basic restorative processes of the brain. Intriguing from a developmental neuroscience perspective is the recent evidence that sleep homeostasis is involved in learning and neural plasticity — the progressive strengthening of neural circuits that occurs through use during wakefulness (Tononi & Cirelli, 2003, 2006). It appears that the progressive increase in synaptic strength from daytime activity must be “downscaled” during sleep to maintain synaptic homeostasis. This homeostatic aspect of sleep also appears to correlate with the sleep stages 3 and 4 (slow-wave) sleep, which is particularly strong early in development.

The second process, often called “Process C,” is the circadian or “biological clock” component. The neurobehavioral underpinnings of this circadian system have been well delineated, including the identification of specific neuroanatomical and molecular components (Carskadon, Acebo, & Jenni, 2004).

From a developmental perspective, both the homeostatic and the circadian processes undergo significant maturational changes (Jenni & LeBourgeois, 2006). Some of these developmental changes have important clinical implications. For example, the circadian phase marker, melatonin, correlates with pubertal stage such that more mature adolescents show a delay in the melatonin excretion pattern, even after controlling for psychosocial influences on sleep–wake patterns in adolescence (Carskadon, 2002). This contributes to the tendency to stay up later and sleep in later among adolescents (see p. 898). Furthermore, evidence is accumulating that the dynamics of sleep homeostatic processes slow down over the course of childhood (i.e., sleep pressure accumulates more slowly with increasing age), enabling children to be awake for consolidated periods during the day (Jenni & Carskadon, 2005; Jenni & LeBourgeois, 2006).

Recent progress in understanding the neural mechanisms involved in key aspects of the basic regulation of sleep and wakefulness (Saper, Cano, & Scammell, 2005; Saper, Scammell, & Lu, 2005) has focused on complex interactions across a number of different cell groups involved in cortical arousal, with a key part being played by sleep-inducing structures in the ventrolateral preoptic nucleus in the hypothalamus. These regulatory systems are becoming understood in greater detail in ways that are likely to inform clinically relevant aspects of sleep problems. Two specific examples discussed briefly include the role of sleep in learning and sleep and emotion regulation.

Sleep, Learning and the Developing Brain
One of the most intriguing lines of sleep research with clinical relevance to child and adolescent psychiatry is the growing understanding of the role of sleep in the consolidation of learning (Hobson & Pace-Schott, 2002; Peigneux, Laureys, Delbeuck, & Maquet, 2001; Stickgold, 2005; Stickgold & Walker, 2005; Walker & Stickgold, 2004). A central hypothesis is that sleep facilitates brain plasticity – the ability to constantly modify cerebral structures and functions depending on specific experience and environmental inputs. This view is supported by studies showing impaired memory consolidation following episodes with sleep loss (Pilcher & Huffcut, 1996), and recently there have been findings suggesting such a link at the cellular and molecular levels (Benington & Frank, 2003; Steriade, 1999). Studies have shown the influence of sleep on post-training consolidation, as well as initial memory encoding (Walker & Stickgold, 2006). One recent study demonstrated that sleep can enhance specific components of language learning in infants (Gomez, Bootzin, & Nadel, 2006).

These data indicate that adequate sleep may be essential to making enduring neural changes through learning. This role of sleep in learning may be particularly important during periods of rapid brain maturation in childhood and adolescence.
These findings have implications regarding the importance of sleep to educational goals as well as clinical relevance, because learning (and its consolidation) underpins many clinical interventions such as cognitive–behavioral therapy.

Sleep and Emotion Regulation
Over the past decade there has been increasing interest in understanding the bidirectional relationships between sleep disturbances and problems with emotion regulation in children and adolescents. There is growing evidence that problems with sleep can create and/or exacerbate emotional problems and that emotional difficulties can interfere with sleep. These bidirectional interactions (and the potential for a vicious cycle of negative effects) may have particular clinical relevance in several clinical domains including anxiety, depression and bipolar disorders in youth (Dahl, 1996a; Harvey, Mullin & Hinshaw, 2006) and with aggression, anger and impulse control (Haynes, Bootzin, Smith et al., 2006).

With respect to sleep and mood, evidence from the sleep deprivation literature suggests that one of the strongest adverse effects of sleep deprivation is increased negative mood (Dinges, Pack, Williams et al., 1997; Pilcher & Huffcutt, 1996; Van Dongen, Maislin, Muddington, & Dinges, 2003). This makes sense given evidence suggesting that REM sleep has an emotional processing and mood regulation function (Stickgold, Hobson, Fosse, & Fosse, 2001). In adults with bipolar disorder, the case for sleep contributing to mood disturbance is fairly compelling: sleep loss is highly correlated with daily manic symptoms (Barbini, Bertelli, Colombo, & Smeraldi, 1996); among patients with bipolar disorder, sleep disturbance is the most common prodrome of mania and the sixth most common prodrome of depression (Jackson, Cavanagh, & Scott, 2003); and induced sleep deprivation triggers hypomania or mania in a proportion of patients (Colombo, Benedetti, Barbini, Campori, & Smeraldi, 1999; Kasper & Wehr, 1992; Leibenluft, Albert, Rosenthal, & Wehr, 1996; Wehr, Sack, & Rosenthal, 1987; Wu & Bunney, 1990; Zwi, Shawe-Taylor, & Murray, 2005). In youth with bipolar disorder, rates of significant sleep disturbance range from 35 to 45% (for review see Harvey, Mullin, & Hinshaw, 2006). However, in these younger samples, research and clinical questions relating to a possible link between sleep disturbance and mood are yet to be addressed.

With respect to sleep and aggression, there are both human and animal data showing increased aggression and impulsivity following experimental sleep loss. For example, rats show increases in aggression and defensive fighting after sleep deprivation. One recent study found that animals who were easy to handle at baseline became irritable and aggressive following modest amounts of sleep deprivation, with evidence of related changes in synaptic plasticity associated with these behavioral changes (Marks & Wayner, 2005). Clinical studies of children and adolescents also have revealed associations between sleep deprivation and irritability/aggression and difficulties with self-regulation in youth (Chervin, Dillon, Archbold, & Ruzicka, 2003; Dahl, 1996b; Ireland & Culpin, 2005). Most relevant is a recent study by Haynes, Bootzin, Smith et al. (2006) which examined behavioral and emotional changes in adolescents with substance-related difficulties undergoing a behavioral sleep treatment. This study reported that improvements in sleep time were associated with significant decreases in the reporting of aggressive thoughts and actions. Taken together, these data suggest that inadequate sleep in adolescence may contribute to aggressive thoughts and actions and that increased or improved sleep may reduce problematic aggression, at least in some cases.

While the clinical research questions about the inter-relationships between sleep and emotional regulation in children are compelling, it is also important to acknowledge that from a clinical practice perspective, traditional polysomnographic studies have not yielded clear evidence of specific sleep abnormalities associated with particular psychopathologies in youth (e.g., ADHD, major depressive disorder [MDD]). Thus, polysomnographic studies are best utilized clinically when a specific sleep disorder is suspected.

Genetic Contributions
To date, scant attention has been paid to investigations of possible genetic contributions to sleep disturbance in children and adolescents. The exception is a study by Gruber, Grizenko, Schwartz et al. (2006), who investigated the hypothesis that the catecholamine-O-methyltransferase (COMT) polymorphism modulates disturbance in children with ADHD. Sleep was measured over 2 weeks with actigraphy. The rationale for investigating COMT is its association with sleep in narcolepsy and Parkinson’s disease and disorders related to dopamine dysfunction. Gruber, Grizenko, Schwartz et al. found that children who had the COMT high-activity allele, val (i.e., val/met or val/met) exhibited greater sleep disturbance compared with children who were met homozygous genotypes (i.e., met/met). The authors interpreted these findings as adding to the accruing evidence base suggesting that sleep disturbance is core to the pathology underpinning ADHD and that there may be a genetic basis for the association between ADHD and sleep disturbance.

Specific Clinical Problems
Problems Going to Sleep and Staying Asleep
Bedtime struggles and middle of the night wakings are not only a source of sleep disruption for children and their parents, but also can be a source of conflict and negative emotion among family members, contributing to negative parent–child interactions, marital discord and, in some rare cases, child abuse. One aspect of the difficulty is that young children often show a “paradoxical” reaction when obtaining insufficient or inadequate sleep. That is, sleep-deprived young children (whether from insufficient or disrupted sleep) often look irritable and impulsive, with some symptoms of distractibility and emotional lability, and may seem overly active. The three most important principles for treating bedtime resistance in young children...
are: (i) creating an emotional state of calmness and safety; (ii) consistent limit setting; and (iii) establishing good habits. Bedtime habits include a wind-down period and a sequence of activities that begin 30–60 min before bedtime. If a child continues to test limits and not to respond to strategies to reward desirable behaviors, it may become necessary to set consequences for the undesirable behaviors. However, this can still be done within a positive framework to avoid the escalating emotional arousals of yelling, screaming and flaring tempers.

Insomnia is a common complaint among older children and adolescents, particularly sleep-onset insomnia. Two theoretical perspectives are helpful for conceptualizing insomnia in children and adolescents. First, a vigilance-avoidance model has particular relevance to understanding sleep problems in childhood and adolescence (Dahl, 1996b). At the most fundamental level, sleep and vigilance represent opponent processes. Physiologically, going to sleep requires turning-off awareness and responsiveness to threats in the external environment. Because of this loss of vigilance and responsiveness, sleep is naturally restricted to “safe” times and places (e.g., animals and birds tend to sleep in safe burrows, nests or temporal niches that minimize dangers). In humans, one important domain for assessing the safe conditions that permit and promote sleep focuses on social and emotional appraisals of threat (Dahl, 1996b; Worthman & Melby, 2002). Individuals experiencing high levels of anxiety, vigilance and perceived threats often have difficulties going to sleep. While these tendencies have adaptive advantages (inhibiting sleep in truly dangerous environments), they also have costs: high levels of anxiety and vigilance based on perceived threats can lead to chronic sleep difficulties. A major source of difficulty for children and adolescents is rooted in presleep onset worries and ruminative thinking at bedtime – which naturally increase vigilance and interfere with going to sleep. Yet, it can be equally problematic if anxious youth avoid these distressing bedtime worries by staying up (or getting back out of bed) to engage in very late hours of school work, watching TV or socializing (via the Internet or cell phones). These patterns of behavior often lead to difficulty getting to sleep until very late on school nights and thus insufficient sleep because of the need to get up early for school. Without effective intervention, this pattern of vigilance and avoidance can lead to extremely problematic sleep habits and patterns in adolescents with anxiety disorders.

Second, a conditioning model of insomnia (Bootzin, 1979; Perlis, Giles, Mendelson, Bootzin, & Wyatt, 1997) emphasizes the contribution to insomnia of multiple pairings of the bed and not sleeping. This set of associations likely results in conditioning between the bedroom environment and heightened arousal, which serves to maintain the sleep disturbance.

The initial assessment of youth with insomnia should start with a thorough clinical interview with the patient and their family members to obtain information about the duration, frequency and severity of night-time sleep disturbance, including estimates of the key sleep parameters: sleep onset latency (SOL), number of awakenings after sleep onset (NWAKE), total amount of time awake after sleep onset (WASO), total sleep time (TST) and an estimate of sleep quality (SQ). This information should encompass both weekday and weekend schedules and should assess the regularity of the schedule as well as the average schedule. The onset and duration of the insomnia and type of symptoms (i.e., sleep onset, sleep maintenance, early morning or late morning awakening problem or combinations of these) should be assessed. A description of the daytime correlates and consequences of insomnia is a key domain of importance as is gauging parental responses to the insomnia. In addition, it is crucial to obtain information about medications (prescription and over-the-counter) and conduct a screen for the presence of psychiatric disorders and medical problems (including other sleep disorders). Asking the patient to complete a sleep diary each morning, as soon as possible after waking, for 1–2 weeks provides a wealth of information including an insight into the night-to-night variability in sleeping difficulty and sleep–wake patterns and the presence of circadian rhythm disorders, such as delayed sleep phase disorder. An assessment of insomnia in youth should include an exploration of the child’s fears, because fear, distress or any cognitive or emotional cue that prevents an overall sense of safety can be antithetical to sleep (because sleep onset requires turning off awareness, responsiveness and vigilance). Children and adolescents can often get into the habit of mentally reviewing or replaying worrisome thoughts or memories of stressful events. Some youth with stressful memories or specific fears manage to avoid these during the day through distracting activities, but at night – especially when trying to fall asleep – the lack of distracters can result in rumination on these thoughts.

The treatment principles are threefold. First, helping the child feel emotionally and physically safe is often a critical component. (The emphasis on the word feel is because the affective appraisal of being safe appears to be extremely important for some youth – they may logically understand the absence of specific threats but unless they have an emotional sense of safety they may experience heightened vigilance that interferes with sleep.) Depending on the age and inclinations of the child, this can involve creative imagery, self-hypnosis techniques or systematic relaxation exercises. In addition, parents are encouraged to contribute to an emotional sense of safety, positive emotions and good associations at bedtime.

The second treatment principle is to establish a regular bedtime routine and consistent sequences of steps and habits. In children, this can involve a bedtime story, special quiet time with the parent and pleasant wind-down time. In adolescence, multiple sleep-interfering factors (e.g., cell phones, the Internet) interact with the pubertal phase delay in the circadian system causing a tendency to shift toward later bedtimes and increased autonomy to decide on bedtimes. Hence, the intervention is to identify sleep-interfering behaviors and work collaboratively with the young person to assist them to find internal motivations for enhancing their sleep by reducing the use of sleep-interfering technologies around bedtime. In addition, derived from the conditioning theory just discussed, there is preliminary evidence that the stimulus control intervention that has
been so successful for adult insomnia (Morin, Bootzin, Buysse et al., 2006) can also be helpful for youth (Bootzin & Stevens, 2005). The therapist provides a detailed rationale for and assists the patient to achieve the following:

1. Use the bed and bedroom only for sleep (i.e., no TV watching or text messaging).
2. Get out of bed and go to another room whenever you are unable to fall asleep or return to sleep within approximately 15–20 min and return to bed only when sleepy again.
3. Arise in the morning at the same time (no later than plus 2 hours on weekends) and gradually move closer to a regular schedule 7 days a week.

Third, based on the vigilance–avoidance model, there is a clear need to address bedtime worry, rumination and vigilance (Dahl, 2002). Interventions for worry and rumination include: diary writing or scheduling a “worry period” to encourage the processing of worries several hours prior to bedtime, creating a “to do” list prior to getting into bed to reduce worrying about future plans or events, training to disengage from presleep worry and redirect attention to pleasant (distracting) imagery, demonstrating the adverse consequences of thought suppression while in bed and scheduling a presleep “wind-down” period prior to bedtime.

The Adolescent with Daytime Sleepiness/Difficulty Waking up for School

After the onset of puberty and throughout the adolescent period, the most prevalent sleep complaints tend to center on difficulty waking up for school in the morning and the associated difficulties with daytime sleepiness, tiredness and irritability. It is important to emphasize that there is a broad continuum of severity. This ranges from normative or mild difficulties that appear to affect up to half of all high-school students in the USA and result in at least some symptoms (National Sleep Foundation, 2006), to a much smaller subset of adolescents with severe difficulties with sleep and schedules that result in significant impairments (such as failures in school) and often meet full criteria for a delayed sleep phase syndrome (DSPS). At the current time, there is an absence of empirical data to help delineate precisely when to diagnose adolescents as having DSPS from the much larger set of youth with mild to moderate problems with erratic and late sleep schedules.

One pragmatic approach advocated in this chapter is that clinicians understand both the physiological and social influences that contribute to these problems, and apply sound behavioral principles aimed at improving and increasing sleep in any adolescent who shows evidence of suboptimal sleep as a result of late nights and erratic schedules. In other words, many of the simple behavioral interventions to regularize sleep–wake schedules and increase total sleep can be tried even in the case of mild to moderate problems (because these interventions have little to no risks or side effects and can result in improved alertness as well as improved mood regulation).

It is important to understand the interaction between biological and social processes underpinning these common problems. Biological changes in the circadian system at puberty shift sleep timing preferences in the direction of delayed sleep phase (Carskadon, 2005; Lee, Hummer, & Jechura, 2004). Unfortunately, these biological changes interact with early school start times, increase in paid work responsibilities and increased amounts of time devoted to socializing in a way that can spiral quickly into a pattern of extreme sleep deprivation. Then most “catch-up” sleep occurs on weekends and holidays on an extremely phase-delayed schedule. The human circadian system adapts more easily to phase delays as endogenous rhythms of body temperature and neuroendocrine function are able to reset quickly to later bed and wake times. However, the circadian system has more difficulty accommodating to phase advances (earlier sleep schedules). This creates an effect that is a bit like “jet-lag” on Monday morning; students try to adjust to a sudden phase advance in which they need to get up for school at a time that is often 3–4 hours (or more) earlier than their biological clock “expects” to wake up.

A thorough and detailed history is essential to evaluate and to characterize the nature of the sleepiness. This should include an assessment of whether the young person is fatigued or unable to stay awake, the frequency and duration of symptoms and whether the symptoms occur at particular times of day or only in certain situations. A family history of increased sleep needs and sleepiness can be important in the consideration of narcolepsy.

In adolescents with true sleepiness (not simply complaints of fatigue), two main categories of problems should be considered:

1. Inadequate amounts of sleep; and
2. Circadian and scheduling disorders.

Inadequate Amounts of Sleep

The most common cause of mild to moderate sleepiness in adolescents is an inadequate number of hours in bed. A combination of social schedules leading to late nights with early morning school requirements can significantly compress the number of hours of sleep. Part-time jobs, sports activities, hobbies and active social lives can exacerbate this problem. The catch-up sleep of naps, weekends and holidays can also contribute to the problem by leading to erratic schedules and even later nights. In taking a sleep history, it is important to ask specific questions about bedtime schedules. Many families will say the adolescent “usually” goes to bed at a certain time, but when asked for an exact time covering the previous few nights, a much later hour is reported. When assessing the amount of sleep an adolescent is getting, it is important to obtain details of bedtime (such as when the child gets into bed as well as lights-out time), estimates of sleep latency, nighttime arousals, time of getting up in the morning, difficulty getting up, and the frequency, timing and duration of daytime naps. It is also essential to get details of sleep–wake schedules on weekends, as well as during the school week. When this type of specific information is obtained either by interview or by having the family maintain a sleep diary, evidence of inadequate sleep is often apparent. A prospective detailed sleep diary provides the most reliable information.
When inadequate sleep is identified, simply recommending that the adolescent go to bed earlier is not likely to be effective. Often, the primary role of the clinician is to help the entire family understand and acknowledge the consequences resulting from the inadequate sleep. Sleep deprivation frequently contributes to many factors that the family identifies as problems, including falling asleep in school, oversleeping in the morning, fatigue and irritability. In cases in which the adolescent’s school or social functioning is significantly impaired by sleep problems, a strict behavioral contract that is agreed upon by the family can be essential. The contract should specify hours in bed (with only small deviations on the weekends) and should target the specific behaviors contributing to bad sleep habits, such as specific late-night activities, erratic napping or oversleeping for school. The choice of rewards for successes and negative consequences for failures, as well as an accurate method of assessing compliance, are essential components of the contract.

Circadian and Scheduling Disorders
The most common specific problem that is relevant to adolescents is delayed sleep phase syndrome (DSPS). DSPS often begins with a tendency to stay up late at night, sleeping in late and/or taking a late afternoon nap. This process often begins on weekends, holidays or summer vacations. Problems become apparent when school schedules result in morning wake-up battles and difficulties in getting to school. Often, these adolescents cope by taking afternoon naps and getting catch-up sleep on the weekends. Although some of these behaviors occur in many normal adolescents, in extreme cases the circadian system can become set to such a late time that even highly motivated adolescents can have difficulty shifting their sleep back to an earlier time. In some instances, the attempts by the adolescent (and their families) to correct the problem go against circadian principles. For example, an adolescent who has been going to bed at 3 AM and getting up at noon during a vacation tries to go to bed at 10 PM the Sunday night before the first day back at school, and finds that her physiology is quite resistant to sleep. For a few days, she manages to get up for school by overriding the system (despite inadequate sleep) but then takes a long nap after school. Despite numerous nights of trying to go to bed at 10 PM she is unable to shift her temperature cycle and circadian system back to an earlier phase.

There is a subgroup of adolescents who appear to have trouble following an early schedule but are not particularly troubled by their late schedule. These adolescents are not motivated to correct the problem, are not particularly troubled by their recurrent experiences of being late for or missing school, and do not show great motivation to change their late-night habits. These adolescents are essentially choosing a late-night schedule. Unless the clinician is able to alter the larger realm of priorities and motivators, these adolescents are very unlikely to respond to any treatment of a sleep schedule problem.

The treatment of DSPS consists of two parts. The first is gradually to align the sleep system to the desired schedule. The second is to maintain that alignment. The process of alignment consists of gradual consistent advances in bedtime and wake-up time (15 min per day). It is often best to begin from the time the adolescent usually goes to sleep without difficulty. It is important during this process to avoid any naps and to be consistent across weekends and holidays. In severe cases, some adolescents on very late schedules respond more favorably to going around the clock with successive delays in bedtime. This process has been described as phase delay “chronotherapy.” As already highlighted, because the biological clock tends to run on a 25-hour cycle, it accommodates phase delays more easily than phase advances. Hence, the schedule changes can proceed with larger (2–3 hour) delays per day. An example is described for an adolescent who has been falling asleep at 3 AM and getting up at noon. On day 1, he stays up until 6 AM then sleeps until 3 PM. On day 2, he goes to bed at 9 AM and sleeps until 6 PM. On day 3, he sleeps from noon until 9 PM; day 4, from 3 PM until midnight; day 5, from 6 PM until 3 AM; day 6 from 9 PM until 6 AM; and day 7, from 10 PM until 7 AM. It is important that the adolescent take no naps during the chronotherapy. Upon waking up, he or she should be active and, if possible, during the day have bright light exposure, such as walking outdoors.

Although many adolescents do very well with this type of phase-delay chronotherapy, the first weekend or vacation of returning to old habits can undo a lot of hard work. Particularly in the first 2–3 weeks following chronotherapy, rigid requirements should be set about wake-up time. Maintenance of the new circadian phase is based on the same principles but usually can be somewhat less rigorous. For example, if the adolescent wants to stay up late on an occasional weekend night, he or she may be able to do so but should not be permitted to sleep more than 1–2 hours later than the usual wake-up time for school. Strict behavioral contracts worked out with the parents, having specific rewards for success and serious consequences for failures, are essential in this type of intervention.

Before moving to the consideration of bright light or melatonin therapy for DSPS in adolescents, it is important to place these comments in a larger context. In our experience, if an adolescent complies with the behavioral program the additional use of a light box or evening melatonin is often not necessary. Moreover, if the adolescent does not comply with the behavioral contract, light and melatonin alone are extremely unlikely to be successful. If the adolescent remains asleep in bed with eyes closed, the bright light beside the bed is not going to exert the needed physiological effect, and if adolescents are continuing to engage in arousing social activities or use of electronic media late at night, taking melatonin is not going to make them go to sleep any earlier. Thus, we conceptualize the use of light or melatonin as a way to augment the (primary) behavioral intervention. For example, an adolescent living in a far northern latitude may experience a complete absence of morning bright light exposure during the winter, awakening and travelling to school in darkness or dim light.

The use of melatonin has also been suggested as a potential treatment for this problem. Currently, there are some preliminary data supporting the use of low-dose melatonin in
the evening to assist with sleep-onset insomnia, presumably resetting of the timing of sleep to an earlier phase (Smits, Nagtegaal, van der Heijden, Coenen, & Kerkhof, 2001; Smits, van Stel, van der Heijden et al., 2003). In some ways, melatonin appears to act as "chemical darkness" to offset the effects of late-night artificial lights in influencing the biological clock. It is important to note the lack of any safety data regarding melatonin use in adolescents. Others have argued that direct control over exposure to light (darkness in the evening and bright light exposure on awakening) can be more effective than melatonin.

Use of Medications for Treating Insomnia and DSPS in Youth

One of the most contentious issues in the domain of treating sleep problems in children and adolescents with difficulty going to sleep is the use of medications to promote sleep onset (Owens, Rosen, & Mindell, 2003). Indeed, there are large numbers of medications prescribed by pediatricians, child psychiatrists and family practitioners for children of all ages in attempts to hasten sleep onset. The medications include an unusual array, ranging from relatively ineffective choices like antihistamines to powerfully sedating medications with an absence of any empirical data on risks or benefits in children and adolescents. Some of the most common agents, such as chloral hydrate and clonidine, not only lack empirical data, but would be regarded by adult sleep clinicians as poor choices regarding the relative degree of somnogenic properties compared to potential side effects (e.g., the dose of clonidine needed to induce sleepiness is relatively close to the dose that lowers blood pressure). Adult sleep pharmacology has seen numerous advances, including new generation agents with a much better specificity for sleep, duration of action, and relatively low risk and side effects in adults. Therefore, one might logically argue that some of these medications might represent better treatment options for insomnia in children and adolescents. However, until we have empirical data and controlled trials using these medications in youth (including dosing, side effects and efficacy), we are reluctant to advocate any specific medication at this time.

Weiss, Wasdell, Bomben, Rea, and Freeman (2006) have reported data on a small sample of stimulant-treated children with ADHD (n=27) and sleep onset difficulty. A sleep hygiene intervention was administered first (effect size = 0.67). This intervention involved regularizing the sleep–wake schedule (negotiating a consistent bed and wake time), addressing parental unrealistic expectations about the child's sleep, and reducing caffeine and naps. Those who did not respond were then randomized to a double-blind cross-over design of 10 days of 5 mg melatonin or placebo. There was a reduction in sleep onset latency of 16 min during melatonin use, relative to placebo (effect size = 0.6). The effect size for the combination of sleep hygiene and melatonin was 1.7. An important next step in evaluating the use of sleep hygiene and melatonin for sleep disturbance in ADHD will be to assess the longevity of the reported improvements in sleep.

Ramchandani, Wiggs, Webb, and Stores (2000) published a systematic review of treatments for settling problems in children aged 5 years or younger. Nine studies met the inclusion criteria: four testing a drug, four testing a behavioral treatment and one testing non-directive education. Although the drugs appeared to reduce sleep disturbance in the short term, long-term effects were considered by the authors to be questionable. In contrast, behavioral interventions showed both short-term and longer-term efficacy. The behavioral interventions included positive routines and graduated extinction of parental involvement in resettling across the night.

The Child with Parasomnias

Parasomnias occur commonly in children as sudden partial awakenings from deep NREM sleep into a mixed state which has some aspects of being awake and some aspects of being in a deep sleep. There appear to be at least two routes to this mixed state:

1. Difficulty leaving deep sleep (stage 4) at the end of the first sleep cycle; or
2. A sudden disturbance or disruption during the middle of deep sleep.

The events include sleepwalking, night terrors and confused partial arousals (some enuretic events can also occur as partial arousals). Although the specific types of arousal (sleepwalking versus night terror) are sometimes considered as separate entities, these behaviors represent a spectrum of related phenomena with respect to sleep physiology. The intense events (with screaming, agitated flailing and running) represent the extreme end of a spectrum of partial arousal behaviors that occur in mild forms (such as calmer movements or a few awkward movements) in many children. The events can last from a few seconds to 20 min, with an average duration of about 3 min. The termination is usually as sudden as the initiation, with a rapid return to deep sleep. During the events, the children may seem confused, often not recognizing their parents, being inconsolable and often appearing incoherent.

Overtiredness from any source (whether sleep deprivation, sleep disruption or erratic schedule) can increase or precipitate partial arousals. Any time a child is adjusting to getting less sleep, or has disturbed night-time sleep, the physiological compensation is to get deeper sleep (especially in the first 1-2 hours after sleep onset). This deep “recovery” sleep appears to be fertile ground for partial arousal events. A second theme of associated features is in the realm of psychological and emotional factors. Particularly with respect to night terrors, much has been written about the association with particular psychological states, such as anxiety, trauma, stressful events and repressed aggression (Ferber, 1989; Klackenberg, 1982). These psychological factors may contribute to sleep loss. For example, emotional and behavioral problems are also associated with difficulty falling asleep, as occurs with depression and anxiety in children (Dahl & Puig-Antich, 1990; Ryan, Puig-Antich, Ambrosini et al., 1987). Likewise, disruptive disorders, such as ADHD and conduct disorder, can be accompanied by oppositional behaviors around bedtime, which may delay
sleep onset, as well as occasional difficulties falling asleep (Dahl & Puig-Antich, 1990).

When a parasomnia is suspected, the clinical interview should include obtaining a careful history of all sleep-related habits, as well as the characteristics, pattern and frequency of the events. The pattern of events should also be assessed. Occurrence in the first third of the night and an increased frequency corresponding to periods of being overly tired are strongly suggestive of typical partial arousal events.

Given the wide range of intensity and clinical significance of these nocturnal partial arousals, the key to therapy is matching the appropriate intervention to the degree of problem. Mild sleepwalking or an occasional night terror in a young child requires only some parental reassurance with general suggestions regarding improved sleep habits and the likelihood that the events will decrease over time. In contrast, frequent, repetitive, intense and agitated arousals in an older child may require very aggressive treatments, because of the risk of self-injury during the events and the possibility of associated pathology. There are three broad principles that guide intervention.

First, educate the family about the events (and what to do during the actual partial arousal event). For mild to moderate events, the parents should try to direct the child to go back to bed and back to sleep. Physically taking the child by the hand and leading him or her back to bed during a mild event can also be effective. Usually, the event needs to take its course and will end spontaneously. During more agitated arousals, interventions trying to direct the child back to bed can result in increased arousal and can inadvertently prolong the event. In general, if mild directing of the child does not work, the parents should let the episode run its course. One very important caveat to this advice is with respect to the need to prevent self-injury. Eliminating factors such as sleeping on the top bunk bed, having a bedroom near the top of the stairs or having windows or dangerous objects in the room are major considerations. In severe cases, in which partial arousals are frequent and not responding to treatment, it may be necessary to install window guards or Plexiglas.

Second, encourage a regular sleep–wake schedule with good sleep habits. Parents should consider an earlier bedtime if there is any evidence that the child is getting inadequate sleep. Specific causes of delayed bedtime or difficulty falling asleep should also be directly addressed. It is important to try to improve the overall quantity and/or quality of sleep of the child when applicable.

Third, help the child feel safe, secure and relaxed at bedtime and to identify and express sources of anxiety and fear in a supportive environment. If there is evidence that anxiety and unexpressed anger may contribute to the frequency of these partial arousal events, the family should be encouraged to facilitate their child expressing sources of anxieties, fears, anger and conflicts in healthy ways while awake. Age-appropriate suggestions of positive family interactions within this realm can be very helpful. Also, helping children focus on positive images and positive relaxation exercises can help to foster feelings of safety and security at bedtime.

Tricyclic antidepressants and benzodiazepines have been shown to have positive effects on partial arousal events. Both medications decrease arousals from sleep, and lighten the deepest stage 4 sleep. Difficulties with pharmacological interventions include tolerance effects, withdrawal effects and questions concerning possible long-term detrimental effects on sleep.

Sleep-Disordered Breathing

It is important for child and adolescent psychiatrists to understand how sleep apnea and a related set of problems called sleep-disordered breathing can contribute to fragmented sleep (and possibly intermittent hypoxia; Gozal & Kheirandish, 2006; Kheirandish & Gozal, 2006), which can contribute to daytime difficulties with cognitive and affective functioning. In particular, difficulties with irritability, attentional difficulties and emotional lability can be created or exacerbated by sleep-disordered breathing in children.

During sleep, and particularly in REM sleep, there is a considerable drop in muscle tone. This decreased tone affects the musculature maintaining the airway and the muscles assisting in respiration. In susceptible individuals, these physiological changes can lead to obstructive sleep apnea syndrome (OSAS). In adults, the clinical picture of OSAS is typically an obese hypsomnolent lethargic individual. In children, the clinical appearance is quite different. The most common cause of OSAS in children is hypertrophy of adenoids and tonsils. Many of these children have little difficulty breathing when awake; however, with decreased muscle tone during sleep, the airway becomes smaller, airway resistance increases and the work of breathing increases. Brief arousals from sleep increase the muscle tone to the neck and pharyngeal muscles, open the airway and allow the child to resume breathing. Although the actual number of minutes of arousal during the night may be small, the repeated chronic but brief disruptions in sleep can lead to significant daytime symptoms in children. It is important to note that the child is usually unaware of waking up, and the parent often describes very restless sleep but usually does not describe the child’s waking up completely. The most frequent symptoms reported by families include loud chronic snoring (or noisy breathing), restless sleep with unusual sleeping positions (attempts by the child to move and open the airway), a history of problems with tonsils, adenoids and/or ear infections, and signs of inadequate nighttime sleep.

There is still a great deal of uncertainty and controversy about the exact clinical threshold for performing formal sleep studies. Treatment decisions and options are also complex clinical decisions. In medical centers with pediatric sleep facilities, consultation with a child sleep specialist can be extremely helpful in making decisions in these cases. Some recent studies provide excellent reviews of these complex issues (Ferber, 1996; Marcus, 1997).

A similar (and even more controversial) situation exists regarding restless legs syndrome (RLS) and periodic limb movement disorder (PLMD) in children. Periodic limb movement
CHAPTER 54

in sleep (PLMS) is characterized by periodic episodes of repetitive and highly stereotypic limb movements during sleep (American Academy of Sleep Medicine, 2005). PLMD is defined by the presence of periodic limb movement during sleep associated with symptoms of insomnia or excessive daytime sleepiness (Chesson, Wise, Davila et al., 1999). RLS is a clinical diagnosis characterized by disagreeable leg sensations that usually occur prior to sleep onset. PLMD and RLS are distinct entities but can coexist. Most patients with PLMD do not manifest RLS symptoms; however, approximately 80% of patients with RLS have PLMS (Montplaisir, Boucher, Poirier et al., 1997).

PLMD has been described in children with somewhat different clinical presentations. Children with PLMD may present with non-specific symptoms such as growing pains, restless sleep and hyperactivity (Picchetti & Walters, 1999). These symptoms are most often unnoticed by their parents, although a family history of RLS and PLMD is common. In a series of studies, Picchetti, England, Walters, Willis, and Verrico (1998) suggested an increased prevalence of PLMD among children with ADHD.

Other studies have suggested that the sleep fragmentation secondary to these disorders is an important contribution to ADHD and that, particularly in the context of symptoms and/or a positive family history of RLS/PLMS, sleep studies should be performed if there is any question that sleep fragmentation is contributing to daytime impairments with attentional control (Cortese, Konofal, Lecendreus et al., 2003; Hoban & Chervin, 2005).

Treatment
The guideline from the Standard of Practice Committee of the American Academy of Sleep Medicine states that no specific recommendation can be made regarding treatment of children with RLS or PLMD (Littner, Kushida, Wise et al., 2005). There is limited information on the dopaminergic medications in children and other medications have not been adequately studied in children. There is some evidence that children with PLMD may have low iron storage as evidenced by low serum ferritin and iron. Children with low serum ferritin (<50 µg/L) have been reported to respond favorably to iron therapy (Simakajornboon, Gozal, Vlasic et al., 2003). However, currently, there are no long-term data on the use of iron treatment. These children also appear to benefit from avoiding caffeine and behavioral interventions to improve sleep habits.

Narcolepsy
Narcolepsy is a chronic neurological disorder characterized by excessive daytime sleepiness. The classic tetrad of symptoms in narcolepsy comprises:

1. Sleep attacks;
2. Cataplexy (sudden loss of muscle tone without change of consciousness);
3. Sleep paralysis (inability to move after waking up); and
4. Hypnagogic hallucinations (dream-like imagery before falling asleep).

These symptoms do not all occur together or consistently in many cases of narcolepsy. Particularly in younger patients, signs of sleepiness may be the only initial symptom. Cataplexy is typically provoked by laughter, anger or sudden emotional changes. It may be as subtle as a slight weakness in the legs, or as dramatic as a patient falling to the floor limp and unable to move. If cataplectic attacks last long enough, full sleep can occur.

It is not a rare disorder, affecting approximately 1 in 10,000 people in the USA. Narcolepsy is a neurological disorder that appears to be caused by an abnormality in the hypocretin-orexin system – often by a loss of hypocretin neurons in the lateral hypothalamus and usually low cerebrospinal fluid (CSF) levels of hypocretin. About 10% of narcoleptics are members of familial clusters; however, genetic factors alone are apparently insufficient to cause the disease. A mutation on chromosome 6 affecting a human leukocyte antigen ([HLA] DR2/DQ6 [DQB1*0602]) is seen in 90–100% of patients; however, this also occurs in as many as 50% of people without narcolepsy. Hence, obtaining a family history of narcolepsy or excessive sleepiness can be helpful, although it is negative in many cases. Traditionally, the onset of narcolepsy is thought to occur in late adolescence and adulthood, but there are well-documented cases that begin in early childhood.

The diagnosis of narcolepsy requires evaluation in a sleep laboratory. Patients with narcolepsy show early REM periods near sleep onset, fragmented night-time sleep, excessive daytime sleepiness in objective nap studies during the day and sleep-onset REM periods in naps. In prepubertal children, this diagnosis can be very difficult to establish (Kotagal, Hartse, & Walsh, 1990). Repeat studies may be necessary before reaching a final diagnosis. At this time, neither HLA typing nor CSF hypocretin levels are routinely indicated in the clinical evaluation of narcolepsy; however, in unusual cases CSF hypocretins can be helpful.

Treatment of narcolepsy is generally focused on:
1. Education and counseling of the patient and family;
2. Adherence to a regular schedule to obtain optimal sleep with good sleep habits (often including scheduled naps);
3. Use of short-acting stimulant medication for treatment of daytime sleepiness (with drug holidays to avoid build-up of tolerance); and
4. Use of REM-suppressant medications (such as protriptyline) when symptoms of cataplexy are problematic.

The differential diagnosis of narcolepsy includes consideration of the following two sleep disorders.

Idiopathic Hypersomnia
Some patients have significantly increased sleep needs without evidence of the REM abnormalities seen in narcolepsy. This condition has been called idiopathic hypersomnia. There is often a familial history of excessive sleep needs, and these individuals show clear objective sleepiness in nap studies despite having obtained what appears to be adequate amounts of night-time sleep. These disorders are also frequently
provide expanding areas of understanding with even greater understanding the role of sleep in the developing brain. It is extremely likely that these rapid advances will continue to further insight into the benefit of these interventions. There are few risks – and potentially many benefits for more studies to provide stronger empirical support and practice. We believe that there is great pragmatic value in understanding the mechanisms and implementing these in many domains of clinical psychology. The importance of sleep

Conclusions

In this chapter we reviewed several important principles relevant to the assessment, diagnosis and treatment of sleep problems in children and adolescents. We have underscored the evidence for interactions between sleep and the regulation of behavior, emotion and learning and the importance of sleep disturbance to many aspects of child psychiatry (and behavioral pediatrics). We have consistently emphasized behavioral principles and behavioral approaches to these problems because we believe that there is great pragmatic value in understanding and implementing these in many domains of clinical practice. There are few risks – and potentially many benefits – from increasing and enhancing sleep in youth through cognitive–behavioral interventions. There is also a clear need for more studies to provide stronger empirical support and further insight into the benefit of these interventions.

Finally, it is important to emphasize the exciting advances in research in neuroscience, genetics and development in understanding the role of sleep in the developing brain. It is extremely likely that these rapid advances will continue to provide expanding areas of understanding with even greater clinical relevance to child and adolescent psychiatry in the near future.

Attachment Disorders in Relation to Deprivation

Charles H. Zeanah and Anna T. Smyke

Although attachment disorders have received increased attention in contemporary literature, there have been more reviews of these kinds of disorders published than systematic studies. In fact, although these disorders have been described for more than 50 years in the literature and have been defined by specified criteria in psychiatric nosologies for nearly 25 years, they have been studied directly only in the past decade. There is now a small but growing database, allowing for a beginning consensus on some points and clearer questions about areas of controversy.

The purpose of this chapter is to review attachment disorders, especially in the context of severe deprivation, and in light of what has been learned in recent investigations. Although different or more expanded versions of attachment disorders have been proposed by some (Minnis, Marwick, Arthur, & McLaughlin, 2006; van IJzendoorn & Bakermans-Kranenburg, 2002; Zeanah & Boris, 2000), these alternative approaches have not been well studied, and we have limited our review to the traditional conceptualization of the disorder, as defined in contemporary nosologies.

Definitional Challenges

The term “attachment” itself has been used variably to refer to somewhat different constructs, and this has led to confusion in the literature. Bowlby, who developed attachment theory, asserted that attachment referred to the young child’s strong disposition “to seek proximity to and contact with a specific figure and to do so in certain situations, notably when . . . frightened, tired, or ill. The disposition to behave in this way is an attribute of the child, an attribute which changes only slowly over time and which is unaffected by the situation of the moment” (Bowlby, 1982, p. 371).

In addition to this description of behaviors, it is often useful to consider attachment as a relational construct. We have suggested, using Emde’s (1989) model, that functions of the parent–child attachment relationship include:

1 Providing and seeking comfort for distress;
2 Providing and experiencing warmth, empathy and nurturance;
3 Providing emotional availability and regulating emotion; and
4 Providing and seeking physical and psychological protection (Zeanah, Mammen, & Lieberman, 1993).

Because the relationship is asymmetrical, the young child is the seeker and the adult caregiver or parent is the provider.

A significant challenge to the definition of attachment disorders is the very ubiquity of attachment in young children. Under species-typical rearing conditions, virtually all children form selected attachments to their caregivers. In children with clinical disturbances of a variety of types, attachment formation or expression may be compromised. Thus, an important question is when the disturbed attachment is the primary problem, in which case it comprises an attachment disorder, and when attachment is merely one of a number of developmental domains that is compromised, in which case it may be an associated feature of some other disorder. An appreciation of the development of attachment under usual circumstances provides a useful foundation from which to begin to answer this question.

Development of Attachment

Parents’ affiliative feelings for their infants often begin prenatally. Studies have indicated that parents are willing to describe a sense of who the baby is and assert that they have a relationship with the baby even before the baby is born (Benoit, Parker, & Zeanah, 1997).

However, infants are not born attached to their caregivers. In fact, two conditions appear to be necessary for infants to become attached. First, they must have a significant amount of interaction on a regular basis with the caregiver, and second, they must reach a cognitive age of about 7–9 months. Phases in the development of attachment, modified slightly from Bowlby’s (1982) original formulation, are described in Table 55.1.

By the end of the first year of life, it is possible to assess the quality of the young child’s attachment to a particular caregiver. Usually, this is accomplished by means of a laboratory paradigm known as the Strange Situation Procedure (Ainsworth, Blehar, Waters, & Wall, 1978). Alternating episodes of separations and reunions between a young child and a familiar caregiver and an unfamiliar adult or stranger, the procedure yields classification of a young child’s pattern of attachment to the caregiver with whom he or she is assessed as secure, insecure/avoidant, insecure/resistant or disorganized. Although secure attachment appears to confer some protection
for young children in high-risk environments, the major risks for psychopathology appear to be associated with disorganized attachments (Green & Goldwyn, 2002).

**Attachment Classifications and Psychopathology**

Infant behaviors in the presence of the parent or caregiver suggesting fearfulness, freezing or other contradictory attachment behaviors (e.g., initial approach followed by avoidance while in close contact with the caregiver) during the Strange Situation Procedure are indices of a disorganized attachment classification. Although disorganized attachment has a prevalence of 14% in low-risk samples (van IJzendoorn, Schuengel, & Bakermans-Kranenburg, 1999), it is as high as 75–80% in maltreated and institutionalized samples (Carlson, Cicchetti, & Bakermans-Kranenburg, 2002). There are a number of problems with this suggestion, including the high prevalence of disorganized attachment in low-risk samples, identification based only on a child’s behaviors (perhaps lasting only a few seconds) in a laboratory paradigm with no established connection to conventional signs or symptoms, an uncertain relation to impairment and the relationship specificity of the disorganized classification. That is, the child’s attachment to another caregiver may be classified disorganized and the child’s attachment to another caregiver as another attachment classification, meaning that the classification is a characteristic of the relationship rather than the child. Therefore, the prevailing consensus is that disorganized attachment is a risk factor rather than a clinical diagnostic category (for a discussion of the relationship between attachment and psychopathology see chapter 13).

Most descriptions of attachment as a clinical disorder have derived from studies of the effects on social and emotional development in young children who have experienced severe deprivation, such as that associated with institutional rearing. Because of that, we turn next to a brief review of the association between institutional care and attachment disorders and consider how studies of institutionalized children informed psychiatric nosologies.

**Historical Considerations**

**Institutional Care and Deprivation**

Maternal deprivation and the material deprivation that often accompanies it have long been recognized as important risk factors to development in humans (Bowlby, 1965; Chapin, 1915; Rutter, 1981; Spitz, 1945), primates (Suomi, Collins, Harlow, & Rupenthal, 1976) and rodents (Hofer, 2006; Zhang, Levine,
DSM-III (American Psychiatric Association, 1980). Disordered
Reactive Attachment Disorder of Infancy first appeared in the
attachment disorder in contemporary nosologies.

groups, which had been noted in previous studies and were
unresponsive and 10 were indiscriminate, attention-seeking
children who remained in the residential nurseries, eight had
remained institutionalized (Tizard, 1977). By age 4, this latter
ambivalence on the part of the mother) and 26 children who
restored to their biological families (often despite marked
adoptions between 2 and 4 years of age, 15 children who were
rearing were studied at age 4 years: 24 children who were
included books, toys and instruction during the preschool years
in small, mixed age groups, in a stimulating environment which
stantially better than those found in older studies (Goldfarb,
Tizard’s Study
Tizard’s (1977) landmark study deconstructed the institu-
tional experience by removing the material deprivation often
associated with institutional care and focusing on the variable
of caregiver–child relationship. She described the cognitive
and socioemotional development of a group of children who
experienced varying lengths of institutional care in residential
nurseries in Great Britain. Caregiver to child ratios were sub-
stantially better than those found in older studies (Goldfarb,
Provence & Lipton, 1962). Children were maintained
in small, mixed age groups, in a stimulating environment which
included books, toys and instruction during the preschool years
(Tizard, 1977).

Three groups of children with histories of early institutional
rearing were studied at age 4 years: 24 children who were
adopted between 2 and 4 years of age, 15 children who were
restored to their biological families (often despite marked
ambivalence on the part of the mother) and 26 children who
remained institutionalized (Tizard, 1977). By age 4, this latter
group had experienced an average of 50 different caregivers
who had cared for the child for at least a week. Of the 26
children who remained in the residential nurseries, eight had
developed a preferred attachment, eight were withdrawn and
unresponsive and 10 were indiscriminate, attention-seeking
and socially superficial (Tizard & Rees, 1975). The latter two
groups, which had been noted in previous studies and were
replicated in subsequent studies, formed the basis of reactive
attachment disorder in contemporary nosologies.

Attachment Disorders in Nosologies
Reactive Attachment Disorder of Infancy first appeared in the
DSM-III (American Psychiatric Association, 1980). Disordered
social and emotional development was a hallmark of the
disorder which was signaled also by the presence of failure to
thrive. Inexplicably, there also was a requirement that the
disorder be manifest prior to 8 months of age; that is, prior
to the age at which preferred attachment ordinarily emerges
(Zeanah, 1996).

Subsequent versions of the DSM removed this curious
requirement and made the age of onset below 5 years of age.
However, in DSM-IV-TR (American Psychiatric Association,
2000), a specified etiology – the child’s signs of disturbed attach-
ment are in response to “pathogenic care” – is included.
ICD-10 (World Health Organization, 1996) criteria are gener-
ally consistent with DSM criteria. ICD-10 criteria do not
specify pathogenic care, but they do caution against making
the diagnosis in the absence of a history of maltreatment.

All revisions in criteria through 2000 occurred in the absence
of systematic research of the disorders; in fact, such research
is only beginning to appear. In addition to DSM-IV-TR and
ICD-10, two other sets of criteria for disorders of attach-
ment have been published recently. The Research Diagnostic
Criteria–Preschool Age (RDC-PA; Task Force on Research
Diagnostic Criteria: Infancy and Preschool, 2003) and the
Diagnostic Classification: 0–3, Revised criteria (Zero to Three,
2005) are quite similar, although they differ from DSM-
IV-TR and ICD-10 in focusing more explicitly on disturbed
attachment behaviors rather than disturbed social behaviors
more generally.

Clinical Disorders of Attachment:
The Phenotype

Attachment disorders describe a constellation of aberrant
attachment behaviors and other social behavioral anomalies
apparent in early childhood which are believed to result from
limited opportunities to form selected attachments. Histori-
cally, attachment disorders have been linked to deprivation
or social neglect. The diagnosis is excluded in the presence of
pervasive developmental disorders to distinguish social abnorm-
alities associated with those disorders. Consistent with the notion
of a disorder, both DSM-IV and ICD-10 require that the signs
of disorder be evident across situations and relationships.

Two clinical patterns of attachment disorders have been
described: (i) an emotionally withdrawn/inhibited pattern, in
which the child exhibits limited or absent initiative or re-
source to social interactions with caregivers, and a variety of
aberrant social behaviors, such as inhibited, hypervigilant,
or highly ambivalent reactions; and (ii) an indiscriminately
social/disinhibited pattern, in which the child exhibits lack of
expectable selectivity in seeking comfort, support and nurtur-
ance, with lack of social reticence with unfamiliar adults, includ-
ing a willingness to “go off” with strangers.

Emotionally Withdrawn/Inhibited
Core features of this subtype of attachment disorder include
lack of social and emotional responses, an absence or near-absence
of attachment behaviors even in times of stress, and serious problems of emotion regulation. Most strikingly, the emotionally withdrawn subtype of attachment disorder involves a paucity of positive affect responses. It also often includes bouts of fear or irritability that are seemingly unprovoked, or at least out of proportion to the putative stimulus. Social and emotional reciprocal interactions are absent or at least severely dampened. Although few data have addressed the issue directly, cognitive delays are an expected associated feature, given that the conditions of neglect believed to lead to this pattern of attachment disorder also are associated with developmental delays.

These signs have been described in young children with a history of severe maltreatment (Zeanah, Scheeringa, Boris et al., 2004) and those being raised in institutions (Smyke, Dumitrescu, & Zeanah, 2002; Zeanah, Smyke, Koga et al., 2005). Interestingly, they have been much less noted in children adopted out of institutions (Chisholm, 1998; Chisholm, Carter, Ames, & Morison, 1995; O’Connor, Bredenkamp, & Rutter, 1999; O’Connor & Rutter, 2000).

Indiscriminately Social/Disinhibited

Core behavioral features of disinhibited/indiscriminately social attachment disorder in young children include inappropriate approach to unfamiliar adults, a lack of wariness of strangers, failure to check back with a caregiver in unfamiliar settings, and a willingness to accompany a stranger and wander away from a familiar caregiver. Indiscriminate behavior also may be associated with lack of appropriate physical boundaries, so that children may interact with strangers intrusively and aggressively and may even seek out physical contact (O’Connor & Zeanah, 2003).

In comparing three different investigative teams’ approaches to indiscriminate behavior, Zeanah, Smyke, and Dumitrescu (2002) were able to show that despite differences in definition, there was overall a substantial convergence about how this type of disorder is identified. Nevertheless, the signs of this type of attachment disorder are not particularly clearly described in DSM-IV-TR or in ICD-10, and concerns remain about the heterogeneity of what we mean by indiscriminate behavior.

For example, some investigators have referred to “indiscriminately friendly” behavior (Chisholm, 1998; Chisholm, Carter, Ames et al., 1995), but others have suggested that these terms imply more than is actually known about the nature of the child’s behavior (O’Connor, 2002; O’Connor & Zeanah, 2003; Zeanah, 2000). Some children exhibit passive lack of reticence and willingness to accompany a stranger, but this may be quite distinct from children who eagerly accompany a stranger without even checking back with their putative attachment figure. Other behaviors subsumed under this description include lack of initial reticence around unfamiliar adults (e.g., sitting in the lap of an unfamiliar adult after just meeting him or her), actively choosing to approach an unfamiliar adult over an attachment figure in times of need, failing to monitor the whereabouts of the attachment figure in unfamiliar settings, displaying inappropriate social boundaries (e.g., making eye contact for too long or asking overly personal questions on initial meeting), or verbally or physically aggressive engagement of unfamiliar adults. These behaviors are not experienced as sociable or friendly by those on the receiving end, and they are not always indiscriminate either (O’Connor & Zeanah, 2003). There is much room for more precise delineation of behaviors subsumed by this term.

Measurement Issues and Differential Diagnosis

Attachment disorders have been assessed both continuously and categorically. Boris, Zeanah, Larrieu, Scheeringa, and Heller (1998) were the first to examine the reliability of categorical diagnostic criteria. This and subsequent categorical studies have demonstrated that attachment disorders can be reliably diagnosed in young children (Boris, Hinshaw-Fuselier, Smyke et al., 2004; Zeanah, Scheeringa, Boris et al., 2004). Studies using continuous measures of disordered attachment also have demonstrated adequate inter-rater reliability in identifying signs of both the emotionally withdrawn/inhibited and the indiscriminately social/disinhibited types of disorder (O’Connor, Bredenkamp, & Rutter, 1999; O’Connor, Marvin, Rutter et al., 2003; Smyke, Dumitrescu, & Zeanah, 2002; Zeanah, Smyke, & Dumitrescu, 2002; Zeanah, Scheeringa, Boris et al., 2004; Zeanah, Smyke, Koga et al., 2005). The two patterns have been reliably identified in extreme populations, such as severely neglected children and those being raised in institutional settings, and they appear to be extremely rare in other populations of children (Boris, Hinshaw-Fuselier, Smyke et al., 2004; Roy, Rutter, & Pickles, 2004).

Regarding convergent validity, Boris, Zeanah, Larrieu et al. (1998) demonstrated more severe parent–child relationship impairments in children with attachment disorders compared to children with other clinical problems. More specifically, Zeanah, Smyke, Koga et al. (2005) showed a moderate convergence between ratings of young children’s attachment behaviors in the Strange Situation with their caregivers and caregivers’ reports of signs of emotionally withdrawn/inhibited attachment disorder in the children. Also, the same group reported convergence of caregiver reports of signs of indiscriminately social/disinhibited attachment behavior and a procedure demonstrating the child’s willingness to “go off” with a stranger (Zeanah, 2006). These preliminary findings are encouraging that there is reasonable convergence among different methods used to identify attachment disorders. Nevertheless, it must be acknowledged that there remains no gold standard method of identification at this point.

Given the earlier noted ubiquity of attachment as a developmental issue, it seems useful to explore whether putative attachment disorders can be distinguished from other types of disturbance. In fact, both types of attachment disorder have been shown to be only modestly or moderately correlated with aggressive behavior problems, language delays and stereotypes.
CHAPTER 55

(O’Connor & Rutter, 2000; Smyke, Dumitrescu, & Zeanah, 2002).

The emotionally withdrawn/inhibited type of attachment disorder shares some features with autistic spectrum disorders, including disturbances in emotion regulation, impaired or absent social and emotional reciprocity and, often, cognitive delays. However, children with reactive attachment disorder should not have a selective impairment in pretend play, repetitive preoccupations or language abnormalities other than delays. In addition, they should have a history of seriously adverse caregiving.

Because both the inhibited/emotionally withdrawn subtype and cognitive delays have been associated with severe deprivation (Zeanah, Smyke, & Settles, 2006), it is reasonable to assume that the emotionally withdrawn/inhibited type also may be confused with intellectual disability. Young children with emotionally withdrawn/inhibited attachment disorder should be distinguishable from children with intellectual disability because the latter group have social and emotional behaviors that are consistent with their developmental age, whereas children with emotionally withdrawn/inhibited attachment disorder have clear evidence of deviance in their social responsiveness and regulation of emotion. Clearly, both conditions may co-occur.

Disinhibited attachment may share features of attention deficit/hyperactivity disorder, particularly social impulsivity. Roy, Rutter, & Pickles (2004) found that school-age children with a history of institutional rearing had high levels of both disinhibited attachment behavior and inattention/hyperactivity, as well as a strong association between the two. In addition to lack of selectivity in relationships with caregivers, the children also showed lack of selectivity with peers, echoing the findings of Hodges and Tizard (1989) with adolescents who had formerly been indiscriminate with caregivers. Because both inattention/hyperactivity and disinhibited behavior have been reported as sequelae of institutional rearing, these findings raise questions about whether they may be part of a unitary “post-institutional” syndrome, at least in a subset of cases, or whether they are distinct disorders that occur comorbidly. Of note, in Roy, Rutter, & Pickles (2004), the combination of lack of selectivity in relationships and inattention/hyperactivity occurred only in boys, whereas there has been no gender specificity reported in other studies of disinhibited attachment.

Prevalence

Signs of attachment disorders and prevalence of attachment disorders are greater in more extreme populations; that is, in young children who have experienced severe deprivation (Boris, Hinshaw-Fuselier, Smyke et al., 2004; Chisholm, 1998; O’Connor, Marvin, Rutter et al., 2003; Smyke, Dumitrescu, & Zeanah, 2002; Zeanah, Scheeringa, Boris et al., 2004). Still, there is a consensus that attachment disorders are rare, even though there have been no careful epidemiological studies.

In a sample of 300 children aged 2–5 years recruited from pediatric clinics in Durham, North Carolina, Egger, Erkanli, Keeler et al. (2006) found no cases of attachment disorders using DSM-IV or the RDC-PA criteria (Boris & Zeanah, 2005). Several recent studies of clinic-referred and high-risk children have assessed signs of disordered attachment using structured interviews and observational assessments. These studies have found that, even among maltreated children, few met criteria for attachment disorders, with the exception of maltreated children in foster care (Boris, Zeanah, Larrieu et al., 1998; Boris, Hinshaw-Fuselier, Smyke et al., 2004; Zeanah, Scheeringa, Boris et al., 2004). In a sample of 12- to 30-month-old children living in institutions in Bucharest, Romania, 10% met criteria for emotionally withdrawn/inhibited attachment disorders and 24% for indiscriminate/disinhibited attachment disorder (Zeanah, 2006). Thus, although signs of the disorder may be common in extreme populations, a minority of children seem to reach the threshold of disorder.

Etiology

Together with post-traumatic stress disorder (PTSD), attachment disorders are one of the few psychiatric disorders in which the etiology is specified as one of the diagnostic criteria. A requirement of DSM-IV is that the signs and symptoms of attachment disorder be brought about by “pathogenic care.” Although pathogenic care is not defined, maltreatment and multiple moves are cited as examples. Although ICD-10 is less insistent on requiring pathogenic care, the clinician is cautioned against making the diagnosis in the absence of a history of maltreatment.

Many questions about the nature of the caregiving compromise necessary to produce attachment disorders remain unanswered. For example, it seems reasonable to presume that neglect is the key feature, but the question of whether physical or sexual abuse alone could lead to a similar clinical picture has not been examined carefully, in part because of the difficulty of determining the nature of maltreatment in preverbal or barely verbal children. There does seem to be some component of institutional rearing that is specifically implicated in underlying indiscriminate behavior. In Roy, Rutter, & Pickles (2004), indiscriminate behavior occurred only in children with a history of institutional rearing and not in those placed in foster care, and in O’Connor, Marvin, Rutter et al. (2003) only in those with a history of institutional rearing and not those adopted within the UK. Because these studies involved institutional experiences that ranged in quality, it appears that even in better quality institutions, children remain at risk. It is also notable that the lone study to consider age at entry into institutions found that only children placed in institutions early showed a pattern of indiscriminate behavior (Wolkind, 1974).

However, anecdotal evidence suggests that even in the absence of pathogenic care, some young children display signs
of disinhibited/indiscriminate attachment behavior. For example, individuals with Williams syndrome have been reported to show high levels of indiscriminate behavior (Jones, Bellugi, Lai et al., 2002). Williams syndrome, a microdeletion on chromosome 7q11.23, is characterized by a tendency for affected individuals to approach persons they do not know and interact with them verbally. Parents of young children with Williams syndrome expend much effort to monitor their children’s whereabouts and teach them to refrain from approaching strangers (Plesa-Skwerer, personal communication). Compared with non-affected individuals, they are unable to distinguish threatening faces, considering them just as trustworthy as non-threatening faces (Jones, Bellugi, Lai et al., 2002).

Fetal alcohol syndrome (FAS) may be associated with indiscriminate behavior in the absence of pathogenic care. Alcohol acts as a central nervous system poison, and FAS results from prenatal exposure to high levels of alcohol. Signs of the syndrome in young children include a specific pattern of facial features as well as cognitive and socioemotional abnormalities, including children being talkative, affectionate, outgoing and overly friendly to strangers (see chapter 30; Jacobson & Jacobson, 2003). FAS has been associated both with increased risk of disorganized attachment (O’Connor, Sigman, & Brill, 1987) and with increased risk of reactive attachment disorder.

Course Over Time

The major impediment to understanding the course of attachment disorders is the paucity of longitudinal data available for review. Based upon preliminary results from several studies, however, it is possible to suggest that the two types of attachment disorder generally have different courses.

Studies of children adopted out of institutions have not reported evidence of the emotionally withdrawn/inhibited type following adoption (Chisholm, 1998; Tizard & Hodges, 1978; O’Connor, Marvin, Rutter et al., 2003). Furthermore, the Bucharest Early Intervention Project (BEIP), the first randomized controlled trial to evaluate an intervention for attachment disorders, included baseline assessments and follow-up at 30, 42 and 54 months of age (Zeanah, Nelson, Fox et al., 2003). At baseline, quality of caregiving, defined by parental sensitivity, stimulation of development, positive regard towards child, absence of detachment, absence of flat affect and absence of intrusiveness, was inversely related to signs of emotionally withdrawn/inhibited attachment disorder, although it was unrelated to signs of indiscriminate/disinhibited attachment disorder (Zeanah, Smyke, Koga et al., 2005). Preliminary results from this study indicate that foster care leads to significant reductions in signs of attachment disorder in young children who had signs of the disorder when they were living in institutions. In the group of young children randomized to foster care following early institutional rearing, such placement effectively eliminated emotionally withdrawn/inhibited attachment disorder and reduced indiscriminately social/disinhibited attachment disorder, whereas both persisted in children who remained in institutions (Zeanah, 2006).

Over a 2-year period in the BEIP, there was no significant reduction in signs of inhibited/emotionally withdrawn reactive attachment disorder for young children who remained in institutions. This latter finding is important, as it represents preliminary evidence of persistence of the disorder in children who remain in an adverse caregiving environment.

In contrast, there is reasonably clear evidence demonstrating that indiscriminate behavior persists over time – sometimes even after improvements in the caregiving environment. This was demonstrated originally in the work of Tizard and colleagues, who showed that young children who had been indiscriminate with caregivers at age 4 years were more likely to have serious peer disturbances at 16 years, including superficial and even indiscriminate behavior with peers (Hodges & Tizard, 1989). Subsequent studies of children adopted into Canada and the UK from Romanian institutions have also demonstrated a tendency for indiscriminate behavior to persist even after the child forms attachments to the adopted family (Chisholm, 1998; O’Connor, Marvin, Rutter et al., 2003). In fact, of those children adopted into the UK from Romanian institutions who had high levels of indiscriminate behavior at age 6 years, more than half continued to show high levels at age 11 years (Rutter, Colvert, Kreppner et al., 2006). Furthermore, in the same randomized controlled trial of foster care described above, indiscriminate behavior was only weakly responsive to removal from institutions and placement in foster care, and persistence was noted in all children who had been reared in institutions (Zeanah, 2006).

Clinical Assessment

In keeping with recent trends in the assessment of early childhood psychopathology (delCarmen-Wiggins & Carter, 2004), attachment disorders are best identified through a combination of caregiver interview and observed interactions. In our view, there are no gold standard interviews nor observational paradigms of interactions between parents and children that must be included, but several useful approaches have been described.

Interviews

Structured interviews specifically focused on the child’s attachment behaviors and signs of disordered attachment (Boris, Hinshaw-Fuselier, Smyke et al., 2004; O’Connor, Bredenkamp, & Rutter, 1999; Smyke, Dumitrescu, & Zeanah, 2002; Zeanah, Scheeringa, Boris et al., 2004) are more likely to be useful than interviews that are less specifically focused. At least two structured psychiatric interviews, the Psychiatric Assessment Preschool Age (Egger & Angold, 2004) and the Diagnostic Infant/Preschool Structured Interview (Scheeringa, 2005) include modules on attachment disorders. These approaches have been able to characterize attachment disorders both categorically and continuously.
Observations

Observations of parent and child together include procedures designed specifically to examine attachment behaviors (Boris, Hinshaw-Fuselier, Smyke et al., 2004; Marvin, Cooper, Hoffman, & Powell, 2002; O’Connor, Marvin, Rutter et al., 2003), or those in which other aspects of parent–child interaction are also assessed (Zeanah, Larrieu, Valliere, & Heller, 2000). It is generally useful to include in the observation some degree of distress that is likely to activate the child’s need for the attachment figure. Conventionally, this has involved brief separations followed by reunions, but other approaches such as a novel (i.e., scary) toy also have been used (Boris, Hinshaw-Fuselier, Smyke et al., 2004). Although it is neither necessary nor necessarily advisable to use the Strange Situation Procedure in clinical assessments, in some circumstances, it may be helpful. The Circle of Security Intervention, for example, includes review of videotaped recordings of a child’s Strange Situation behavior with the parent as a part of the intervention (Marvin, Cooper, Hoffman et al., 2002). What is important clinically is not to confuse attachment classifications derived from the Strange Situation with attachment disorder diagnoses. Although systematic observations of the child’s behavior in paradigms designed to elicit attachment behaviors are often clinically valuable, naturalistic observations of a child’s attachment behaviors also may yield important data.

Interventions

Given that the database on disordered attachment is so small and so recent, it is not surprising that studies of intervention efforts for reactive attachment disorder are limited. Intervention efforts to date have been guided by the principle that enhancing the caregiving environment will ameliorate signs of attachment disorder. There are case reports documenting substantial improvements in young children removed from severely neglecting environments and placed in foster care (Hinshaw-Fuselier, Boris, & Zeanah, 1999; Zeanah & Boris, 2000; Zeanah, Mammen, & Lieberman, 1993). Stovall and Dozier (2000) also reported a descriptive study indicating that attachment behaviors in a small sample of young children became organized towards their new caregivers within days to weeks of placement in foster care.

Studies of children raised in institutions have also begun to appear. Smyke, Dumitrescu, & Zeanah (2002) studied signs of attachment disorder in young children being raised in a large institution for young children in Bucharest. This institution had implemented a pilot unit designed to reduce the number of caregivers responsible for each child. In fact, compared to the more standard units, which included large numbers of rotating caregivers, on the pilot unit no more than four caregivers were responsible for each child on the day and evening shifts. Caregivers on the pilot unit reported that children had significantly fewer signs of both emotionally withdrawn/inhibited attachment disorder and indiscriminately social/disinhibited attachment disorder. Importantly, this reduction was evident even though the ratio of caregivers to children remained at 1:12 on the pilot unit (the same as on the standard units).

Studies of young children adopted out of institutions are also useful to examine because they represent such a dramatic change in caregiving environments. Two longitudinal studies of young children adopted out of Romanian institutions are particularly instructive.

A longitudinal study of young children adopted into Canada from Romanian institutions used parent reports of attachment and indiscriminate behavior. They found significant increases in attachment to adoptive parents during the first several years following adoption, although indiscriminate behavior persisted in a minority of children (Chisholm, 1998; Chisholm, Carter, Ames et al., 1995).

Another longitudinal study of children adopted from Romanian institutions into families in the UK assessed signs of disordered attachment from parent reports at ages 4, 6 and 11 years (O’Connor & Rutter, 2000; O’Connor, Marvin, Rutter et al., 2003; Rutter, Colvert, Kreppner et al., 2006). They reported little change in the numbers of children with high levels of indiscriminate behaviors between 4 and 6 years, but some decline by age 11 years (O’Connor & Rutter, 2000; Rutter, Colvert, Kreppner et al., 2006). To date, however, there has been no demonstration that quality of care in adoptive homes is inversely related to signs of indiscriminate social/disinhibited attachment in children.

In summary, findings from studies of children living in institutions and those adopted out of institutions suggest that signs of the indiscriminate/disinhibited type are remediated by enhanced caregiving only in some children. It is unclear whether this represents individual differences among children or partial remediation with persistence in those most severely affected initially. To date, adoption studies have not included assessments of children in the institutions prior to adoption, making it difficult to explain individual differences in response.

The only contemporary intervention study that included assessments of children’s attachment prior to removal from institutions and placement in an enhanced caregiving environment is the BEIP, described earlier. Preliminary results from this study indicate that foster care leads to significant reductions in signs of attachment disorder in young children who had had signs of the disorder when they were living in institutions (Zeanah, 2006).

At this stage, clinicians must be guided by data indicating that secure attachment is fostered by caregivers who are emotionally available and sensitively responsive, who know and value the child as an individual, and who place the needs of the child ahead of their own needs. Preliminary data indicate that psychoeducational approaches involving training parents to respond sensitively to their child (van den Boom, 1995) and to understand their own and their child’s attachment pattern (Hoffman, Marvin, Cooper, & Powell, 2006) have been shown to promote attachment security in the child. These interventions are reasonable starting points for developing an evidence base about intervening in disordered attachments.
Conclusions

Our understanding of attachment disorders has deepened considerably in the past decade as a result of the publication of a number of systematic studies of children with histories of severe neglect or institutional rearing. These studies have confirmed the reliable identification of both the emotionally withdrawn/inhibited and the indiscriminately social/disinhibited types of attachment disorder described in contemporary nosologies. They also have supported the link between pathogenetic care and attachment disorders, and have suggested that the specific “pathogen” is any environment in which young children have limited opportunities to form selective attachments, as happens in cases of severe social neglect or in settings in which the child lacks regular and consistent contact with an emotionally involved caregiver (e.g., institutional settings).

These studies have suggested that although the two types of attachment disorders arise from similar conditions of risk, they have different correlates and different courses. In particular, placement in enhanced caregiving environments seems to lead to rapid and complete elimination of signs of emotionally withdrawn/inhibited attachment disorder, but the indiscriminately social/disinhibited attachment disorder remains persistent in some children, apparently for years.

However, a number of questions remain to be addressed. First, nothing is known about individual vulnerabilities to the disorder in particular why such phenotypically distinct syndromes arise from similar conditions of risk. Genetic polymorphisms, temperamental dispositions and differential caregiving experiences should all be examined. In addition, the relationship between the two types of disorder – if any – needs to be clarified. Second, why some children with indiscriminately social/disinhibited attachment disorder seem to respond to enhanced caregiving and others do not is unclear. Third, the specific components of enhanced caregiving that are crucial for amelioration of signs of the disorder are unclear. This is especially important given the heterogeneity of outcomes in post-adoption studies. Fourth, the putative social cognitive abnormalities that characterize indiscriminate behavior need to be delineated. It seems reasonable that such abnormalities are the most concerning aspect of the disorder from the standpoint of functional impairment. Finally, the underlying neurobiology of these disorders is largely unexplored. The links between indiscriminate behavior and Williams syndrome and FAS, each of which has begun to be explored neurobiologically, may suggest hypotheses about functional impairments to be examined in children with deprivation-induced indiscriminate behavior. Answers to these questions will assist clinicians concerned with helping children recover from the long-term effects of early adversity.

CHAPTER 55

Wetting and soiling are widespread, and can be distressing. A recent epidemiological study of over 13,000 English children (Avon Longitudinal Study of Parents and Children [ALSPAC]) found from parental reports that at 7 years of age 15.5% children wet the bed sometimes, 7.7% sometimes wet during the day, 6.8% had daytime soiling and only 0.8% had night-time soiling (Butler, Golding, Northstone et al., 2005a). There is an overall reduction in prevalence with age: by late adolescence 1–2% continue bedwetting (Verhulst, van der Lee, Akkerhuis et al., 1985), 1% day wet (Hellström, Hanson, Hansson, Hjälmås, & Jodal, 1990) and very few soil (Bellman, 1966). However, the picture is not one of universal improvement. Children with the severest form of wetting or soiling (at least twice a week, in line with the DSM-IV diagnostic criteria) are much less prevalent (2.6% for bedwetting at age 7, 1% for daytime wetting and 0.8% soiling; Butler, Golding, Northstone et al., 2005a), but an epidemiological survey by Yeung, Sreedhar, Sihoe, Sit, and Lau (2006) suggested that for these more severely affected individuals the prevalence profile remains flat, with enuresis tending to continue into late adolescence.

There is accordingly a complex issue about the point at which these forms of incontinence should be defined as problematic. One way of answering is developmental: to define an age at which there is a discontinuity and a sudden increase in the proportion becoming dry or clean. On this basis, Verhulst, van der Lee, Akkerhuis et al. (1985) identified a rapid decrease in the prevalence of nocturnal enuresis at about age 5 for girls and 8 for boys. A definition on this basis, however, would overlook the psychological distress for families with children (especially boys) who are enuretic but younger than the age of rapid decrease. A different approach, in line with recent evidence, suggests intervention to set out the child’s needs. Both Yeung, Sreedhar, Siho et al. (2006) and Butler, Golding, Northstone et al. (2005a) suggest that those wetting less frequently than the DSM-IV definition of twice a week, now termed “inrequent wetters,” will fairly quickly achieve dryness, and so are inappropriate for evidence-based treatment interventions, and are best supported in terms of management (e.g., regular drinking, regular toileting). However, children meeting the DSM-IV definition (wet at least twice a week) appear likely to continue wetting throughout childhood and need to be identified early and treated appropriately.

This chapter follows the DSM-IV approach of definitions based on both chronological age and frequency of occurrence, as set out in the following sections; but with the option of recognizing that treatment may be appropriate for some children who are distressed or impaired by the symptom even if they do not meet all the other criteria.

Children with wetting and soiling are usually seen in primary care or in community-based clinics, with more complex problems referred into pediatric or child mental health services. Wetting and soiling become of particular interest to clinical psychology and psychiatry in the context of comorbidity, family dynamics and lack of response to treatment intervention. Coexistence of the problems is common: in the ALSPAC study, the small proportion (2.6%) with severe bedwetting (more than twice per week) also had a substantially increased rate of severe day wetting and a few also showed daytime soiling (Butler, Golding, Northstone et al., 2005a). Behavioral problems, including attention deficit/hyperactivity disorder (ADHD), are often identified as coexisting with nocturnal enuresis (von Gontard, Pluck, Berner, & Lehmkuhl, 1999). Urinary tract infection (UTI) can provoke overactivity of the detrusor muscles leading to painful voiding, urgency and day wetting (Hellström, Hanson, Hansson et al., 1990). An accumulation of fecal mass in constipation can compress the bladder, leading to uninhibited bladder contractions and day wetting (Kodman-Jones, Hawkins, & Schulman, 2001).

Girls present a variable epidemiological profile (Verhulst, van der Lee, Akkerhuis et al., 1985) with a higher likelihood of secondary wetting (a return of wetting after being dry for at least 6 months). Secondary enuresis has repeatedly been found to be associated with a high incidence of distressing events, including parental separation and disharmony (Jarvelin, Moilanen, Vikevainen-Tervonen, & Huttunen, 1990; von Gontard, Hollmann, Eiberg et al., 1997). A minority of parents may hold the belief that wetting or soiling is under the child’s control, leading to intolerance, and such reactions seem antagonistic to some of the treatments available.

An awareness of the heterogeneity of each problem can prove beneficial, both in terms of understanding the psychological ramifications and deciding on the apposite intervention. Nocturnal enuresis is divisible into monosymptomatic or polysymptomatic forms (based on the absence or presence of
bladder overactivity); day wetting can be considered as either urge incontinence, voiding postponement or detrusor-sphincter dyscoordination; and soiling can reflect a lack of bowel control, intentional inappropriate deposition or constipation with overflow. Clinicians enhance their effectiveness by assessing a child’s particular needs, applying evidence-based treatment interventions and drawing, where possible, on a knowledge of pre-treatment predictors of outcome (Butler & Stenberg, 2001).

**Nocturnal Enuresis**

Although parental concern and child distress should undoubtedly be considered in determining clinical significance, nocturnal enuresis is defined as an involuntary voiding of urine during sleep in children over 5 years with a severity of at least twice a week for at least 3 consecutive months when not provoked by congenital or acquired defects of the central nervous system (American Psychiatric Association, 2000).

The psychological associations of bedwetting have been reviewed by Butler (2001) and although the diversity of methodology hinders firm conclusions, the ALSPAC study suggests a tendency towards social avoidance, vulnerability to victimization and increased activity and impulsivity at 7 years compared with controls (Joinson, Heron, Emond, & Butler, 2007a). However, as a group, there are few differences between those with primary nocturnal enuresis (in the absence of daytime wetting) and controls in terms of emotional adjustment, self-construing (Butler, Redfern, & Holland, 1994; Joinson, Heron, Emond et al., 2007a) or behavioral presentation (Friman, Handwerk, Swearer, McGinnis, & Warzak, 1998; Hirasing, Van Leerdam, Bolk-Bennink, & Bosch, 1997).

However, children with more complex presentations appear more psychologically vulnerable than controls. Emotional vulnerability and behavior problems have both been linked to secondary nocturnal enuresis (von Gontard, Hollmann, Eiberg et al., 1997) and associated daytime wetting. There are probably several developmental pathways accounting for the associations between wetting and mental disturbances. The epidemiological basis of the findings makes it clear that referral bias is not the explanation. The timing of associations is an important clue: Rutter, Yule, and Graham (1973) drew on epidemiological data and reported that children who developed secondary enuresis were more likely to have shown psychological deviance before the enuresis started. This indicated that the psychological symptoms did not wholly result from the impact of wetting; rather, they either led to the wetting or resulted from a common cause, such as stressful life events and social adversity (see Chapters 25 and 26).

There may well be a further pathway from enuresis to psychological symptoms. Fergusson and Horwood (1994) reported longitudinal epidemiological data showing a predictive effect of childhood wetting on later adolescent disturbance. The effect survived allowance for potentially confounding factors, but its size was small. Clinically, it is common to find that children are upset by both the experience of wetting and the reaction of other people; specific treatment of enuresis, such as the alarm, has reduced psychological symptoms in randomized trials (Longstaffe, Moffatt, & Whalen, 2000). The higher rates of disturbance when daytime wetting is present suggest that the public nature of the problem may provoke a troublesome dilemma (Feehan, McGee, Stanton, & Silva, 1990). While most parents remain tolerant towards the wetting, a notable proportion become intolerant and punitive (Tissier, 1983), which can lead to early withdrawal from alarm-based treatment. Where parental intolerance is apparent, a package of interventions is advocated – designed to maintain contact with the family, immediately reduce hostile feelings and challenge parental attributions of controllability (Butler & McKenna, 2002).

**Assessment**

Physical examination should exclude organic causes such as neurological incontinence. Urine analysis is necessary to check for infection (UTI; Mikkelsen, 2001). A primary clinical objective is the identification of bedwetting as either monosymptomatic (MSNE) or polysymptomatic (PSNE) based on the absence or presence of bladder overactivity, respectively (Table 56.1). The three systems approach (Butler, 2004; Butler & Holland, 2000), a conceptual formulation drawing on empirical evidence, offers an explanatory model for children while aiding practitioners in selecting appropriate treatment interventions.

Urine volume is normally reduced and concentrated through arginine vasopressin (AVP) secretion, enabling continuous sleep throughout the night. However, children with MSNE appear to lack circadian rhythmicity of AVP leading to urine volumes that exceed bladder capacity (Nørgaard, Pedersen, & Djurhuus, 1985; Rittig, Knudsen, Nørgaard, Pedersen, & Djurhuus, 1989). Clinical identifiers of low AVP include wetting soon after going to sleep and large wet patches (Butler & Holland, 2000; Nørgaard, Rittig, & Djurhuus, 1989). Studies of overnight cystometry recordings of children with nocturnal enuresis suggest 30–32% have uninhibited bladder contractions during sleep with small functional bladder capacities at the point of wetting (Kruse, Hellström, & Hjalmás, 1999; Watanabe, Imada, Kawauuchi, Koyama, & Shirakawa, 1997). Such children are regarded as having PSNE and are identified by daytime urgency, frequent daytime voiding (more than 7 times per day), low voided volumes, variability in size of the wet patch and waking during or immediately after wetting (Butler, Robinson, Holland, & Doherty-Williams, 2004a; Yeung, Chiu, & Sit, 1999). Voided volumes are assessed by inviting the child to void into a measuring jug when the bladder “feels full,” avoiding the first void of the morning (Watanabe & Kawauuchi, 1995). The highest measurement provides an estimate of maximum voided volume, which is compared with expected voided volume, by employing the formula (up to 14 years), age × 30 + 30 (mL).

Approximately 80% of non-enuretic children sleep through the night without waking to toilet, yet they are more likely to wake spontaneously to void compared to enuretic children (Bower, Moore, Shepherd, & Adams, 1996), leading both
children and parents to believe bedwetting is a deep sleep phenomenon. However, electroencephalography (EEG) investigations of sleep physiology suggest similar sleep architecture to that of non-enuretic children (Mikkelsen, Rapoport, Nee et al., 1980; Neveus, Stenberg, Lackgren, Tuvelo, & Hetta, 1999). Wetting episodes occur during all sleep stages in proportion to the amount of time spent in that stage (Wolfish, 1999) and occur when the bladder is filled to the equivalent of maximal voided volume (Nørgaard & Djurhuus, 1993). Further, there are no apparent differences in sleep pattern on dry compared with wet nights (Gillin, Rapoport, Mikkelsen et al., 1982). What appears problematic for bedwetting children is being unable to arouse from sleep to bladder signals (Watanabe, Imada, Kawauchi et al., 1997).

Etiology
The heterogeneity of nocturnal enuresis suggests the possibility of differing etiologies. Arguably, the influential effect of any etiological determinant is through increasing vulnerability towards suboptimal nocturnal AVP secretion, bladder overactivity and/or reduced arousal response to bladder signals during sleep. Genetic influences play a part. Community surveys have shown high rates of enuresis in the families of people who are slow to acquire continence of urine at night (Fergusson, Horwood, & Shannon, 1986; Jarvelin, Moilanen, Kangas et al., 1991). Familiality by itself does not imply heritability, but the rate of nocturnal enuresis in the identical twins of bedwetters is much higher than in non-identical, suggesting a genetic contribution (Bakwin, 1971); and a genetic contribution to the acquisition of night-time dryness is clear from twin studies even in 3-year-olds (Butler, Galsworthy, Rijsdijk, & Plomin, 2001a) and 4-year-olds (Hublin, Kaprio, Partinen, & Koskenvuo, 1998). Psychosocial theories of etiology are supported by findings indicating the coexistence of bedwetting with low socioeconomic status (Chiozza, Bernardinelli, Caione et al., 1998), families in overcrowded housing (Foxman, Valdez, & Brook, 1986), unemployment of father (Devlin, 1991), large family size (Hanafin, 1998) and, interestingly, the absence of breastfeeding (Kalo & Bella, 1996; Liu, Sun, Uchiyama, Li, & Okawa, 2000). A well-conducted study with matched controls drawn from an unselected population (Jarvelin, Moilanen, Vikevainen-Tervonen et al., 1990) found that disruptive experiences (particularly splitting of the family through separation or divorce) during a sensitive stage in the development of bladder control (around 2–3 years) were related to the later development of nocturnal enuresis. Such disruptions may contribute to other potentially adverse experiences, including poorer living conditions, emotional turmoil and adaptation to new family dynamics and structures. The consequent anxiety could interrupt either the acquisition of co-ordinated muscular responses, leading to bladder overactivity, or the inhibition of AVP secretion (Houts, 1991).

Management
Facilitating an understanding of the three systems, often through pictures, enables an awareness of cause and the direction of treatment and emphasizes the importance of not attaching blame. Many parents adopt strategies for helping their child, with lifting and fluid restriction (Haque, Ellerstein, Gundy et al., 1981; Butler, 1987) being the most frequently reported. However, both may inadvertently prolong bedwetting. Lifting (toileting at night, usually without waking the child) in effect encourages children to empty the bladder while asleep, while fluid restriction may precipitate bladder overactivity. Good clinical practice encourages regular daytime drinking and invites
the child to test what fluid intake (both volume and type) is appropriate before bedtime. The only parental strategy that appears effective is the adoption of regular daytime toileting (Butler, Golding, Heron et al., 2005b), which encourages development of control over the bladder.

**Effective Treatment**

Treatments for nocturnal enuresis are broadly categorized as either psychological, which typically aim for complete cessation, or pharmacological, which usually aim for wetting reduction. The three systems approach (Butler & Holland, 2000) encourages consideration of the child's needs, with desmopressin or the enuresis alarm being appropriate for MSNE, and bladder training, usually combined with anticholinergic medication, being applicable for PSNE (Table 56.1).

**Desmopressin**

Desmopressin, a synthetic analog of vasopressin, is considerably more resistant to metabolic degradation than natural AVP. The mode of action is antidiuretic, with decreased urine production and increased urine concentration (Rushton, Belman, Skoog, Zaontz, & Sihelnik, 1995). An excellent review of randomized controlled trials found 70% response rate with 24.5% complete cessation of bedwetting while taking desmopressin (Moffatt, Harlos, Kirshen, & Burd, 1993). When employed specifically with MSNE, higher response rates are reported (Caione, Arena, Biraghi et al., 1997; Devitt, Holland, Butler et al., 1999). With the correct dose, dry nights are realized immediately. Thus, where a rapid response is desired (e.g., sleepover, parental intolerance), desmopressin is preferable to the enuresis alarm. Because desmopressin has no detectable effect on endogenous AVP release (van Kerrebroeck, 1999), very few side effects, even with long-term medication. Thus, long-term treatment is often advocated. Pretreatment predictors of success include older children, less severe nocturnal enuresis and no bladder overactivity (Butler & Stenberg, 2001).

There are nasal spray, tablet and melt formulations with doses of 20–40 μg, 200–400 μg and 120–240 μg, respectively, taken just before bedtime with a break after 3 months to check if further treatment is indicated (Rittig, Knudsen, Nørgaard et al., 1999). Very few side effects, even with long-term treatment, are reported (Hjalmars, Hanson, Hellström, Kruse, & Sillen, 1998; Miller, Goldberg, & Atkin, 1989) provided the child does not drink excessively before bedtime or throughout the night. However, there are rare reported cases of hyponatremia although of 11 cases reported, 6 were caused by excess fluid intake (Robson, Leung, & Bloom, 1996).

**Enuresis Alarm**

The enuresis alarm is considered the optimal intervention for MSNE (Mellon & McGrath, 2000). The essential principle is to alert and sensitize the child to respond quickly and appropriately to full bladder signals, converting the signal from one of urination to that of inhibition of urination and waking (Butler, 1994). A key to success is not stimulus intensity of alarm triggering, but the child's preparedness to wake and respond to the signal (Wolfish, 1999, 2001). Reviews of controlled studies with undifferentiated samples indicate 65–75% success with duration of 5–12 weeks and relapse of 30–45% in the 6 months following treatment (Butler & Gasson, 2005; Forsythe & Butler, 1989). Compared with desmopressin, rate of response with alarm treatment is slower but relapse less likely (Houts, Berman, & Abramson, 1994; Monda & Husmann, 1995).

The expanding literature pertaining to pretreatment predictors of outcome should enhance clinical efficacy. Failure is associated with multiple wetting at night, associated daytime wetting, lack of motivation, family distress and concomitant behavioral or psychiatric problems (Devlin & O’Cathein, 1990; Moffatt & Cheang, 1995). Early withdrawal has repeatedly been found where there is parental intolerance (Butler, Brewin, & Forsythe, 1988) and relapse tends to occur with multiple wetting, associated daytime wetting and secondary enuresis. With regards to within-treatment variables, failure is associated with lack of waking to alarm triggering (Butler & Robinson, 2002).

The mode of action remains open to conjecture, particularly as the majority of children who become dry sleep through the night, although theoretically it is assumed they learn to arouse to full bladder sensations (Butler & Robinson, 2002). Possible explanations include avoidance conditioning whereby alarm triggering is avoided by inhibition of micturition, increased functional bladder capacity or increased production of AVP in response to waking to the alarm (Butler & Stenberg, 2001).

**Bladder Training**

Bladder training aims to promote voluntary control over voiding, generating a change from unstable to stable bladder functioning at night. Fundamentally, children are encouraged to drink regularly (6–7 times per day), void at predetermined times, deal with urgency by voiding immediately if the sensations persist and keep regular checks of voided volumes. An uncontrolled clinical trial of children with PSNE found 68% response (>50% reduction in bedwetting) after 1 month of bladder training (Kruse, Hellström, & Hjalmars, 1999).

**Anticholinergic Medication**

Oxybutynin is a smooth muscle relaxant specifically targeting the detrusor muscles, both reducing overactivity and increasing functional bladder capacity (Kosar, Arikan, & Dincel, 1998). With unselected samples, oxybutynin has proved ineffective (Lovering, Tallett, & McKendry, 1988), yet in selected groups of children with PSNE, in uncontrolled case studies, success rates of 67–90% are reported (Kosar, Arikan, & Dincel, 1998; Watanabe, Kawauchi, Kiramori, & Azuma, 1994). Potential side effects include dry mouth, constipation and flushing.

**Relapse Prevention**

Although there are no published reports on relapse prevention with anticholinergic medication, clinical practice suggests removal is effective once the voided volume is age appropriate. Traditionally, overlearning, which involves increased
drinking in the hour before bed, has been advocated with the enuresis alarm although there are both theoretical (regarding the mechanism of action) and clinical concerns (children being dispirited by emergence of wetting). With desmopressin, gradual reduction of dosage is advocated, but reduction is prolonged (up to 3 years) and emphasizes medication as the effective agent, and at best only 50% of children remain dry (Miller, Goldberg, & Atkin, 1989).

In becoming dry, children tend to attribute success to treatment (alarm or medication) so, in effect, externalize success. Relapse may arise through removal of what the child believes to be the effective agent. Recently, Butler, Holland, and Robinson (2001b) have reported a program specifically designed to prevent relapse after removal of medication, with 75% success. The program focuses on engaging the child in a process of internalizing success and highlighting the effective process by which this is accomplished, whether it is increased arousability or improved AVP release.

### Daytime Wetting

According to DSM-IV, daytime wetting is considered an involuntary voiding of urine into clothing, with a severity of at least twice a week, in children over 5 years when not provoked by congenital or acquired defects of the central nervous system. The age criterion is not based on secure evidence, and Robson, Leung, & Bloom (1996) contended that daytime wetting is problematic at 4 years.

#### Assessment

All children deserve a careful history, pediatric physical examination, urinalysis to detect UTI and abdominal examination to rule out fecal impaction. Children with a difficulty initiating voiding, interruptions of the stream or constant dribbling require urological investigation. Von Gontard (1998) suggested non-invasive techniques should include a 24 h diary of fluid intake and urinary output; ultrasound to detect structural anomalies.

ADHD, attention deficit/hyperactivity disorder, PSNE, polysymptomatic nocturnal enuresis; UTI, urinary tract infection.
anomalies and residual urine; and uroflowmetry to identify detrusor–sphincter dyscoordination, although some clinicians rely on listening to the stream. Table 56.2 outlines the three main forms of daytime wetting.

**Urge Incontinence**
Urge incontinence results from sudden unexpected detrusor contractions. When access to a toilet is restricted children are unable to hold and counteracting the urge to void with pelvic floor contraction may lead to small voided volumes, inappropriate postponement of defection and constipation. Wetting tends to occur when playing outdoors, shopping or walking home from school (van Gool & de Jonge, 1989).

**Voiding Postponement**
Voiding postponement is common in preschool children (Robson, Leung, & Bloom, 1996) although there are no reliable epidemiological estimates. During absorbing activities (play, television, computers), children ignore (or fail to register) a need to void, with bladder pressure building until the detrusor contracts and wetting occurs.

**Dysfunctional Voiding**
Several patterns are apparent, with overactivity of the pelvic floor muscles during micturition being a common denominator. Detrusor–sphincter dyscoordination is the most common. Although rare, because of potentially severe medical consequences, diagnosis and specific treatment are vital. Epidemiological data are lacking, although von Gontard (1998) suggested relatively high rates in psychiatric settings.

Less common forms of day wetting include the following:

**Giggle Micturition**
This is sudden involuntary complete bladder emptying, usually provoked by laughter, tickling or excitement. Of the few cases reported, 70% are girls. It may resolve in adolescence but can persist into adulthood. There are no evidence-based treatments but Schmitt (1982) advocated stream interruption exercises.

**Stress Incontinence**
Involuntary loss of urine when, in the absence of detrusor contractions, intravesical pressure exceeds the maximum urethral pressure (Nørgaard, van Gool, Hjälmås, Djurhuus, & Hellström, 1998). Voiding may be provoked through coughing and exertion such as running, jumping and gymnastics.

**Resistive Wetting**
Schmitt (1982) suggests that some children become resistive about using the toilet and deliberately wet themselves. Usually occurring with boys, with a history of pressurized or punitive toilet training, there is often non-retentive soiling. There is a need to reduce tension within the parent–child relationship, foster praise for appropriate toileting and encourage the child to take positive responsibility for bladder functioning.

**Etiology**
From inconclusive evidence, von Gontard, Schaumburg, Hollman, Eiberg, and Rittig (2001) suggested an autosomal mode of inheritance in urge incontinence; environmental and psychological determinants with voiding postponement, whereas dysfunctional voiding was considered to have a genetic predisposition in the form of a delayed development of sphincter–detrusor coordination.

**Management**
Although lacking empirical evidence, many strategies continue to be adopted by clinicians. These include explanation of bladder function; regular daytime fluid intake; keeping records of voiding; sitting on the whole seat when voiding with feet supported; voiding with a relaxed pelvic floor, bending slightly forwards; completely emptying the bladder; voiding in one go, listening to the sound; developing bladder awareness through linking behaviors (e.g., fidgeting) with a desire to void; measuring voided volumes; undertaking action replay (waiting a short while after voiding and trying again, to prevent residual urine); reinforcing all actions that improve the chances of staying dry; remaining calm as a parent as over-eager toileting may foster anxiety and fear over the toilet; and treating any wetting as a matter of fact and a chance for both renewed efforts and an opportunity to learn about what provoked wetting.

**Effective Treatment**

**Cognitive–Behavioral Therapy**
For children with urge incontinence, bladder training as described for nocturnal enuresis is the preferred intervention, with the aim of establishing a sense of voluntary control over bladder functioning. Briefly, it consists of regular drinks (6–7 times per day), regular toileting (approximately 6 times per day), coupled with toileting rather than holding when urgency is experienced. Non-directive prompts to assist a child in making decisions to use the toilet regularly are preferable to direct prompts where parents are often construed as “nagging.” For children with voiding postponement, the goal is to increase frequency of daytime voiding with a watch triggering every 2 h to aid remembering.

**Body Worn Alarm**
Halliday, Meadow, and Berg (1987) reported 66% success although a non-contingent alarm schedule was equally as effective as triggering contingent on wetting, suggesting that regular toileting, rather than conditioning bladder signals, is the important factor (in contrast with nocturnal enuresis, where alarm triggering contingent with wetting is important).

**Biofeedback**
Van Gool, Vijverberg, and de Jong (1992) employed a program embracing bladder training (voiding at first sensation of urge, decreasing number of voids) with biofeedback involving visual (uroflow) and acoustic (electromyography [EMG]) readings of flow curves displayed for the child, who is encouraged to
CHAPTER 56

urinate with a steady flow. They reported 60% success in disappearance of urge syndrome and voiding dysfunction.

Medication
There is little evidence of medication being helpful for children with daytime wetting, although good controlled trials are lacking. Anticholinergic medication (oxybutynin), with a specific action on reducing detrusor overactivity, is regularly employed for children with urge incontinence. Oxybutynin is usually prescribed at 5 mg twice a day, with slow-release preparations administered only once a day (Hjalmas, Passerini-Glazel, & Chiozza, 1992). Side effects include dry mouth, constipation, skin flushing, blurred vision and headache (Robson, Leung, & Bloom, 1996).

Combination Therapy
Hellerstein and Zguta (2003) used bladder training coupled with anticholinergic medication with urge incontinence and found 47% complete recovery and 42% improvement. Vijerberg, Elzinga-Plomp, Messer, van Gool, and de Jong (1997) described a 10-day in-patient program for both urge incontinence and dysfunctional voiding involving biofeedback with uroflowmetry to display good (smooth curve) or poor (interrupted curve) micturition patterns; bladder training (regular fluid intake, voiding to a regular pattern and reacting appropriately to urge signals); and goal setting (six voids per day). They reported 68% success, especially with older children. The challenge is to develop similar programs for out-patients and discover the effective components of the program.

Fecal Soiling

According to DSM-IV (American Psychiatric Association, 2000), this is the repeated passage of feces into inappropriate places, after the chronological or mental age of 4 years, at least once a month for 3 months without any structural abnormality or physical cause. I would prefer to reduce the age criterion to 3 years to avoid excluding such youngsters in need of treatment.

In terms of the usual development, Clayden (2001) suggested the sensation to defecate occurs when rectal contents impinge on the upper part of the temporarily relaxed anal canal. With increasing rectal filling and distension, defecation is postponed by contraction of the external sphincter and pelvic floor muscles. The rectum contracts every 1–2 min and the sensation to defecate increases in intensity until the rectum is emptied. The sensation may be diminished where there is either sensory nerve loss (neuropathic rectum) or where the rectum is persistently full, especially where the fecal mass is firm (constipation) and prevents all but loose or liquidized feces passing through (overflow incontinence). The strength of the anal sphincter is likely to be affected by trauma such as abuse.

Appropriate defecation is dependent on this physiological response and is assisted where there is sufficient diet (fiber and fluid) to promote movement of feces through the bowel. The child needs to attend and respond to bodily cues related to peristalsis, rather than ignore them, to discriminate between appropriate and inappropriate places for defecation, have an inclination to use the toilet and to relax and tighten the stomach muscles to eliminate feces. Thus, the physiology is aided by behavioral responses. Stein and Susser (1967) showed bowel control was achieved by 50% of children at 24 months and by almost all children (both day and night) by 2.5 years.

Findings relating to impact of fecal soiling are equivocal. There is a need to clarify type of soiling in future empirical work. The clinical impression is that children with fecal soiling often live in fear of discovery, have poor peer relationships, tend to withdraw socially and avoid social events (Landman, Rappaport, Fenton, & Levine, 1986). The ALSPAC study showed that those soiling more frequently have greater levels of emotional problems (e.g., separation anxiety, social fears, general anxiety and sadness) and were more likely both to report being victimized and to bully others compared with controls (Joinson, Heron, Butler et al., 2007b). Parental ratings of behavior can be influenced by the fact of soiling (halo effects), but an association between soiling and psychological disturbance is still present when the latter is rated by teachers (Rutter, Tizard, & Whitmore, 1970).

With respect to behavior, studies with strict inclusion criteria have found increased rates of behavior problems in those with fecal soiling compared with controls (Benninga, Bueller, & Heymans, 1994; Loening-Baucke, Cruikshank, & Savage, 1987). Foreman and Thambirajah (1996) reported more behavioral problems in those with secondary encopresis compared to primary encopresis. Other behavioral issues found to be associated with fecal soiling are obsessive compulsiveness and attention and activity problems (Joinson, Heron, Butler et al., 2007b). Both Landman, Rappaport, Fenton et al. (1986) and Joinson, Heron, Butler et al. (2007b) reported reduced self-esteem in children with soiling problems.

Psychologically, vicious cycles are likely to develop as a result of soiling (Levine, 1982). Parents may attribute avoidance of toileting as willful or controlling, and diarrhoea-like soiling as laziness. With the resultant blame and admonishment, children experience hostile parental reactions despite being unable to feel a need to toilet. Consequently, they may hide soiled underclothes to avoid detection and humiliation. Children may fail to notice the resultant smell as the olfactory apparatus accommodates to incessant odors and thus children may have limited awareness of soiling and the consequences. It is also possible that soiling can result from pre-existing disturbance or from stresses (like those affecting wetting, see above) on the child that may be linked to psychological problems.

Assessment

Possible physical and organic factors need screening. The list of rare organic conditions involving soiling is long and well elucidated by Loening-Baucke (2002). Urinalysis and urine culture are necessary in the evaluation with girls because...
of a susceptibility to UTI. Clayden (2001) suggests the more normal the consistency of the stool in the clothing, the less likely there is to be a structural abnormality of the anus or rectum. Levine (1982) favored X-ray of the lower abdomen for the detection of abundant retained feces, or a clinical examination may reveal a constipated colon.

Careful history-taking is imperative to elucidate the type of soiling. Areas to cover include:

1. Precipitating factors: life events such as parental separation, birth of siblings, traumatic accidents, abuse, starting school, hospitalization;
2. History of soiling including age of onset;
3. History of toilet training;
4. Current toilet use, which defines pattern of toileting, and parental and child motivation;
5. Antecedents of soiling accidents;
6. The child’s attitude and access to toilet/s (at home and school) and reasons for avoidance;
7. Severity of soiling, eliciting the intervals, amount and consistency of bowel movements (with the aid of the Bristol Stool Chart) deposited into the toilet and clothing;
8. Dietary habits;
9. Co-occurring problems;
10. Family attitudes to the child;
11. Family dynamics and coping strategies;
12. How accidents are dealt with: parental reactions, responsibility, denial, hiding underwear;
13. The child’s understanding of the problem; and
14. Exceptions: are there times when motions and toileting are appropriate and what defines such episodes?

Empirically validated subtypes of fecal soiling have yet to be established (Mellon, Houts, & Lazar, 1996) leaving classification dependent on clinical acumen. There is potential confusion arising from interchangeable terminology yet a functional classification proves valuable in differentiating treatment. Clayden (2001) provided a useful three-way clinical classification (Table 56.3) based on descriptions of soiling behavior and proposed underlying psychological mechanisms.

This chapter used “encopresis” to define one pattern of secondary non-retentive soiling in which children control the physiological process of defecation but deposit normal motions in unusual places (e.g., behind sofa, in the deep freeze, parents’

Table 56.3 Types of fecal soiling.
CHAPTER 56

bed. It is hypothesized that this form of soiling is provoked by psychological events including sexual abuse (Boon & Singh, 1991), family stress and punitive reactions. Encopresis is of particular importance to mental health professionals, who may need to consider family dynamics in order to fully understand the presentation.

**Constipation with overflow** accounts for approximately 85% of fecal soiling (Loening-Baucke, 2002). A typical pattern may involve either physical or psychological factors:

1. Avoidance or fear of the toilet, either because of painful defecation (e.g., hard feces; anal fissure) or tension around toileting (e.g., overdemanding or punitive parental reactions);
2. Stools are held back, the rectal wall is stretched affecting contractibility and sensory feedback from the bowel is reduced with a loss of feeling and diminution in the normal call to stool;
3. With increased water absorption from the fecal matter, feces become larger and harder, leading to constipation and impaction;
4. The functioning of the external and internal sphincters become compromised, allowing seepage of soft diarrhoea-like feces around the impaction; and
5. Further toilet avoidance increases constipation, leading to more concerted efforts and/or punitive reactions on the part of parents.

**Etiology**

Primary soiling has been found to be related to developmental delay, whereas secondary soiling is associated with more psychosocial adversity and behavioral problems (Foreman & Thambirajah, 1996). Clinically, fecal soiling is best understood as an interaction of physiological and psychological factors, with differing influences depending on type of soiling. Clayden (2001) outlines the main pediatric causes:

- Developmental delay as a result of learning difficulty or social deprivation;
- Neuropathic rectum and sensory deficiency as a result of spinal cord defects;
- Abnormal internal sphincter as a result of anorectal anomaly or trauma such as abuse;
- Inhibited internal sphincter as a result of rectal fecal retention—fear of pain on passing motions is a major factor in constipation (Bernard-Bonnin, Haley, Belanger, & Nadeau, 1993);
- Increased motility and diminished awareness of sensation as a result of psychological distress.

The “encopresis” subtype particularly can reflect psychological causes, and family interactions need special consideration.

**Management**

There are a raft of clinically useful suggestions that appear to help both children and parents understand and approach the problem in a more enlightened manner. Many clinicians now suggest avoidance of early introduction to potty training unless the child makes clear signals they are ready to try. Levine (1982) appropriately discusses the prevalence of soiling, to counter any sense of isolation. Promoting an understanding, through drawings and diagrams, of normal bowel function-

and how constipation leads to soiling is important. Children are often relieved to discover their lack of control is understood, by hearing how a distended colon becomes less sensitive, leading to a lack of a warning of the need to defecate and ultimately to seepage.

Discussions with child and parent may highlight that no-one is perceived as being at fault or accused of causing the problem. Parents need to refrain from attributing blame or expressing anger and frustration towards the child. Soiling episodes are best handled in a matter-of-fact way, with an older child expected to clean up and place soiled clothing in the laundry. Maintaining a positive focus is imperative with parents encouraged to praise appropriate effort and toileting (e.g., trying; passing motions in toilet).

Promoting realistic expectations is important, given that treatment may be prolonged and that success is dependent on the bowel regaining muscle tone. The theme of treatment might be described as similar to a training program an athlete might use to develop better muscles and skills. It is important to enhance the appeal of the toilet at home (with décor, reading matter) and ensure access to toilets at school. Keeping a record of toilet sitting (prompted or child initiated), passage of motions, soiling accident (small stain; small formed bowel movement; full formed bowel movement) is considered useful (Houts, Mellon, & Whelan, 1988; Stark, Opipari, Donaldson et al., 1997).

**Effective Treatment**

Few prospective controlled studies have been undertaken, limiting an understanding of effective treatment interventions. McGrath, Mellon, and Murphy (2000) found only 42 well-designed studies, of which 13 were single-case designs. Often, studies failed to specify characteristics of the population, creating problems in knowing whether children had constipation with overflow or encopresis. Treatment aims and interventions evidently differ according to the type of soiling, something future research needs to address before a good clinically relevant evidence base is established. McGrath, Mellon, & Murphy (2000) provided an excellent review of treatment interventions. Although most approaches involve a package of techniques and approaches, interventions will be discussed here in relation to the specified aim.

**Medical Interventions**

Regimes for initial clear-out of impacted fecal matter and removal of pain vary across studies but usually include suppositories, enemas, laxatives, mineral oil and stool softeners. Arguably, oral methods of bowel clean-out are preferable, given that enemas may be considered psychologically unsuitable. There is a need to seek an understanding from children as to the impact of various forms of bowel clean-out.

For prevention of reaccumulation of stools, long-term laxatives are likely to be required, with the dosage gradually decreased once regular bowel movements (once or twice per day) are established. On their own, enemas, laxatives and mineral oils may increase soiling initially in an effort to
Wetting and Soiling

Correct constipation. The mechanism of action is assumed to relate to the debulking effect of chronically retained stools, although it is possible that the stimulation of colonic smooth muscle not only increases colonic motility itself, but also increases awareness of motility and rectal filling (Nolan, Debelle, Oberklaid, & Coffey, 1991). Medical interventions are rarely employed on their own, with Cox, Sutphen, Ling, Quillian, and Borowitz (1996) finding that only 9% were significantly helped with just a laxative.

**Diet**

Diet theoretically offers an alternative means of correcting constipation that, although slower, has a more lasting solution than laxatives. The combination of fiber and water promotes bowel movement. Increased dietary fiber includes fruit, cereals containing bran, brown rice, baked beans, vegetables, baked potato and avoidance of milk products. Houts, Mellon, & Whelan (1988) and Mellon, Houts, & Lazar (1996) outlined an appropriate fiber intake, using points linked to amount of fiber. However, there is little evidence that dietary factors alleviate functional constipation once stool withholding becomes a problem (Loening-Baucke, 2002). Mellon, Houts, & Lazar (1996) found a dietary program to improve fiber intake was no more effective and took longer to take effect than mineral oil.

**Behavioral Interventions**

These aim to increase appropriate toilet use and encourage regular bowel movement but do not address the problem of constipation.

Bowel training, a customary intervention, consists of regular toilet sitting some 15 min after meals to coincide with the gastrocolic reflex which stimulates movement of feces through the bowel. As toilet sitting twice a day may be construed as tedious, the length of sitting should be a maximum of 5 min and contingent praise and rewards offered for the passage of stools. Children need to perceive the process as training not punitive. Cox, Sutphen, Ling, Quillian, and Borowitz (1998) found bowel training, coupled with medical intervention and positive reinforcement, to be 85% successful. Nolan, Debelle, Oberklaid et al. (1991) found the addition of laxative to bowel training improved success rates, although they found 12.5% failed to comply with bowel training.

Other behavioral approaches, often enmeshed within bowel training, include reinforcement (tangible or star charts) contingent on behaviors the child can control (e.g., increased fiber intake, self-initiated toileting, motions in toilet); differential attention (Stark, Opipari, Donaldson et al., 1997), where soiling is treated in a neutral matter-of-fact way; overcorrection or cleanliness training, where the children are involved in washing the soiled clothing and cleaning themselves up; and awareness techniques, where children are encouraged to identify bowel sensations and behaviors as cues for toileting.

Biofeedback

Children with chronic constipation and encopresis are thought to have abnormal defecation dynamics with an inability to relax the external anal sphincter during attempted defecation. As this sphincter is striated muscle, theoretically amenable to modulation, biofeedback aims to enhance relaxation of the sphincter during defecation. Loening-Baucke (1990) employed a balloon, inserted in the anus at the level of internal and external sphincter, which transmitted pressure changes to an oscilloscope. Children were trained to alter their sphincter responses voluntarily using anal and buttock muscles. With reported success of 86% in relaxing the external anal sphincter and recovery from constipation in 55–60%, it was suggested that biofeedback was a promising intervention, complementary to good conventional treatment. However, being labor intensive, biofeedback may be reserved for those who have failed to respond to conventional treatment. There remains a question of clinical applicability for children and Cox, Sutphen, Ling et al. (1996) described a more convenient and accessible procedure involving electromyographic (EMG) biofeedback of the external anal sphincter. However, Loening-Baucke (1996) and Cox, Sutphen, Ling et al. (1996) reported no advantage of biofeedback over bowel training in randomized controlled studies. Further, van der Plas, Benninga, Buller et al. (1996) found that the addition of five sessions of biofeedback to the normal medical intervention plus bowel training did not improve success rates. They concluded that abnormal defecation dynamics do not have a crucial role in the pathogenesis of childhood constipation.

**Psychotherapeutic Interventions**

For children with non-retentive forms of fecal soiling, a raft of psychotherapeutic interventions have been advocated including play therapy, child psychotherapy and family therapy to reduce guilt, shame and anxiety. However, empirical investigations of such approaches are still required.

**Pretreatment and Treatment Predictors**

Treatment failure has been found to occur with children with severe constipation with overflow; when soiling happens in school or during sleep; and with associated behavioral problems, intellectual disability or psychiatric problems (Boon & Singh, 1991; Levine & Bakow, 1976; Stark, Spirito, Lewis, & Hart, 1990). There are few treatment predictors, but both lack of compliance in treatment (Levine & Bakow, 1976; Nolan, Debelle, Oberklaid et al., 1991) and lack of initial progress in the first 2 weeks (Cox, Sutphen, Ling et al., 1996) have been associated with failure.

**Composite Programs**

Treatment of fecal soiling should involve the employment of a package of interventions; accordingly, comparative studies are limited and could conceal the impact of any one component. Taking those studies with the largest samples, Nolan, Debelle, Oberklaid et al. (1991) with n = 83 found that a combination of medical intervention, diet, bowel training and contingent reinforcement produced 51% success at 12 months. Van der Plas, Benninga, Buller et al. (1996) applied a similar composite program to 94 children, with 33% success after 6 weeks, 52%
at 6 months and 59% at 1-year follow-up. Stark, Opipari, Donaldson et al. (1997), employing a similar package for 52 children with retentive enuresis, found soiling decreased by 85%, with 67% considered a success (one or fewer soils per week).

On a cautionary note, McGrath, Mellon, & Murphy (2000) suggest that adding components to a treatment package does not necessarily improve outcome, and may indeed decrease efficacy. Dietary recommendations and biofeedback have both been found to reduce efficacy when attached to medical interventions and bowel training (van der Plas, Benninga, Buller et al., 1996).

Relapse Prevention
When relapse rates are reported, they tend to be high. Nolan, Dehelle, Oberklaid et al. (1991) found 51% relapse with laxative treatment, while 37% of those treated with bowel training relapsed. Once soiling is relieved there may remain dynamics of family involvement that recreate the problem. Children with fecal soiling may therefore need continued support for a protracted time.

Conclusions
Nocturnal enuresis, daytime wetting and soiling often coexist, but are clinically best considered as discrete, each having heterogeneity. A differentiation between subtypes is imperative in both clinical and research contexts. The clinician is faced with an array of potential management and treatment interventions, many of which require an evidence base. However, there are proven treatments for all three problems, both medical and psychological, and with a thorough understanding of the child’s problem the clinician is now well placed to determine an appropriate treatment. Pretreatment predictors are potentially useful in fine tuning treatment options although many need replication. Parsimony of treatment is important and combination programs should therefore integrate interventions to meet a child’s particular needs. Composite treatment packages are often applied in clinical practice, but require clarification; component analysis would prove beneficial in determining effective and redundant aspects.

There is a need to clarify outcome measures, as has been done with nocturnal enuresis (Butler, Robinson, Holland, & Doherty-Williams, 2004b), and develop consistency across studies. Methodology tends to employ “convenience” samples and, apart from a few notable exceptions, randomization into different treatment groups is lacking. Relapse following treatment is readily apparent and yet methods to help prevent relapse are lacking – particularly in relation to daytime wetting and fecal soiling.

Once children overcome wetting and soiling problems there are demonstrated improvements in psychological functioning. For example, successfully treated children with nocturnal enuresis exhibit an increase in self-esteem (Moffatt, Kato, & Pless, 1987) and develop into young adults no different psychologically from adults who were never enuretic (Stromgren & Thomson, 1990). For psychologists and psychiatrists, wetting and soiling provide interesting areas of study, because with clearly defined dependent variables, there is an ideal opportunity to test out particular theories and models. As Houts, Berman, & Abramson (1994) suggest, for most problems mental health workers confront, the therapeutic goal is management and improvement. However, wetting and soiling are exceptions – complete recovery is a realistic goal.

Acknowledgments
I am extremely grateful to Leeds Primary Care Trust, Dr. Philip Holland, Professor Eric Taylor and Leeds Mental Health Library for the support and assistance they kindly provided in the writing of this chapter.

CHAPTER 56

Psychiatric Aspects of Somatic Disease
Seija Sandberg and Jim Stevenson

Chronic somatic disease affects an estimated 10–20% of all children during childhood or adolescence (Abraham, Silber, & Lyon, 1999; Northam, 1997). Pediatric chronic diseases are illnesses that affect a person for an extended period of time, often for life, and that require medical care and attention above and beyond the normal requirements for a child or adolescent. Improved medical outcomes for many childhood diseases mean that a vast majority survive into adulthood, thus emphasizing psychosocial and quality of life issues. This chapter studies both the contribution of psychological factors to physical ill health and the consequences for mental health of physical illness. The approach to the latter topic is that of Wallander and Varni (1998). This differentiates between non-categorical (i.e., general) and categorical (i.e., illness-specific effects).

Psychological and Psychosocial Factors in Development of Somatic Disease

Evidence of Effects
Children with psychosocial stress are significantly more likely to experience illness and hospitalizations as well as use health services more frequently than other children (Haavet & Grünfeld, 1997). Stress as a precipitating factor has been implicated for asthma, appendicitis, rheumatoid arthritis and leukemia. Prospective and experimental studies have also shown that adverse life events and other stressful experiences significantly increase a person’s susceptibility to acute and recurrent respiratory infections (Cobb & Steptoe, 1998), and often precede acute exacerbations of asthma (Sandberg, Paton, Ahola et al., 2000; Sandberg, Jarvenpaa, Penttinen et al., 2004).

Mechanisms Producing Risk
The mechanisms by which psychosocial stress increases the risk of somatic disease involve cognitive, psychological, physiological and immune functions. It has been postulated that the mediators of stress response (glucocorticoids and catecholamines) have an immediate protective function (allostasis). However, when repeatedly activated they generate what has been called allostatic load, which itself creates risk of later diseases (McEwen, 2000; Turner-Cobb, 2005). For example, in the cardiovascular system, catecholamines promote adaptation by modifying heart rate and blood pressure to sleeping, waking and physical exertion. However, a concerted repetition of such blood pressure changes in response to stress can accelerate atherosclerosis and, acting jointly with metabolic hormones, can produce type 2 diabetes (McEwen, 1998).

Stress may compromise the body’s immune responses to viral infection, with the individual differences in susceptibility possibly explained by differences in psychobiological reactivity (for review see Segerstrom & Miller, 2004). The immune system and the central nervous system form a bidirectional communication network (Heim, Ehlert, & Hellhammer, 2000) in which proinflammatory cytokines have a pivotal role.

Role of Somatic Disease in Increasing the Risk of Psychiatric Illness

Evidence of Effects
Chronic or life-threatening illness increases the risk of psychiatric disorder in children and adolescents. The risk is highest in conditions affecting the central nervous system or impairing motor functioning (Eiser, 1990). A meta-analysis by Lavigne and Faer-Routman (1992) confirmed the above, with those having a chronic somatic disease showing twice the rate of psychopathology as children in the comparison groups. However, in spite of the higher prevalence, only a minority of children with chronic disorders appeared maladjusted.

Few studies have addressed the specific types of mental health problems in children associated with somatic illness. Consequently, the evidence remains non-specific, although it points to anxiety and other emotional disorders being more common than behavior disorders (Thompson & Gustafson, 1996; Wallander & Varni, 1998). Even more notable is the paucity of longitudinal research to allow examination of individual differences in vulnerability and resistance.

Mechanisms Producing Risk
As searches for distinctive behavioral features or personality characteristics within individual illness groups have been unsuccessful, studies of psychosocial aspects of specific diseases have increasingly been replaced by the examination of various psychological and psychosocial effects associated with...
somatic disease in general (Geist, Grdisa, & Otley, 2003; LeBlanc, Goldsmith, & Patel, 2003; Lewis & Vitulano, 2003; Stewart, 2003).

According to Wallander and Varni (1998), chronic physical disorders are most usefully conceptualized as sources of ongoing chronic strain for both the children and their families. Chronic strains are defined as persistent objective conditions requiring continual readjustment and repeatedly interfering with the performance of ordinary role-related activities. Their impact is determined by the nature of the onset and course of the illness, its potential fatality and the degree of incapacitation caused.

Complex vulnerability and protective mechanisms are also involved. These need to be considered in relation to a child’s individual characteristics as well as to their contextual properties. In the context of a child’s chronic physical illness, family stress is negatively associated with child adjustment. However, the effect will vary depending on the presence of other mediating factors. The strength or the direction of the relationship may depend on the type of coping used and a significant association may only emerge when a parent or child copes in a maladaptive manner.

Non-categorical Illness, Child- and Family-Related Factors Increasing Risk of Psychiatric Disorder

Age of Child at Time of Illness
It is important to view the onset of the illness in a developmental context. Early studies of hospitalization suggested that those necessitating separation from primary attachment figures are particularly difficult for children in their second to fourth year of life. Hospitalizations at an even earlier age, especially if reoccurring, have been shown to be associated with increased later behavior problems (Quinton & Rutter, 1976). However, for a school-age child, illnesses that disrupt participation in normal family and school life can become sources of stress (Vitulano, 2003). During this period gender differences also begin to emerge. For boys, illnesses that impair sports abilities are more difficult to cope with, while girls appear more sensitive to health problems that prevent accessing peer group support. In adolescence, illnesses interfering with the strive for greater independence are especially problematic, as belonging to a peer group and developing intimate relationships become critical developmental challenges (Greydanus, Rimsza, & Newhouse, 2002; Meijer, Sinnema, Bijstra et al., 2002).

Accuracy and Timeliness of the Establishment of the Diagnosis
The process by which the diagnosis is established can affect the child’s and parents' ability to adapt. Here, important factors include the duration of time required to reach the diagnosis and the certainty with which it can be made, as well as the sensitivity with which the diagnosis and its implications are conveyed. A rapid and accurate diagnosis can facilitate forming a “partnership of care” and improve the prognosis. Conversely, a misdiagnosis can lead to an acutely adversarial situation.

However, some illnesses are more easily recognized than others. Prodromal symptoms of some forms of leukemia, for example, can remain vague and their significance minimized for some time. In cases where malignancies are discovered at relatively advanced stages, answering the question why appropriate early investigations were not ordered is always difficult, but avoiding the issue may jeopardize subsequent treatment. Communicating a confirmed grave or terminal diagnosis to a child is a challenging responsibility (Young, Dixon-Woods, Findlay, & Heney, 2002; Young, Dixon-Woods, Windridge, & Heney, 2003). The task can become even more intricate if the physician, or parent, is ambivalent about the need to share the prognosis with the child. When faced with a grave diagnosis to share, many physicians try to cope by focusing on treatment while avoiding addressing the crucial emotional issues. An opportunity to consult a psychologist or child psychiatrist is often helpful in such situations.

Interference with Function
There is a strong association between the level of disability and the severity of the illness, but there also exists great variability in types and levels of disability (Morad, Kandel, Hyam, & Merrick, 2004). However, this variability in functional capacity is frequently ignored as an independent risk factor despite clear links with long-term adaptation (Vitulano, 2003). Likewise, differences in the impact of the same disability with regard to the child’s developmental level may get overlooked. Illness-related interference with cognitive processing has a negative effect at all stages of development, but cognitive deficits have even wider implications for a child facing academic examinations, for example.

Impact on Physical Appearance
Some somatic diseases can involve extensive physical disfigurements (e.g., atopic dermatitis), while others, although serious or incapacitating, usually have no effect on the physical appearance (e.g., diabetes or asthma). Some diseases, such as cystic fibrosis, involve complex dietary and medication regimes that older children, and especially adolescents, may perceive as socially stigmatizing. Given the importance of a positive physical appearance to the sense of self-worth, it is not surprising that stigmatizing illnesses are associated with emotional vulnerability (Breslau & Marshall, 1985).

Anxiety about being physically different from their peers is a common concern of chronically ill children. This becomes progressively more important during school years and reaches its peak in adolescence. With the peer group assuming greater importance, emotional rejection based on negative response from others can precipitate depression or lead to other emotional problems. Despite the obvious importance of these issues, little systematic research has been carried out on this topic.
Persistent of Symptoms
Childhood diseases vary in their pattern of symptom expression and consequent impact on the child’s life. Asthma and epilepsy can involve long symptom-free periods and thus allow the child extended opportunities to lead a near-normal life. Diabetes and cystic fibrosis, however, demand strict daily adherence to special diets and medication routines, and in spite of these remain unremitting or result in gradual worsening and disability.

Illnesses with persistent or unremitting symptoms would be expected to have greater negative impact on psychological adaptation. Surprisingly, little evidence that this is so exists. However, it is also true that some children with chronic illness cope with their situation by getting compensatory rewards from academic achievement, or by excelling in music, art or some other skill.

Hope for Recovery
A brief encounter with a serious illness that results in complete recovery is unlikely to have significant impact on emotional health but children with a more precarious prognosis live with persistent uncertainty about their long-term survival. The primary concern for the mental health of children with a terminal prognosis is helping them not to lose hope prematurely or succumb to depression, with a likely detrimental effect on their illness. Some children manage to maintain strong optimism about their eventual recovery even in the face of the gravest of odds. Another core aspect of work with children who have a terminal prognosis is to help them and their family to reach some level of acceptance of the inevitability of their impending death.

Child’s Personality Attributes Modifying or Mediating Risk
Many studies comparing children with even a severe physical illness with healthy peers have failed to find differences (Hocking & Lochman, 2005; Meijer, Sinnema, Bijstra et al., 2002; Phipps & Steele, 2002). The same studies have also established that the lack of apparent anxiety even in a gravely ill child with cancer, for example, is explainable by the child’s style of coping. Avoidant coping has been shown to predict poor adjustment characterized by low self-esteem and high social anxiety, whereas confrontation and readiness to seek social support predict positive adjustment (Meijer, Sinnema, Bijstra et al., 2002), and defensive coping is associated with low generalized anxiety (Phipps & Steele, 2002). Tendency to repress feelings, especially anger, is another commonly found characteristic of children with serious physical illness. However, there is no evidence that any particular coping style is uniformly the best protection against psychological problems. Rather, it depends on the child’s personality or temperament and social situation, including the availability of emotional support.

Psychiatric Aspects of the Child’s Reactions to Somatic Disease
Functional impairment may result from psychological distress or psychiatric illness presenting itself in covert forms. Geist, Grdisa, & Otley (2003) list four common presentations, found singly or in combination, often indicating underlying psychosocial issues: medical symptoms unexplainable by organic factors alone; poor adherence to treatment recommendations; school refusal; and engagement in risky behaviors involving sex/sexuality or use of substances.

A change in a child’s overall functioning can alert parents and professionals to possible difficulties in the disease management, treatment adherence or adjustment to illness. However, few assessment tools specific to pediatric populations exist, and measures developed for healthy children, or modifications of adult assessments, are often used instead. The questionnaire “Living with Chronic Illness” (LCI; Adams, Streisand, Zawacki, & Joseph, 2002), represents one exception. It provides an assessment from both a parent’s and the patient’s perspective across a variety of chronic conditions and has the advantage of distinguishing between social difficulties related to the illness and those resulting from other factors. Of the therapeutic approaches, cognitive–behavioral methods and psychoeducational interventions have proved most helpful (Barlow & Ellard, 2004; Christie & Wilson, 2005).

Parental Responsibility for the Treatment of the Illness
Parental response to the illness can affect the child’s adaptation in many ways (Madden, Hastings, & Vant-Hoff, 2002; Wray & Sensky, 2004). Sensitive and effective parenting promotes optimal outcome, but inconsistent parenting (e.g., because of stress or depression) promotes poor adaptation. Age and developmental stage also determine the level of parental responsibility and degree of supervision of the child’s treatment. Protective parenting may be appropriate in the case of a young child, but highly attentive and controlling parental behavior can be problematic for a teenager. Their growing need for independence includes increased responsibility for their treatments – a responsibility that is also open to exploitation. Chronic illness is a stressor that can negatively impact on the parents’ mental health and marital relationship, and impair their ability to parent not only the sick child, but also the non-affected siblings. The increased risk for psychological problems in the siblings of chronically ill children has been well highlighted (Houtzager, Oort, Hoekstra-Weebers et al., 2004; Sharpe & Rossiter, 2002; Van-Riper, 2003). Interventions combining educational and psychological approaches have proved helpful in reducing family stress and promoting better mental health in parents and siblings (Barrera, Fleming, & Khan, 2004; Williams, Williams, Graff et al., 2003).

Role of Non-illness-related Psychosocial Stress
Children with somatic illness, like any other children, are vulnerable to the effects of psychosocial stressors, both acute life events and long-term adversities. These stresses may stem from the child’s family life (e.g., parental ill health/deviance or marital conflicts/separations), school environment (e.g., academic pressures), peer group (e.g., being a victim of bullying), or result from acute life events (e.g., accidents or loss of
someone close). For discussion of the mechanisms through which psychosocial stressors exert their influence see chapters 25 and 26.

Protective Factors and Mechanisms
Compared with the volume of research on the effects of negative experiences on children’s health, far fewer studies focusing on protective factors exist. A confiding relationship with a close adult relative has been shown to protect children from a psychiatric disorder when faced with stressful life events and chronic psychosocial adversity (Sandberg, Rutter, Giles et al., 1993). It is reasonable to believe that this would also be the case in children with somatic disease, although no empirical evidence so far exists. In children with asthma, family rituals and routines, as a proxy measure of good parenting, have been shown to protect against anxiety in the context of high parental stress (Markson & Fiese, 2000). Positive life events, such as the child’s personal achievements, and minor rebelliousness also protected against the increased risk of new asthma attacks associated with stressful life events (Sandberg, McCann, Ahola et al., 2002; Sandberg, Taskinen, Oja et al., 2003).

Specific Conditions

Asthma
Of the chronic diseases of childhood, asthma is probably the most common, with up to one child in four being affected. Reports from different countries are consistent in indicating an increase in the prevalence of asthma and allergies, especially in industrialized societies (Asher, Montefort, Björkstén et al., 2006).

Most childhood asthma begins in infancy. Adverse events in early life, allergen exposure, suboptimal feeding practices, viral infections and environmental pollutants seem important precipitating factors (Wright, Cohen, & Cohen, 2005), with gene–environment interactions determining illness manifestation (Hoffjan, Nicolae, Ostrovnaya et al., 2005). Lately, research has focused on the potential link between exposures to microbial sources and the development of allergic diseases (for review see Schaub, Lauener, & von Mutius, 2006). The term “hygiene hypothesis” refers to a theory attempting to encompass the complex associations between viral and bacterial infections, exposure to substances produced by microbes in the environment, immune responses and the person’s genetic background.

A growing body of evidence suggests that psychosocial stress contributes to the development of wheezing illnesses and asthma, especially during early childhood, and predicts greater morbidity in children who already have asthma (Bloomberg & Chen, 2005). Prospective studies of genetically predisposed infants have highlighted the role of early caregiver stress. It has been shown to predict repeated wheeze in the first year and was associated with an atopic immune profile (Wright, Cohen, Carey et al., 2002; Wright, Finn, Contreras et al., 2004) and, together with early parenting difficulties, the onset of asthma by age 3 (Mrazek, Klinnert, Mrazek et al., 1999), and occurrence of asthma up to age 8 (Klinnert, Nelson, Price et al., 2001).

Many clinicians also hold the view that asthma frequently gets worse following a stressful experience. That this is so was shown in a prospective study (Sandberg, Paton, Ahola et al., 2000; Sandberg, Järvenpää, Penttinen et al., 2004) involving children with chronic asthma. Severely negative life events significantly increased the risk of a new asthma attack both immediately and in the coming few weeks. The magnitude and timing of the maximum risk were influenced by the presence or absence of chronic psychosocial stress. Subsequently, a molecular genetic study by Miller and Chen (2006) showed that, in children with asthma, concurrent experience of acute and chronic stress alters the properties of genes responsible for fighting infection and keeping airways open.

Emotional arousal itself can act as a potential precursor of asthmatic symptoms (for review see Lehrer, Feldman, Giardino, Song, & Schmaling, 2002). The main focus has been on negative emotions such as anger, sadness and depression (Rietveld, Everaerd, & Creer, 2000; Ritz, George, & Dahme, 2000a). A non-reciprocal pattern of autonomic functioning has been proposed as the underlying physiological mechanism (Ritz, Steptoe, DeWilde, & Costa, 2000b), with the immediate and delayed effects of stress likely to involve different processes (Klinnert, 2003). In the presence of chronic or repeated stress, the physiological response to acute stress appears to result in more sustained effects on the immune system (Chen, Hanson, Paterson et al., 2006). A less active hypothalamic–pituitary–adrenal (HPA) system in combination with high stress has been proposed as another explanation for the delayed effects (Ball, Anderson, Minto, & Halonen, 2006; Heim, Ehlert, & Hellhammer, 2000).

An association has been demonstrated between asthma severity and the child’s ability to regulate negative emotions (Klinnert, McQuaid, McCormic, Adinoff, & Bryant, 2000), possibly reflecting wider physiological dysregulation indicating a common genetic vulnerability (Mrazek, 2003). These conclusions are supported by the Early Treatment of the Atopic Child study (ETAC; Stevenson, 2003) and a UK birth cohort study (Calam, Gregg, Simpson et al., 2005). Behavior problems, as possible markers for stress, preceded the development of asthma.

Regarding psychiatric morbidity, emotional disorders, especially anxiety (separation anxiety being the most common) and depression, has been the most consistent finding (Feldman, Ortega, McQuaid, & Canino, 2006; Klinnert, Nelson, Price et al., 2001; McQuaid, Kopel, & Nassau, 2001). Prior emotional problems also predicted a further increase in the risk of new asthma attacks associated with stressful life events (Sandberg, Taskinen, Oja et al., 2003).

Of late, experimental intervention programs have been implemented in school settings with encouraging results. In a controlled study, McCann, McWhirter, Coleman, Calvert, and Warner (2006) showed that an intervention delivered as part science curriculum combined with staff training resulted
in significant improvements of subjective well-being and less need for prescribed medication (for a review of psychological interventions see Lehrer, Feldman, Giardino et al., 2002).

**Atopic Dermatitis**

Atopic dermatitis, commonly known as eczema, is an allergic skin condition that nearly always begins in infancy, and usually resolves during childhood, often even in the second year of life. It is a familial illness with evidence for a genetic etiology involving heritable hypersensitive immunoglobulin E (IgE) response (Ball, Anderson, Minto et al., 2006; Wright, Cohen, & Cohen, 2005). Studies in the fields of psychoimmunology have highlighted a probable connection between atopy and emotional dysregulation, possibly reflecting a common genetic vulnerability (Wright, Cohen, & Cohen, 2005). An increased rate of behavior problems in young children with atopic dermatitis (Stevenson, 2003), and a genetic association between atopy and emotional disorders in school-age children (Wamboldt, Schmidt, & Mrazek, 1998), indicate early difficulties in emotional regulation. Caring for a young child with atopic dermatitis can be a distressing task for parents as the child is often in discomfort, and therefore miserable, for long periods of time. This situation has the potential for major disruption of the early caregiving relationship. Because of a lack of systematic studies, however, little is known about the long-term psychological consequences of severe eczema in the early years of life.

**Cystic Fibrosis**

Cystic fibrosis (CF) is a complex multisystem disease with the patients often facing a number of physical and psychological problems (Bourke, 2003). It is caused by a defective gene, leading to thick sticky mucus that obstructs the airways, the digestive system and other organs, resulting in chronic infections and inflammation of the lungs and difficulty in digesting food and nutrients. CF is usually diagnosed in infancy or early childhood and prenatal screening now enables intraterine detection.

Medical treatment has led to a substantial increase in life expectancy, and more children with CF are surviving into adulthood. Despite this promising outlook, children and adolescents with CF continue to live with a life-limiting disease, with CF influencing their relationships, education and plans for future employment, marriage, etc. Progress in the medical aspects of care has not been matched by comparable advances in psychological interventions.

The treatment regimens, involving strict adherence to special diets, multiple administrations of medicines and nutrition replacements, as well as “aggressive” daily physiotherapy, restrict the daily lives of the children and parents and may become a source of stress. “Successful” adherence to these regimens can also promote developmentally inappropriate dependence in the child and make negotiating the inevitable adolescent challenges problematic. Along with adolescence comes a transition to adult medical care with expectations for the patient to take responsibility for their disease management. To many adolescents with CF, moving to an adult clinic means taking a step closer to their death. Clinical problems associated with impending mortality are often challenging to manage. As the disease progresses, the young people and their families need extra support to cope with their feelings of anticipated loss and frustrations associated with the limitations of therapeutic interventions.

A full range of psychiatric problems has been reported in children and adolescents with CF, with depression and eating disorders specifically noted (for review see Christian, 2003), and family interactions – especially during mealtimes – are often strained (Janicke, Mitchell, & Stark, 2005). Avoidance and denial are common psychological coping mechanisms. Such coping strategies may be viewed as “negative” or maladaptive by professionals if they include non-compliance with treatments, but from a young person’s perspective they may be adaptive, as a means of escaping from the world of CF for a while.

**Juvenile Onset Diabetes Mellitus**

Diabetes mellitus affects approximately 2% of the population in the UK and refers to a group of metabolic diseases characterized by hyperglycemia occurring as a result of defects in insulin secretion, insulin action or both. Long-term hyperglycemia is a serious problem and can lead to dysfunction of a number of organs including eyes, kidneys and the circulatory system. A distinction is made between types 1 and 2 diabetes, with the first requiring the administration of insulin to maintain health. Type 2 diabetes has usually been seen as a condition with onset in middle age. However, there is a substantial increase in type 2 diabetes amongst children and young people. This occurrence of type 2 diabetes in young people is of relatively recent origin and its clinical management is less well understood (Gungor, Hannon, Libman, Bacha, & Arslanian, 2005). The most obvious reason for the rapidly rising rate of type 2 diabetes in children and adolescents is a combination of low physical activity and the absence of a well-balanced low-fat and high-fiber diet. Action to prevent obesity in this age group is the only satisfactory way in which this alarming rise in type 2 diabetes can be controlled (Vivian, 2006). The psychological consequences of type 2 diabetes in children and young people are not well understood. There is some evidence that boys experiencing this condition are at increased risk of depressed mood compared with boys with type 1 diabetes. In turn, depressed mood is related to relatively poor metabolic control as indicated by mean glycosylated hemoglobin (HbA1c; Lawrence, Standiford, Loots et al., 2006).

The care of children with type 1 diabetes is well established (Silverstein, Klingensmith, Copeland et al., 2005). It is important to recognize, however, that the care of these children needs to take into account differences in the way in which the disease needs to be managed at different ages.

It has long been recognized that psychological factors can play a significant part in the course of diabetic illness (Wysochi, Buckloh, Lochrie, & Antel, 2005). Type 1 diabetes
is a condition that arises from the interaction of genetic and environmental risks (Haller, Atkinson, & Schatz, 2005). The significance of emotional stresses in the onset of the disease is equivocal. However, it is clear that the management and course of the disease are strongly influenced by psychosocial factors.

For both children and adults, diabetes has been a major area of the application of behavioral science to medicine. The range of analyses and applications of psychobehavioral approaches to the condition has been reviewed by Gonder-Frederick, Cox, and Ritterband (2002). The significance of the specific association between type 1 diabetes and depression is given particular weight by the finding that suicidal ideation was a feature shortly after the onset of type 1 diabetes symptoms. Although relatively few attempted suicide, the misuse of insulin in the suicide attempts should be noted (Goldston, Kovacs, Ho, Pharrone, & Stiffler, 1994).

In addition to the association between the illness and psychiatric disorder, which the above findings suggest have a reciprocal effect on each other, the presence of type 1 diabetes has an adverse effect on family functioning more broadly. In a study of children between the ages of 1 and 14 years, Northam, Anderson, Adler, Werther, and Warne (1996) found that during the immediate period after diagnosis both children and parents exhibited a mild degree of psychological distress. Within 1 year this had largely resolved and the residual impact on the family was largely seen in terms of families becoming less flexible in their functioning. These complex interactions between the course of the disease and family and individual functioning led to an emphasis on psychological interventions to support children and their families with type 1 diabetes.

There is an extensive number of studies of efforts to intervene to enhance the psychological health of the children and their families (Northam, Todd, & Cameron, 2005). Many of these studies have suffered from methodological inadequacies including low participation rates, small unrepresentative samples and the use of unstandardized measures (Northam, Todd, & Cameron, 2005). They have tended to use interventions focused on increasing compliance rather than targeting a broader range of psychological distress. There have also been few attempts to evaluate interventions with younger children. Nevertheless, across the adult and child age range, the evidence suggests that interventions can be effective both in terms of enhancing the psychological well-being of individuals with type 1 diabetes and also, to a lesser extent, promoting good metabolic control (Hampson, Skinner, Hart et al., 2000).

Cancer

There are a number of childhood cancers, the most common of which is acute lymphoblastic leukemia (ALL). This comprises about 25% of childhood cancers and 75% of leukemias. It is a malignant disease of the lymphoid cells and the bone marrow, which are carried in the blood to most organs including the central nervous system. Brain tumors are the second most frequently diagnosed cancer of childhood (Strother, Pollack, Fisher et al., 2002). Advances in medical treatment have substantially improved the survival rates for children with ALL to about 75%, with higher rates in Hodgkin’s disease and lower rates in other cancers (Eiser, 1998). In considering the physical and psychological consequences of childhood cancer, the following conclusion has been drawn by Patenaude and Kupst (2005, p. 11): “From these studies emerging over the past 2 decades, we have learnt with increasing specificity that no child with cancer remains unchanged by the experience.” The level of adjustment difficulties in pediatric cancer patients is near to the levels of normal healthy children (Patenaude & Kupst, 2005). However, there appear to be about 25–30% of children and families who experience considerable psychological or social difficulties. These include low academic achievement, impaired social relationships and poor self-concept and low self-esteem. It needs to be recognized that for some children and families the experience of childhood cancer has a positive effect on psychological health with increased resilience and enhanced social relationships (Eiser, Hill, & Vance, 2000). Patenaude and Kupst (2005) were able to identify a number of factors that were associated with a worse psychological outcome. Among the disease and treatment factors were diagnoses of cancer involving the central nervous system (CNS), bone tumors, CNS irradiation and intense chemotherapy, shorter time since diagnosis and a shorter period of treatment. The personal characteristics associated with a worse psychosocial outcome were younger age at diagnosis, poor psychological health before diagnosis, higher levels of perceived stress and lower cognitive ability. Those family and environment factors that have a role were low adaptability and cohesiveness, a lack of open communication, low social support and fewer socioeconomic resources.

There are a number of instruments that have been developed to measure psychosocial outcome in pediatric cancer patients. An appraisal of the merits of alternative measures of health-related quality of life, including measures specifically targeted at pediatric cancer, can be found in Eiser and Morse (2001).

There are still unresolved issues concerning the neurocognitive consequences of some aspects of the treatment of childhood cancers. Waber, Carpentieri, Klar et al. (2000) found that children treated for ALL with dexamethasone performed less well on cognitive tests than those on prednisone. Chemotherapy for children with ALL has also been implicated in generating attentional deficits (Buizer, de Sonneville, Van Den Heuvel-Eibrink, & Verman, 2005). However, others have suggested that treatment for leukemia that does not involve the use of cranial irradiation does not produce cognitive losses or attentional deficits (Rodgers, Markus, Kears, & Windebank, 2003). Indeed, Eiser, Davies, Jenney, Stride, and Glaser (2006) suggest that dexamethasone does not have an adverse effect on the health-related quality of life of children. There is some evidence that methylphenidate may help reduce any attentional and social difficulties experienced by children being treated for childhood cancer (Mulhern, Khan, Kaplan et al., 2004).
**CHAPTER 57**

**Chronic Fatigue Syndrome**

The definition of chronic fatigue syndrome (CFS) in children is usually taken to be the same as for adults, and it is generally accepted that the key features are also similar (Garralda & Chalder, 2005; Garralda & Rangel, 2002). These consist of incapacitating chronic fatigue after comparatively little effort, unimproved by rest and unexplained by physical or psychiatric illness. Besides fatigue, CFS involves a characteristic constellation of physical symptoms such as headaches, a variety of other bodily pains and altered sleep and eating patterns. CFS commonly starts with an acute illness episode, such as “flu” or glandular fever, but it can also have insidious gradual onset. The condition can be intensely debilitating and follows a chronic, sometimes fluctuating, course. Children with CFS often receive repeated specialist medical consultations, and a variety of diagnoses, as the parents seek explanations for their ailments. Controversy has surrounded CFS stemming from strong beliefs held by patients and their advocates that the condition has a medical cause. For this reason, some prefer the term ME (myalgic encephalitis). It is also possible that the terms such as fibromyalgia, neurasthenia and post-viral fatigue syndrome are used to refer to the same condition.

Emotional distress and mood changes are common associated psychological problems, and psychiatric comorbidity, especially anxiety and depressive disorders, as well as personality problems, are identified in 50–75% of children and adolescents severely affected with CFS (Rangel, Garralda, Levin et al., 2000b; Richards, Turk, & White, 2005), with some of this probably secondary to CFS (Garralda & Rangel, 2005). Independent genetic etiologies for depression and unexplained disabling fatigue were also indicated in a study by Fowler, Rice, Thapar, and Farmer (2006).

A variety of interventions have been used in the treatment and management of CFS, with considerable differences of opinion about the most appropriate and effective management. According to a systematic review (Whiting, Bagnall, Sowden et al., 2001) of 44 controlled trials (36 of these randomized), involving 2801 mainly adult participants, the interventions with the most promising results included cognitive–behavioral therapy (CBT) and graded exercise therapy. A controlled clinical study of children and adolescents with CFS similarly demonstrated a clear superiority of active rehabilitation programs over traditional supportive care (Viner, Gregorowski, Wine et al., 2004).

Outcome studies have at best involved a few dozen children and adolescents with CFS. Nevertheless, they have produced surprisingly uniform findings, showing that a distinct majority of severely affected young people eventually make a complete recovery, and many more improve sufficiently to lead near-normal lives (Rangel, Garralda, Levin et al., 2000a).

**Failure to thrive/deprivation dwarfism**

Failure to thrive (FTT) can be defined as weight for age below the third percentile for a protracted period of time during the first year of life. Children falling into this group may do so for a variety of reasons, and historically a distinction was made between those with a known organic basis for growth faltering and those deemed to be non-organic. This differentiation is far from straightforward (Reilly, Skuse, Wolke, & Stevenson, 1999). The key question is whether such a group, even if heterogeneous in the origins of their FTT, are at risk for continuing developmental difficulties. That this may not be the case is highlighted by the marked developmental catch-up children can demonstrate even having experienced severe early deprivation (Rutter, 1998).

The prevalence rate of FTT has been estimated to be 3.5% and it is a relatively common cause of referral to pediatricians (Skuse, 1993). Such children are likely to present with a wide array of associated medical conditions. These will reflect both factors leading to their growth deficiency and the consequences of acute or chronic malnutrition.

The treatment of FTT will often require the joint expertise of a team of social workers and nutritionists as well as psychiatrists (Iwaniec, 2004). The value of a wide-ranging psychosocial intervention for children with FTT was shown in a study by Black, Dubowitz, Hutcheson, Berenson-Howard, & Starr (1995). They randomized 130 children (mean age, 12.7 months) recruited from low-income families into two groups: clinic plus home intervention or clinic only. All children received services in a multidisciplinary growth and nutrition clinic. Families in the home intervention group received weekly home visits for 1 year by lay home visitors, supervised by a community health nurse. Children’s weight for age, weight for height and height for age improved significantly during the 12-month study period, regardless of intervention status. However, the enhanced cognitive and behavioral changes in the home intervention group led Black, Dubowitz, Hutcheson et al. (1995) to conclude that early home intervention can promote a nurturant home environment effectively and can reduce the developmental delays often experienced by low-income urban infants with FTT.

A meta-analysis of the extent to which FTT was associated with later poor cognitive development was produced by Corbett and Drewett (2004). They suggest that the adverse effect of FTT to later cognitive ability was −0.28 standard deviation (95% confidence interval [CI], −0.16 to −0.41), equivalent to 4.2 IQ points. This overall pattern of results is also illustrated by the findings from Boddy, Skuse, and Andrews (2000). Their longitudinal study of children who had FTT (defined as being at 3 months at least below the 3rd percentile of weight) indicated a diminishing effect of early malnutrition on cognitive ability as the children became older.

This pattern of emerging results, suggesting a relative benign outcome for children with FTT during early infancy, has led Rudolf and Logan (2005) to suggest that an “aggressive approach to the identification and management of failure to thrive needs reassessing.” The key issue is that of identifying which of the children within this group might benefit from intervention. This is particularly significant given what they suggest are the equivocal results that have emerged from randomized controlled trials of intervention directed at this group as a
whole. As yet there is no clear evidence of which children with FTT might benefit most from such intervention.

**Sickle Cell Disease**

Sickle cell disease (SCD) is a common blood disorder of genetic origin. It results in red blood cells that when partially or totally deoxygenated form into sickle-shaped cells that may obstruct blood vessels. This may cause a lack of oxygen in tissues in a wide variety of locations. The medical complications include delayed growth and sexual maturation, pulmonary dysfunction, stroke retinopathy and chronic pain (Edwards, Scales, Loghlin et al., 2005). The condition therefore comprises pain, anemia, organ failure and a variety of other comorbid conditions.

Pain is a core feature of SCD. The psychological difficulties this creates have been reviewed by Anie (2005). The ability of the child with SCD to cope with pain is crucial to their quality of life. A specific measure has been developed to assess these coping mechanisms (Coping Strategies Questionnaire – SCD; Gil, Abrams, Phillips, & Keefe, 1989). Using this measure, Anie, Steptoe, Ball, Dick, and Smalling (2002) were able to show that there were three coping patterns:

1. **Active coping** (e.g., distraction or increased activity);
2. **Affective coping** (e.g., positive thoughts and feelings); and
3. **Passive adherence coping** (e.g., taking rests and fluids).

Pain severity was related to the use of passive adherence coping independently of other clinical markers of severity of SCD.

The risks of developing behavioral problems and poor psychological health were higher for children (Hurtig & White, 1986) than for adolescents (Hurtig & Park, 1989). The evidence for an elevated rate of clinical cases of anxiety disorders or depression in SCD is equivocal when compared with non-affected sibling controls (Anie, 2005). There is stronger evidence of neuropsychological deficits arising as a consequence of the cerebral infarcts associated with SCD (Kral, Brown, & Hynd, 2001). Some children develop overt strokes and the associated deficit is determined by the site of the consequent lesion. For those experiencing silent infarcts identified only by brain imaging, the area primarily affected is the frontal lobes and the cognitive problems are usually associated with attention and executive function (Anie, 2005).

**Burns**

SCD is a condition where the child is faced with the problem of chronic pain. For children who experience burns there may be sudden onset acute pain followed by an extended period of subsequent pain. There are a range of psychological methods that can augment pharmacological pain relief (Stoddard, Sheridan, Saxe et al., 2002). The subsequent emergence of acute stress symptoms 1 month after experiencing a burn (primarily a scalding) was examined by Stoddard, Saxe, Ronfeldt et al. (2006) in a sample of 64 children aged 1–4 years. They found that there were two routes to acute stress symptoms. One was a direct reflection of burn severity (total body surface area [TBSA]). The other was via the parents’ stress reactions in response to the child’s demonstrated pain symptoms. There are clear clinical implications of these findings whereby attention to pain management and relieving stress in parents of children with burns of large body areas are likely to be effective.

To identify the factors that predict how well a child will be functioning 6 months after a burn, Tyack and Ziviani (2003) studied 68 children experiencing 1–35% burns of TBSA. They found that injury factors (e.g., TBSA), premorbid child factors (e.g., psychiatric problems or learning disability), parenting factors (e.g., anxiety and depression) and demographic factors (e.g., age and gender) each made a significant independent contribution to functional outcome 6 months after the burn. A more detailed study of the emergence of post-traumatic stress disorder (PTSD) in children experiencing burns was undertaken by Saxe, Stoddard, Hall et al. (2005). They suggested that PTSD could arise via two routes. The first was via the impact of size of burn and the amount of pain experienced on acute separation anxiety in the children. The second was via dissociation, again being more marked the larger the size of the burn. These two psychological mechanisms could explain over half of the variance in PTSD symptomatology 3 months after the burn.

**Organ Transplantation**

There have been a number of studies on psychiatric aspects of organ transplantation (e.g., liver and kidney) in children (for a review see Qvist, Jalanko, & Holmberg, 2003). The main set of studies are those concerning children receiving heart or heart–lung transplants. Survival rates for heart transplantation are improving and attention has therefore turned to psychosocial aspect of their functioning and to later quality of life (Mintzer, Stuber, Seacord et al., 2005). Investigations into the cognitive development and psychological well-being of children after heart transplantation were reviewed by Todaro, Femmell, Sears, Rodrigue, and Roche (2000), who concluded that in general there was no adverse impact of surgery on the neuropsychological function of children receiving transplantation. A later study suggested that for younger children rather than adolescents, transplantation may indeed have some adverse effects on cognitive development (Wray & Ralday-Smith, 2005). Moreover, a subset of studies suggest that those experiencing a more complex course of treatment, recurrent surgery or organ rejection may show more adverse effects of cognitive functioning. In addition, academic performance is adversely affected by recurrent hospitalization in these children.

The pattern of findings also suggests that most children receiving transplants have good psychological adjustment 1 year after transplantation; however, there is a subgroup of about 25% of children who show emotional and behavioral difficulties. Todaro, Femmell, Sears et al. (2000) suggest that it is the stresses associated with transplantation, such as intense medical treatment and the reduced opportunities to socialize with peers, that result in negative affect, decreased social competence and behavioral problems in this minority of transplant recipients. These emotional and behavioral difficulties may adversely affect adherence and thereby influence the long-term health of children (for recommendations on how to increase
CHAPTER 57

medical compliance in these circumstances see Griffin & Elkin, 2001).

Physical Symptoms Without Evidence of Somatic Etiology
Complaints of physical symptoms unexplainable by known somatic etiology are common presentations in children and adolescents. These mostly involve stomach aches, headaches and joint pains, manifest in a range of severity, and are associated with functional impairments interfering with normal social interactions (Eminson, 2001a; Garralda, 1999; Taylor, Szatmari, Boyle, & Offord, 1996). They can cause the child to avoid school, attend repeated medical appointments and undergo painful investigations. The parents, or even the whole family, may become adapted to the notion that the child has an organic illness, and thus reinforce the child’s tendency to communicate by physical symptoms.

The children are often shy and compliant outside the home and somatic complaints are used to express emotional distress, usually in a long-standing pattern, accompanied by family traits of anxiety, overprotectiveness and somatization. The underlying psychosocial issues, however, may be difficult to identify and treat. Depression and anxiety disorders are the most common associated psychiatric disorders (Egger, Costello, Erkanli, & Angold, 1999; Eminson, 2001a; Garralda, 1999).

The etiology of somatizing disorders is complicated by the difficulty of distinguishing between factors relevant to the experience of physical symptoms and those contributing to illness behavior (Brown, Schrag, & Trimble, 2005). There is also a shortage of good-quality etiological studies. A variety of predisposing, precipitating and maintaining factors has been noted, although none is either necessary or sufficient on its own (Eminson, 2001a). A combination of vulnerability and trigger factors relates to issues unique to each child and family. The families are often characterized by a tendency to experience many somatic symptoms, limited verbal communication about emotional issues, including conflict, and parental history of somatoform illness or anxiety/depression. Conscientiousness, emotional lability or low self-esteem serve as predisposing factors in the children themselves. There may also be a history of abuse. Stressful life events, an episode of physical illness, peer group problems or academic pressures often precipitate the onset, and chronically stressful family situations or school-related problems may contribute to symptom maintenance.

Lately, the concept of somatization has been subjected to a major review in the light of psychoneuroimmunological research (Dantzer, 2005; Rief & Barsky, 2005; Thayer & Brosschot, 2005). It has been proposed that the brain cytokine system can become sensitized to repeated activation or exposure to environmental stressors in response to stimulation in the early stages of development. When sensitized, the system is less likely to turn off when the danger is over, and more likely to be triggered by extrinsic non-immune stimuli. This results in a sickness response along with its subjective, behavioral and metabolic components. Future research will no doubt either confirm or refute these propositions.

Factitious Illness by Proxy
The condition labeled Munchausen syndrome by proxy was formulated by Meadow (1977). Since that time there has been considerable controversy over the veracity of this concept, how frequently it occurs and its status within legislation and professional practice concerning child abuse. The current view is that this should be seen as a specific form of abnormal illness behavior (Pilowsky, 1997). This is shown by abnormalities in care-eliciting behaviors and relationships with health care professionals. By extension, this abnormal illness behavior can be generated by proxy via the manipulation of the health symptoms of a child. The term factitious illness by proxy has now been adopted.

The current criteria (American Psychiatric Association, 2000) for identifying factitious disorder by proxy are as follows:
1 Intentional production or feigning of physical signs or symptoms in another person who is under the individual’s care.
2 The motivation for the perpetrator’s behavior is to assume the sick role by proxy.
3 External incentives for the behavior, such as economic gain, are absent.
4 The behavior is not better accounted for by another mental disorder.

One of the most salient features of factitious illness by proxy is a history of abnormal illness behavior in the parent. For example, in a series of 37 families studied by Gray and Bentovim (1996), 18% of the mothers who had induced an illness in their child also had a history of factitious illness. In this sample, a total of 49% of the mothers presented with a psychiatric history. Very similar figures were obtained by Adshead and Bluglass (2005), with 21% showing a history of behaviors indicating personality disorder and 10% having a diagnosis of somatizing disorder. There was a history of psychiatric treatment in 52% of the mothers.

These findings by Adshead and Bluglass (2005) came from a study making a detailed examination of the attachment representations of mothers with factitious illness by proxy using the Adult Attachment Interview. The sample had been referred for medicolegal assessment to a psychiatrist with a specialist practice in this area. They found a very high rate of insecure attachment representation (85%). They conclude that “mothers with factitious illness by proxy are more like a clinical group than not and therefore are likely to have unmet treatment needs, which may be relevant to future risk.”

The reoccurrence of instances of unexplained deaths of young children led to the claim by Meadow that the parents may have murdered their children (Meadow, 1999). The evidence to support this conclusion and the flawed logic adopted have been extensively criticized. The principles governing expert witness testimony highlighted by this case have been outlined by Butler-Sloss and Hall (2002).

An extensive collation of material on cases of factitious illness by proxy was produced by Sheridan (2003). The characteristics of 451 cases were described based on reports in journal papers. A substantial majority of the perpetrators
were mothers (just over 75%). Gender was not related to the risk victim status. The average age at diagnosis was 48 months but with a wide range extending up to 204 months. Just fewer than 10% had long-term or permanent disability with a further 6% with fatalities. Of the known siblings, a substantial proportion were either dead or had symptoms similar to the victims. The most common conditions and symptoms that are created or faked by parents are apnea (27%), feeding difficulties (25%), diarrhea (20%), seizures (17%), cyanosis (12%), asthma (9%) and allergy (9%). The age of the child involved in factitious illness by proxy is an important consideration. The issues in older children have been reviewed by Awadallah, Vaughan, Franco et al. (2005) and include the collusion of the older child with the perpetrator and the fear of the consequences of disclosure.

The difficulties in establishing parental involvement in factitious illness by proxy have led some pediatricians to advocate the use of covert video-recordings (Southall, Plunkett, Banks, Falkov, & Samuels, 1997). The dilemmas for clinicians have been clearly set out in a paper by Morley (1998) and its associated commentary. He concluded that, “Covert video surveillance is an infringement of the liberty of the parent and child and should be undertaken only as a last resort – when a group of people has assessed the case and no other way exists to diagnose the child’s problem.”

Presentation of Psychiatric Disorders in the Form of Somatic Symptoms

Dissociative Disorders
Dissociative disorders, also known as conversion disorders, are characterized by a loss of function in any modality, suggesting a neurological or other physical condition, which is in fact not present (Goodyer, 1981; Leary, 2003). They appear from middle childhood onwards. An apparent loss of motor function is the most common presentation. Loss of sight, hearing, sensation and consciousness (as in a pseudoseizure), or partial loss (as in fugue state), have also been reported.

These are not uncommon disorders although little is known about their true prevalence. This is mainly because the most transient disorders are not necessarily brought to medical attention or, if taken to an accident and emergency department or clinic, will often remit quickly with reassurance. Prolonged reactions usually lead to a referral to child and adolescent mental health services. However, a psychiatric referral does not necessarily exclude organic pathology, as demonstrated by a survey of over 10,000 patient records by Caplan (1970). One-third of the 28 children given the diagnosis of “conversion hysteria” were subsequently found to have an organic illness.

Precipitating factors include life stresses of all types, involving either the child directly, or the whole family. The family characteristics follow two broad patterns: chaotic social circumstances with multiple symptomatic family members, and those with high expectations for achievement and high anxiety about illness and loss (Grattan-Smith, Fairly, & Procopis, 1988). The children themselves are often described as unusually good and compliant, with anxiety or depression as a predisposing factor (Kozlowska, 2001). Taylor (1986) articulated four key elements of childhood conversion disorder: an intolerable predicament for which all solutions are blocked; a presence of an ally to promote sickness; an available model for sickness; and possession of the necessary social skills.

The diagnosis involves reviewing existing medical investigations and conveying to the child and parents that there is no physical illness. Gaining their confidence to explore alternative explanations, such as feelings and life stresses, is a key task in establishing therapeutic alliance. Intervention begins with an acknowledgment that the young person has a real illness seriously disrupting their life. The presenting disability may be explained in terms of the body’s physical functions with a person’s feelings/emotions and social/interpersonal situation interacting with one another. Of the therapeutic approaches, both behavior therapy and graded physiotherapy programs have proved effective (Leary, 2003). Prognosis varies from good to poor. Favorable prognostic features include a recent onset and monosymptomatic manifestation, whereas conditions associated with a history of sexual abuse or pre-existing anxiety disorder or depression may become chronic.

Epidemic Hysteria
Apart from “hysterical conversion” disorders that occur in individual children, there is the rather different variety of “epidemic hysteria” (McEvedy, Griffith, & Hall, 1966; Moss & McEvedy, 1966). The topic was succinctly reviewed by Hersov (1997), who noted that, unlike the individual form, which is equally common in both sexes, epidemic hysteria much more frequently affects girls. It typically occurs among adolescents or pre-adolescents in a relatively closed community such as a boarding school or hospital. The phenomenon commonly involves a pattern of events with one person first developing “hysterical” attacks of falling or convulsions, overbreathing or some similar phenomenon; then another does, and soon the hysteria spreads to involve a large number of youngsters in the community. The individuals first to develop the hysterical attacks are usually found to have severe psychological disturbances, but this is less often the case with the later affected ones, who may be more dependent and show more neurotic traits than average, but are otherwise fairly ordinary youngsters. The reasons for the spread of disorder relate to the social milieu as much as to the personality features of the affected individuals. Usually, those who start the epidemic have a dominant and influential position within their peer group, and the epidemic starts at a time when group anxieties (e.g., sexual activities, worries about pregnancy, work stresses or the death of a classmate) create an emotional vulnerability. Stresses relating to the youngsters’ families of origin, such as parental divorce or death of a close relative, may also be behind the symptoms of the first affected individuals (Small & Nicholi, 1982). Outlining the main principles of managing mass hysteria, Hersov (1997) emphasized the need to first isolate the key initiating individuals. Following that, attention then needs
to be paid to both the group tensions and emotions, and to the personal problems of the main instigators.

Pseudoepilepsy

Pseudoseizures or psychogenic seizures present as epileptic seizures but are not accompanied by abnormal patterns of electroencephalogram (EEG) activity. The prevalence rate is not known accurately but there are far fewer reports of psychogenic seizures in children than in adults. In a review of 883 patients assessed over a 6-year period in one pediatric epilepsy monitoring unit, 15% were classified as having paroxysmal non-epileptic events. Of these, the proportion with psychogenic seizures increased from 3% in the preschool years, to 43% and to 87% in the age ranges 5–12 and 12–18 years, respectively (Kotagal, Cota, Wyllie, & Wolgamuth, 2002). There is a concomitant decline with age in the proportion of these paroxysmal non-epileptic disorders that are physiological or organic in origin. Often, psychiatric disorders are found concomitant with pseudoepilepsy (Thompson, Osorio, & Hunter, 2006). There is an increased rate of epilepsy and of developmental delay in these children. However, those with pseudoepilepsy as well as epilepsy form only a small proportion of those with true epilepsy – Kotagal, Cota, Wyllie et al. (2002) estimate that they constitute just 1.5% of those with epilepsy.

Families where Psychological Factors are Seen as Important for Child’s Somatic Symptoms

When assessing a child with somatic symptoms, a greater than usual level of attention may be required to engage the young person and their parents with psychiatric services. A careful narrative approach to the history of the illness, its impact and management is often helpful (Eminson, 2001b). Understanding the family’s beliefs about the illness, the level of conviction that there is a physical cause, satisfaction with investigations already carried out and views about psychiatric referral is critical for successfully engaging the child and family (Garralda, 1999).

It may also be helpful to canvass the family’s medical history more widely to establish whether other family members have had similar physical symptoms, whether a serious illness was the cause for them and whether the symptoms remained unexplained, as well as the outcome of the illness. A past failure of medical colleagues to find the cause of a family member’s complaints (sometimes with serious consequences) may undermine parental confidence in medical opinions.

The individual assessment of the child or adolescent should proceed as normally, taking note of somatic symptoms, physical state and functional mobility, mental state and ability to relate and engage, as well as sleep, appetite, relationships, school attendance and ability to perform academic work. It is important also to enquire about the young person’s views about the cause of the illness, although these usually quite closely mirror parental views.

Conclusions

The child psychiatrist has a significant part to play in the care of children with a range of physical illness. There is also an increasing involvement of specialists from other disciplines. Pediatric psychology is maturing as a research field in its own right and as a specialization in clinical and health psychology. The application of both child psychiatry and psychology expertise is developing more effective and evidence-based methods of intervention in pediatric settings (Drotar & Lemanek, 2001).

Because of the steadily increasing rates of HIV infection in women of childbearing age, HIV/AIDS has become a major worldwide threat to the health and psychosocial well-being of children and adolescents, particularly in low-resource countries with limited access to antiretroviral treatment (ART). Even in high-resource countries where the use of ART has dramatically reduced rates of morbidity and mortality, many children and adolescents continue to live either with their own or a parent’s HIV illness as a highly stigmatized, chronic or fatal transmittable illness with dramatic implications for their health, mental health and general well-being.

This chapter provides a review of the mental health and neuro-developmental issues associated with perinatal or maternal HIV infection in children and adolescents. The majority of research on mental health issues has come from the USA and European countries. Until recently, most research on children from low-resource regions such as Africa has focused on the economic, material and health care needs considered most critical to survival (Foster, 2002). Psychosocial factors have been neglected or seen as secondary to other life-threatening issues. However, there is an increasing awareness that ignoring these psychosocial factors may ultimately hinder children’s ability to obtain economic, material and basic health care resources and thus, their overall well-being (Foster, 2002).

Epidemiological Overview of the HIV Epidemic as it Affects Children and Adolescents

By the end of 2005, across the world, 40.3 million people were living with HIV/AIDS; 17.5 million were women and 2.3 million were children under the age of 15 years (UNAIDS, 2005a). Despite improved medical treatment options and ongoing prevention efforts, the death rate from AIDS continues to grow and new infections continue to emerge, particularly in women and children in low-resource countries. In 2005, 1.1 million women and 570,000 children died from AIDS (56% of the total deaths from AIDS) and 2.3 million women and 700,000 children under the age of 15 years were newly infected with HIV. In addition to the direct effects of HIV infection, millions of children worldwide are affected by HIV illness in their family members. Recent estimates of HIV-related orphaning in the USA were that 51,473 women have died from AIDS leaving 97,376 children motherless (Lee & Fleming, 2003). By the end of 2004, 15 million children across the globe, most significantly in sub-Saharan Africa, had lost one or both parents to AIDS (UNAIDS, 2005a).

Over 90% of children with HIV/AIDS worldwide acquire the virus through mother–infant (vertical) transmission either during birth or through their mother’s breast milk (UNAIDS, 2005b). In high-resource countries such as the USA, widespread HIV counseling and testing, prophylaxis against opportunistic infections and the use of ART, including during pregnancy (Abrams, Weedon, Bertolli et al., 2001) have significantly reduced both the incidence of and mortality associated with HIV/AIDS. Overall, the estimated numbers of deaths among persons with AIDS in the USA decreased by 8% from 2000 through 2004. In the USA, and in other developed countries, perinatal transmission of HIV infection has been substantially reduced by the use of ART by women during pregnancy and birth. For example, in the USA there were 1750 HIV-infected infants born each year during the early to mid-1990s; in 2004, there were just 47 cases (CDC, 2006).

Unfortunately, standard medical treatments utilized in the developed world for the treatment of HIV infection and the prevention of vertical transmission have only recently begun to reach much of the developing world, where the vast majority of new HIV infections occur. In developing countries, economic conditions and health infrastructure inadequacies have limited access to ART, including women’s access to ART during pregnancy. This is a particular problem in sub-Saharan Africa, where over 75% of the world’s HIV/AIDS cases exist, and HIV rates in pregnant women in antenatal clinics have been estimated to be as high as 40% (UNAIDS, 2005b). In the absence of ART treatment, vertical transmission rates are estimated at 25% (NIAID, 2004).

Whereas pharmacological advances in the treatment of HIV may reduce overall mortality, there is still a risk for poor health and mental health outcomes. Women and children infected and affected by HIV/AIDS in the USA are disproportionately ethnic minorities living in impoverished urban communities (CDC, 2004) who have been found to receive fewer health care services, including treatment with ART, and to have a greater risk of death (CDC, 2004; Cunningham, Hays, Duan...
et al., 2005; Shapiro, Morton, McCaffrey et al., 1999). Furthermore, although heterosexual contact is now the primary risk factor for HIV infection in women with AIDS in the USA (43%), 37% of women acquire AIDS through intravenous drug use (IDU; CDC, 2004). In the USA, 51% of children under 13 years with AIDS were born to women whose risk factor for HIV infection was IDU by themselves or their partner (CDC, 2004). As mortality decreases in HIV-infected adults, many continue or reinitiate substance use (Rotheram-Borus, Lee, Leonard et al., 2003) and thus their children are not only coping with parental HIV, but also the detrimental effects of parental substance abuse (see chapter 36).

In low-resource areas, such as sub-Saharan Africa, the huge numbers of children infected and affected by HIV/AIDS represent a major threat to the stability of the region. South Africa, which has one of the highest rates of HIV-infection in the world (UNAIDS, 2005a), also has one of the highest poverty rates; 60% of its children live in extreme poverty (Giese & Hussey, 2002). Many Black children in South African cities live in informal settlements, exposed to violence, environmental degradation, racism and poor school districts; many also grow up in single-parent homes (Barbarin, Richter, & deWet, 2001; Richter, 2003), and as a consequence of poverty are subject to material scarcity and disruptions in caregiving (Werner & Smith, 2001; Williamson, 2006).

Because of the marked discrepancies in access to health care, the medical trajectories of the HIV/AIDS epidemics now differ significantly between the developed and the developing world. However, there remain striking commonalities in the psychosocial vulnerabilities of HIV-infected women and children across the globe, with poverty, minority status, family reconfiguration and exposure to violence and substance abuse complicating children’s and families’ adjustment to HIV/AIDS-related illness.

**Perinatal HIV Infection in Children and Adolescents**

**Medical Treatment Issues**

Prior to the advent of ART, the rate of disease progression among children with HIV varied considerably, but was typically more rapid in children than in adults, regardless of the mode of infection (Abrams & Kuhn, 2003). In the first decade of the HIV epidemic, perinatally HIV-infected children had a considerably shortened life expectancy. In 1995 in the USA, 75–90% of infected children were expected to have symptoms by 1 year of age; 25–30% would have clinical AIDS. Two relatively distinct courses were described: a rapidly progressive course occurring in 20% of children and a more common, slowly progressive course. The death rate was greatest during the first year of life (more than 15%) but slowed after 2 years, with many children remaining stable throughout their first 10 years of life (Abrams & Kuhn, 2003).

In the USA, the introduction of protease inhibitors in 1996, and the development of combination ART regimens with superior efficacy in viral suppression, provided substantial clinical benefits to HIV-infected children (Kline, 2005). These advances in ART led to substantial improvements in neurodevelopment, growth and immunological and virological status. Combination therapy is now recommended for all infants, children and adolescents who are being treated with antiretroviral agents (HIV/ATIS, 1999). By 1999, the median lifespan for perinatally HIV-infected children in the USA was 8.6–13 years (American Academy of Pediatrics, 1999). By 2005, 46% of pediatric HIV/AIDS cases in New York City, one of the epicenters of the US epidemic, were 13–19 years of age and 9% were 20 years and older (NYCDOH, 2005). Thus, in high-resource countries such as the USA in which new cases of pediatric HIV are increasingly rare, pediatric HIV infection is evolving into an adolescent disease.

In spite of enormous successes in decreasing morbidity and mortality in the USA, ART is not uniformly beneficial. Recent US studies indicate that standard combination ART regimens are effective in only 50% of children, most likely because of multidrug resistance associated with prior exposure to less than optimal HIV treatment, and poor adherence (Yoge, 2005). However, recent advances in new ART treatments have the potential to ameliorate the effects of drug resistance. Unfortunately, the toxicity of long-term ART use resulting in significant side effects (e.g., insulin resistance, cardiomyopathy, lipodystrophy) may still influence adherence. It is possible that in low-resource countries, where children and adolescents have had limited exposure to prior HIV treatments associated with drug resistance, recent trends in increasing availability of superior ART regimens (Domek, 2006) have the potential to improve outcomes significantly for children.

**Neurodevelopmental Sequelae of HIV Infection**

From the beginning of the epidemic, there have been consistent findings of significant neurological, developmental, cognitive and language deficits in HIV-infected children (Belman, Muenz, Marcus et al., 1996; Brouwers, Belman, & Epstein, 1991; Coplan, Contello, Cunningham et al., 1998; Droter, Olness, Wiznitzer et al., 1999; Epstein, Sharer, & Goudsmit, 1988; Mellins, Levenson, Zawadzki, Kairam, & Weston, 1994). In general, the severity of neurological and neuro-psychological compromise increases with the severity of HIV-related illness; specifically higher viral loads and the most severe non-neurological health-related symptoms (Jeremy, Kim, Nozyce et al., 2005; Pulsifer & Aylward, 2000).

**HIV-Associated Encephalopathy**

Prior to the advent of ART, two relatively distinct neurodevelopmental patterns were described in largely untreated HIV-infected infants and children: progressive encephalopathy and static encephalopathy (Brouwers, Belman, & Epstein, 1991; Epstein, Sharer, & Goudsmit, 1988). Static encephalopathy, characterized by non-progressive deficits in cognitive, motor and/or language function, is not considered to be directly attributable to HIV and is most likely associated with non-HIV risk factors such as prenatal drug exposure, pre-
maturity, low birth weight and genetic risk factors (Epstein, Sharer, & Goudsmit, 1988; Mellins, Levenson, Zawadzki et al., 1994). Progressive encephalopathy, corresponding with the AIDS dementia complex in adults, is characterized by the loss of developmental milestones in young children, declining IQ scores and increasing difficulties with language, attention, concentration and memory in older children. Encephalopathic children also manifest apathy, decreased social behavior and symptoms of depression and irritability compared to non-encephalopathic children (Moss, Brouwers, Wolters et al., 1994; Moss, Wolters, Brouwers et al., 1996). This neuromotor pattern is considered to be a direct effect of HIV on the central nervous system (CNS) and has been associated with a poor overall health prognosis. Before the development of ART, HIV-related encephalopathy was a common sequela, reported in 35–50% of children with pediatric AIDS (Cooper, Hanson, Diaz et al., 1998; Lobato, Caldwell, Ng, & Oxtoby, 1995; Rigardetto, Vigliano, Boffi et al., 1999).

ART and Neurodevelopment

Early reports indicated that ART had the potential to ameliorate the development and progression of HIV-related CNS compromise. Zidovudine treatment alone was shown to be associated with improvements in cognitive and neuropsychological functioning (Brady, McGrath, Brouwers et al., 1996; Brouwers, Moss, Wolters et al., 1990; McKinney, Maha, Connor et al., 1991; Pizzo, Eddy, Fallon et al., 1988). Current treatments, which combine several antiviral agents to achieve near total viral suppression, have the potential to reduce the prevalence and severity of CNS disease in that they prevent HIV progression. Since the advent of ART, the rate of HIV encephalopathy has declined markedly. In a study of neurobehavioral outcomes in 126 children perinatally infected with HIV, the rate of progressive HIV encephalopathy was 1.6% (Chiriboga, Fleishman, Champion, Gaye-Robinson, & Abrams, 2005). Progressive HIV encephalopathy, which historically was considered a poor prognostic sign, was found to respond to ART. Yet, in spite of better prognosis, those children who experienced progressive encephalopathy showed higher rates of residual neurological, cognitive and academic difficulties (Chiriboga, Fleishman, Champion et al., 2005). In a recent study of more subtle neuropsychological outcomes (e.g., vocabulary), treatment with ART, consisting of a protease inhibitor regimen for 48 weeks, did not significantly affect performance, even when the treatment reduced HIV RNA viral load significantly (Jeremy, Kim, Nozyce et al., 2005).

Differential Diagnosis of Neuropsychological Deficits in HIV-infected Children and Adolescents

More recent studies in the USA have evaluated the neuropsychological functioning of larger samples of older HIV-infected children, most of whom have had some experience with ART (Nozyce, Lee, Wiznia et al., 2006; Smith, Malee, Leighty et al., 2006). These studies generally report cognitive delays and deficits when comparing HIV-infected children to population norms. However, in US studies utilizing appropriate comparison groups (such as perinatally HIV-exposed but uninfected children), investigators have failed to find differences between the HIV-infected and comparison groups (Fishkin, Armstrong, Routh et al., 2000). In a sample of HIV-infected, long-term surviving and ART-naïve Ugandan children, HIV-infected children did not differ significantly in neurological and cognitive assessments when compared with gender-matched HIV-exposed but uninfected and HIV-negative children (Bagenda, Nassali, Kalyesubula et al., 2006). However, when studies consider severity of illness as a variable affecting neuropsychological outcomes, progression to AIDS has been consistently associated with poorer outcomes (Nozyce, Lee, Wiznia et al., 2006; Smith, Malee, Leighty et al., 2006). In conclusion, because of the high-risk backgrounds of HIV-exposed children, both in the USA and internationally, the effects of HIV infection on cognitive functioning, in the absence of disease progression, are often difficult to disentangle from other background characteristics that are also known to affect neuropsychological outcomes.

Emotional and Behavioral Disorder in HIV-Infected Children and Adolescents

Rates of Mental Health Problems and HIV Causality

In general, high rates of emotional and behavioral disorders have been reported in HIV-infected children and adolescents (Havens, Whitaker, Feldman, & Ehrhardt, 1994; Mellins, Brakis-Cott, Abrams, & Dolezal, 2006a; Moss, Bose, Wolters, & Brouwers, 1998; Nozyce, Lee, Wiznia et al., 2006; Papola, Alvarez, & Cohen, 1994), although determining whether HIV infection has a causal effect on children’s emotional and behavioral functioning is difficult.

There have been very few studies utilizing appropriate comparison groups and no large-scale epidemiological studies are available. Havens, Whitaker, Feldman et al. (1994) found that 21% of a small sample of HIV-infected children met criteria for attention deficit/hyperactivity disorder (ADHD). However, these rates were no different from those in a matched control group of children from similar backgrounds (children living in foster care who had been born to women who had used drugs during pregnancy). Similarly, Mellins, Kang, Leu, Havens, and Chesney (2003) in one of the largest controlled prospective longitudinal studies following perinatally HIV-exposed children (96 HIV-infected children and 211 seroconverters) also found high rates of emotional and behavioral problems, but failed to find an association between either HIV status or prenatal drug exposure and poor emotional and behavioral outcomes. The strongest correlates of increased behavioral symptoms were demographic characteristics (gender, ethnicity, maternal education).

Given the results of the above studies, caution is warranted in attributing HIV causality to the high rates of behavioral problems found in studies that do not include appropriate
control groups (Nozyce, Lee, Wiznia et al., 2006) given the association of HIV with other risk factors. Features associated with prenatal drug exposure and parental substance abuse, such as prematurity, low birth weight, exposure to trauma, abuse and neglect, and parental psychopathology may actually be more potent mediators of mental health problems in HIV-infected children than HIV itself (Campbell, 1997; Havens, Whitaker, Feldman et al., 1994; Mellins, Levenson, Zawadzki et al., 1994; Merikangas, Dierker, & Szatmari, 1998; Singer, Farkas, & Kliegman, 1992; Walsh, Macmillan, & Jamieson, 2003; Whitaker, Orzol, & Kahn, 2006; Wilens, Hahesy, Biederman et al., 2005).

**Psychotherapeutic Issues in Helping Perinatally Infected Children Cope with HIV**

Regardless of causality, HIV-infected children are at risk for neurodevelopmental and mental health problems which need to be considered by mental health providers. These factors tend to differentiate HIV disease from other chronic illness of childhood and adolescence and frequently complicate young people’s adjustment to HIV infection.

**Communication About Health**

HIV disclosure to the perinatally infected child remains one of the most clinically challenging issues for families and providers, in part because of the tremendous stigma that still exists. In general, age and developmental level dictate the child’s capacity to understand the meaning of their illness. Across illnesses, preschoolers and young school-age children generally cannot grasp the concept of chronic illness and understand episodes of HIV-related illness as discrete and unconnected events (Bibace & Walsh, 1980; Wiener, Mellins, Marhefka, & Battles, 2007). Because of the stigma and young children’s inability to contain information discretely, they are usually not informed about their HIV infection. Most providers agree that as children age, communication about their health problems becomes more important, both to secure their participation in health regimes and to facilitate adjustment to living with HIV. Often older school-age children who are not directly informed of their diagnosis will deduce it from clues in the medical care environment or elsewhere. A lack of open communication in these cases may isolate the child from adult help with issues related to HIV. These issues include coping with secrecy, stigma and potential peer rejection, coping with chronic illness, and anxiety about the future (Wiener, Mellins, Marhefka et al., 2007).

Studies with HIV-infected children indicate that parents or other family caregivers often resist communication with the HIV-positive child about his or her health in an effort to protect the child from emotional distress (Mellins, Brackis-Cott, Dolezal et al., 2002). Other reasons include the adult’s fear of experiencing more pain about the child’s diagnosis; biological parents’ fears about disclosing their own HIV infection through disclosure of the child’s infection and parental guilt about having transmitted the virus to the child and their own HIV risk behaviors (e.g., sexual behavior, drug use) and concerns that the child will disclose family secrets about HIV in undesirable ways (Wiener, Mellins, Marhefka et al., 2007).

In 1999, the American Academy of Pediatrics published guidelines stating that all adolescents should know their HIV status and that disclosure should be considered for school-age children (American Academy of Pediatrics, 1999). Clinical reports have indicated positive outcomes associated with disclosure including the promotion of trust, improved adherence to treatment, enhanced access to support, open family communication and better long-term health outcomes (Wiener, Mellins, Marhefka et al., 2007). However, disclosure of HIV to children still remains a difficult and controversial issue for families and providers, and relatively few research studies have been conducted to evaluate the following:

1. Most appropriate timing and determinants of disclosure;
2. Psychosocial effects of HIV disclosure;
3. Impact of disclosure on adherence and sexual behavior; and
4. Most effective strategies for full disclosure.

Lessons learned from pediatric oncology are applied to HIV disclosure, even though the population of children affected by HIV differs dramatically, in terms of socioeconomic and cultural variation, and the incomparable social stigma that surrounds HIV/AIDS. The few studies that have actually been conducted were recently reviewed (Wiener, Mellins, Marhefka et al., 2007) with mixed findings: some showed psychological benefits of disclosure, others risks and still others showed no mental health differences between youth who knew and those who did not know their diagnosis.

Whereas for adults the specific diagnosis of HIV is often a highly charged, overwhelming element in their efforts to communicate to the child about health issues, it is in fact only a single component, which may in part explain differences in study findings. The child may be more concerned about medications, medical appointments and procedures associated with a chronic health condition, or with impingement on functioning. Establishment of effective communication with the child on the broad range of health-related issues is of great importance. What is most critical to remember is that disclosure is a process and that process must reflect a child’s developmental understanding of illness and death. It is not a discrete event that can be forgotten once it occurs (Lipson, 1994). Children’s needs for information and emotional response to the information change over time, as has been shown in the pediatric oncology literature (Spinetta, 1980).

**Adherence to Medical Regimens**

HIV-infected children need to adhere to complicated medication regimens, attend frequent medical appointments and undergo frequent diagnostic procedures. Optimism about the success of treatment has been tempered by the significant challenges to maintaining long-term adherence to these multi-drug ART regimens (Chesney, 2003; Mellins, Brackis-Cott, Dolezal, & Abrams, 2004). A number of studies of pediatric adherence to ART indicate that adherence ranges from 57%
to 81% (Mellins, Brackis-Cott, Dolezal et al., 2004), comparable to results from adult HIV studies (Chesney, 2003). Although 80% adherence may be sufficient for some health conditions, it is well below what is necessary for successful HIV treatment. Even brief episodes of missed medication can permanently undermine efforts to suppress HIV RNA viral load (Macilwain, 1997).

In studies of other chronic childhood diseases (e.g., asthma, cancer, diabetes), a combination of child, caregiver and provider psychosocial characteristics has been associated with adherence (see chapters 57 and 70). For HIV-infected children, the possibility of stigma and discrimination may complicate adherence to medications that must be taken throughout the day, often when the child is in school (Armistad, Forehand, Steele, & Kotchick, 1998). Given that HIV-infected children are not always told their diagnosis, they may not cooperate with treatment, particularly given that HIV medications often have unpleasant tastes and significant medical side effects. Variables associated with increased non-adherence include older child age, female gender, worse parent–child communication, worse child and caregiver cognitive or educational function, stressful life events, youth mental health problems, parent–child relationship factors including less supervision and monitoring and less parent–child involvement, caregiver HIV status, and youth engagement in other risk behaviors (e.g., sexual intercourse; Mellins, Brackis-Cott, Dolezal et al., 2004; Mellins, Brackis-Cott, Dolezal et al., 2006b; Williams, Storm, & Montepiedra, 2006).

These data suggest that efforts to improve children’s adherence to ART would benefit from behavioral and mental health interventions addressing psychosocial and familial issues, although intervention studies are only now under way. Based on clinical experience, many families will need support administering the complex regimen of medication for the child, and in managing the child’s potential opposition to taking medication. Behavioral treatment may be helpful to families (see chapter 62). Finally, caregivers may give children too much responsibility for taking their medications before they are ready to manage the regimens effectively. Working with families to develop realistic expectations of older children’s ability to manage their medication independently is important.

**Promotion of Optimal Development and Education**

The mental health issues for infected children change over the course of the disease. There are an increasing number of HIV-infected children who remain relatively symptom free for long periods of time. They may not know their diagnosis and their lives may be relatively unaffected by illness. However, they may be very stressed by the illness of a parent, substance abuse in the family, disrupted placements and ruptured attachments, or other problems faced by families at highest risk for HIV. Interventions for these problems and attention to promotion of the child’s optimal development may be of more relevance in his or her mental health care than a narrow focus on HIV (Rosen, Mellins, Ryan, & Havens, 1997; Ryan, Havens, & Mellins, 1997).

A part of optimal development is the capacity for adequate school functioning. Often, the various systems that should serve the HIV-infected child – the family, child welfare agencies, foster agencies, public school and health care institutions – fail to ensure that the child’s education needs are met. HIV-infected children are at high risk for school-related problems given neuropsychological deficits, frequent absence because of health problems and multiple medical appointments. Thus, HIV-infected children require regular psychosocial evaluations to monitor possible deterioration. Teachers may not know about a child’s HIV infection, given rules of confidentiality. They may misinterpret frequent absence and potential lack of motivation as reflecting a lack of interest or commitment to school. HIV-infected children may require special education resources. As their health deteriorates, home-based education may become necessary. It is important to the general well-being of these children that as normal an education experience as possible be maintained.

**Issues in Adolescence**

In the USA and other countries with widespread access to ART, perinatal HIV infection has become an adolescent epidemic. Adolescence is a developmental stage that poses many challenges for youth without chronic health conditions. Perinatally infected adolescents must confront the social ramifications of having a chronic and stigmatizing disease, including disclosure of illness and ostracism and possible transmission of the virus to others.

Many perinatally infected youth have delays in physical development, including the onset of puberty. These delays, as well as threats to body self-image posed by having a chronic health condition, present another risk factor for poor outcomes, given that adolescence is a time of increasing interest in body image, and several studies link body image with mental health and sexual risk outcomes in both boys and girls (Benjet & Hernandez-Guzman, 2002; Wingood, Diclemente, Harrington, & Davies, 2002).

Because ART did not become routinely available to children in the USA until 1998, many perinatally infected adolescents were exposed to years of less than optimal treatment and thus, active HIV disease (De Martino, Tovo, Balducci et al., 2000; Gortmaker, Hughes, Cervia et al., 2001), which in turn may have led to CNS insult and neurodevelopmental and cognitive deficits. Furthermore, adolescence is a time when certain psychiatric disorders may emerge. One study reported that over 50% of 9- to 16-year-old perinatally infected youth from a New York City medical clinic sample met criteria for a psychiatric disorder (Mellins, Brackis-Cott, Abrams et al., 2006a).

As congenitally infected children move through adolescence and young adulthood and become sexually active, they require significant support in managing the complex issues of integrating healthy sexual development with their HIV infection. Because many of these youth were not expected to live until adolescence, their caregivers and providers have not necessarily engaged them in conversations about sexual health and sexual risk behavior. Open and honest communication around
patterns of sexual behavior, disclosure to sexual partners and strategies for the prevention of the spread of HIV are essential. Secondary prevention among HIV-infected youth must be addressed, so that these youth do not re-expose themselves or infect others.

Other notable issues for HIV-infected adolescents include high rates of non-adherence (Mellins, Brackis-Cott, Dolezal et al., 2006b). Non-adherence has not only individual health consequences (e.g., development of drug-resistant strains of HIV; poor immune function), but also public health consequences given the possibility of transmission of drug-resistant strains of the virus to potential partners. Again, this suggests that there is a need for interventions to promote healthy development and reduce risk in this population.

Reliance on parents or other adult family members for health care may lead to regression and difficulty seeing oneself as a young adult. One major goal is to help an effective transition into independent adulthood. Helping youth develop strategies to deal with their illness, the stressful life events that they experience and will encounter in the future, develop a support system, and navigate adolescence are critical tasks for therapeutic interventions.

Unfortunately, to date there have been very few interventions aimed at promoting optimum development and reducing risk behavior in the transition from childhood to adulthood. In one of the few examples, CHAMP+ (McKay, Block, Mellins et al., 2006), multiple family groups are brought together to promote family communication, increase parental supervision and support of children, reduce youth sexual risk behavior and promote adherence and general well-being. It is clear from the experience of the investigators that interventions are needed to help parents and children communicate about adolescent issues, negotiate changing roles and youth autonomy in appropriate ways, and consider reduction of risk behaviors.

**Psychopharmacological Management of HIV-Infected Children and Adolescents**

Psychopharmacological management of psychiatric disorder, delirium and dementia in HIV-infected children is often a necessary component of adequate treatment. However, it is complicated by drug–drug interactions with ART medications used to treat HIV disease (an issue in all HIV-infected children undergoing such treatment) and potential CNS impairment secondary to HIV infection (a particular issue in those children with advanced HIV disease). Psychotropic medications in pediatric HIV should be initiated at doses lower than standard treatment and titration upward should be slow and carefully monitored.

When evaluating children with behavioral syndromes who are treated with antimicrobial, antifungal and/or antiviral agents, potential neuropsychiatric side effects must be included in the differential diagnosis. When planning pharmacological treatment of HIV-infected children on antiretroviral medication, potential drug interactions must be taken into consideration (Sahai, 1996). Of particular importance in drug interactions is the family of cytochrome P450 isoenzymes, which are responsible for the metabolism of many psychotropic medications and antiretrovirals, especially the protease inhibitors. Other HIV-related medications, including antimicrobial and antifungal medications used in treatment and prophylaxis, also interact with cytochrome P450 isoenzymes. It is important when initiating treatment with psychoactive medications to review the metabolism of the medication(s) with the entire treatment regimen to identify interactions and contraindications. As little is known on treating HIV-infected children with psychotropic medication, treatment should proceed cautiously and with frequent monitoring (Fauci, Bartlett, & Goosby, 1999; Heylen & Miller, 1996a,b; Oleske & Scott, 1999).

In a case series, Havens and McCaskill (1999) described the psychostimulant treatment of 12 HIV-infected children and adolescents, eight with ADHD and four with HIV-related dementia. Two-thirds of the children tolerated psychostimulants with good efficacy as measured by the Efficacy Index of the Clinical Global Impressions. The maintenance dosage of methylphenidate was in the range 0.2–1.2 mg·kg⁻¹, and the one child on dextroamphetamine required 0.6 mg·kg⁻¹. Four of the 12 children treated (three out of the ADHD sample) experienced adverse side effects precluding their continuation of methylphenidate. While the neuropsychiatric adverse effects argue for caution in the psychostimulant treatment of this population, such treatment should not be withheld when clinically indicated. Two out of the three children who could not tolerate methylphenidate were managed with clonidine.

**Therapeutic Support for the Child and Family with End-stage Disease**

There has been limited research on this topic in HIV-infected children. However, much of the work conducted on other terminal illnesses such as cancer is most likely applicable (Hurwitz, Duncan, & Wolfe, 2004). With disease progression, children must confront the physical and mental decline associated with AIDS. As they approach late-stage illness, they and their families must confront the terminal nature of the disease. Often, families are overwhelmed at this stage and have difficulty communicating with the child about issues related to prognosis and death. Sensitive mental health intervention by clinicians with an ongoing relationship with the child and their family can provide a place for the child to express the inevitable anxieties and fears about separation from family members and dying, and to help the child, if old enough, to communicate their wishes about medical treatment. Special attention must be paid to issues of pain management at this stage, particularly for young children with limited ability to communicate information to health care providers effectively (Havens, Ryan, & Mellins, 1999).

As children approach the end of life, they may experience confusion and great anxiety. Parents or other caregivers and perhaps even health care providers may find communicating with the child about the approach of death so difficult and overwhelming that they avoid it. Dying children need a venue in which death can be discussed with the opportunity to express
their thoughts and fears, and receive reassurance. For many children, separation from family is the most worrisome aspect of death. A therapist may be able to draw on elements in the family’s spiritual or religious belief system to sustain hope of continuity of attachment between the deceased and surviving family members (Havens, Ryan, & Mellins, 1999; Ryan, Havens, & Mellins, 1997).

Mental Health Issues in Children Living with Parental HIV Illness

There is a growing US literature suggesting that uninfected children and adolescents of HIV-infected parents show higher rates of depression, anxiety, learning problems, criminal activity, poor school functioning, diminished family and social support, risky sexual behavior and substance use than youth with unaffected parents (Esposito, Musetti, Musetti et al., 1999; Forehand, Jones, Kotchick et al., 2002; Rotheram-Borus, Leonard, Lightfoot et al., 2002; Rotheram-Borus, Lee, Leonard et al., 2003).

The mental health issues associated with HIV illness in families evolve over the dynamic course of HIV illness and vary depending on the stage of their parents’ illness (Havens, Mellins, & Pilowski, 1996). The stages begin with diagnosis of HIV infection and include asymptomatic illness, illness progression, late-stage illness, death and reconfiguration of the family with the children in new care arrangements. With the development of effective ART, at least in the developed world, the inevitability of the linear progression through these stages has been reduced.

Children exhibit a variety of responses to parental HIV diagnosis, illness or loss at any stage in this process. These responses may be characterized as one or more of the following: 1 Normative responses requiring supportive counseling and/or increased access to existing social supports; 2 Responses complicated by developmental histories of poor or disrupted attachment and/or trauma (particularly common in children also affected by parental drug addiction), indicating a need for individual or family psychotherapy; and 3 Exacerbations of pre-existing psychiatric disorder or precipitations of new-onset disorder, in which syndrome-specific treatment must be among the interventions (Havens, Ryan, & Mellins, 1999; Ryan, Havens, & Mellins, 1997).

Issues in differential diagnosis within the stage model of HIV illness are reviewed below.

Diagnosis and Disclosure of HIV

Infected parents frequently withhold information about their HIV diagnosis from their children. The majority do not tell children prior to early or even middle adolescence (Lee & Rotheram-Borus, 2002; Mellins, Brackis-Cott, Dolezal et al., 2002). Parents are often concerned about the child’s negative emotional response, anger and inability to maintain the secret (Pilowski, Sohler, & Susser, 2000; Vallerand, Hough, Pittiglio, & Marvicsin, 2005). Even in the absence of direct communication, many children and teenagers develop their own suspicions about the parent’s health problems from clues such as medications, symptoms or multiple medical appointments. Children experience a great deal of distress suspecting that a parent is struggling with HIV-related illness, yet because they are not “supposed to know” they remain unable to reach out for adult support and reassurance.

Research on disclosure of parental HIV has resulted in mixed findings, with some studies suggesting that children do worse after learning about parental HIV and other studies showing no difference (Mellins, Brackis-Cott, Dolezal, & Meyer-Bahlburg, 2005; Murphy, Marelich, & Hoffman, 2002; Vallerand, Hough, Pittiglio et al., 2005). In part this may be because of variations in the ages of the children, the outcomes being studied, the length of time since disclosure occurred and the availability of support for the child and family. Also, as noted above, disclosure is often misunderstood as a discrete event that can be accomplished as a single communication. It is more appropriately handled as an ongoing process, with new information provided with any change in parental health status.

Parents and other adult caregivers of the HIV-affected child should be counseled about the importance of developmentally appropriate communication about the parent’s health. The family’s established style of communication about emotionally charged information may not be sufficiently flexible to allow for complete disclosure, but may be able to tolerate communication of part of the truth without specifying the precise diagnosis (“Mommy has an infection in her blood. She’s taking medicine to keep her healthy.”). Adults should be counseled to provide children with realistic reassurance about the parent’s health, and about their own future care and security. HIV-negative children may worry that they themselves are infected because their parent is, and should be assured that they and their siblings are uninfected. In cases where there is uncertainty about a child’s serostatus or where additional reassurance is indicated, HIV testing can be very helpful.

Progression of HIV Illness

When parental HIV disease progresses, children are confronted with deterioration in the parent’s ability to function as well as separations resulting from hospitalizations. Use of ART means that parental death is no longer inevitable and parents often experience episodes of severe HIV-related illness with subsequent recovery with changes in their medication regimen. The importance of communication with children about parental illness increases as HIV disease progresses. Responding to a parent’s physical, cognitive or functional decline without accurate information about illness and prognosis is very difficult for a child. The normal sadness, anger and anxiety experienced by children living with an ill parent can be exacerbated by the need to manage these feeling without support from adults who are unable to allow open communication about their illness.

Given the high-risk backgrounds of many HIV-affected families, children’s responses to the parent’s illness may also be complicated by underlying psychiatric disorder, developmental
difficulties in the child’s attachment to the parent, and difficulties in the family environment. When working with families affected by both drug use and HIV, it is important to carefully assess children presenting with symptoms in response to parental illness; the attribution of symptomatology to HIV-related stressors alone is often clinically inappropriate (Havens, Mellins, & Pilowski, 1996).

**Permanency Planning**
With ongoing progression of HIV disease in the parent, caregivers may require counseling about planning for the placement of children following parental death. Communication about HIV illness and permanency planning tend to be closely intertwined, with difficulties in one area being reflected in the other. Family-based permanency planning that actively involves the children, particularly teenagers, is more likely to have a successful outcome than that which excludes the affected young people. Effective permanency planning can be undermined by active substance abuse and untreated psychiatric disorder in family members, as well as by family dynamics related to substance abuse.

**Bereavement and Family Reconfiguration**
Loss of a parent can lead to adverse consequences (see chapters 26 and 27). A positive relationship between the parents prior to the death and a strong surviving parent to keep the family intact have been identified as protective against elevated risk of mental health problems (Harris, Brown, & Bifulco, 1986; Kranzler, Shaffer, Wasserman, & Davies, 1990). Among the predictors of complicated bereavement are prior child emotional difficulties, emotional lability and poor impulse control (Kranzler, Shaffer, Wasserman et al., 1990). Many of the factors associated with complicated bereavement in childhood are present in HIV-affected children and adolescents. Furthermore, the effect of parental death in this population is exacerbated by the stigma associated with losing a parent to AIDS, which can lead to secrecy and social isolation, limiting the extent to which children and their families are able to access support (Draimin, Hudis, Segura, & Shire, 1999).

Grieving HIV-affected children and adolescents most commonly move into reconfigured families with extended family members also mourning the loss of the loved one. In countries with well-developed health services, the social and concrete service supports available to the families by virtue of the parent’s AIDS diagnosis generally diminish or disappear following the parent’s death. Generally, children and adolescents orphaned by AIDS are moving from one situation of poverty to another, with the responsibility for the care of these children falling on financially limited and often overwhelmed extended family members. In those cases where children and adolescents move into non-relative foster care, they must make the difficult adaptation to new family members and often very different family lifestyles.

Education for the grieving child and counseling for his or her adult caregivers are very useful in many families. It is helpful to distinguish the usual course of mourning of adults (a sustained period of dysphoria, followed by a gradual return to normal mood) from that more typical of children, especially pre-adolescents (immediate periods of dysphoria punctuated by apparently normal play or socializing, with periods of grieving throughout the developmental trajectory). When a child’s deceased parent has been absent or otherwise deficient in their role with the child, adult caregivers may be puzzled by the child’s mourning over the loss: they need an explanation that the loss of inadequate parenting may in fact complicate rather than minimize the child’s grieving process.

**Issues of Bereavement in Low-Resource Countries**
Internationally, one of the most significant effects of the HIV epidemic is the staggering number of children with very few resources who are or will become orphaned because of HIV. Multiple losses, stigma and chronic social vulnerability hinder a therapeutic bereavement process among AIDS orphans. Also, because of high death rates in AIDS-affected African communities, orphans experience multiple losses (Foster, 2002). Studies from African countries have found that compared with non-orphans, AIDS orphans (defined as children who have lost at least one parent to AIDS) had more unmet basic living needs, less access to school and more psychological problems, including negative mood and pessimism (Atwine, Cantor-Grae, & Bajuniwe, 2003; Makame, Ani, & Grantham-McGregor, 2002; Sendengo & Nambi, 1997; UNAIDS, 2004). Given the devastating effects of family and community destruction resulting from years of poverty, racism, family relocation and migration, violence and famine, many African children orphaned by AIDS are at great risk for poor mental health and health outcomes given limited resources, stigma, exploitation by new caregivers and a dearth of appropriate caregivers.

**Conclusions**
Over 25 years into the HIV epidemic, HIV/AIDS continues to affect millions of children and adolescents worldwide. In the developed world, medical advances in both ART and prevention of vertical transmission have decreased morbidity and mortality in infected children and in their infected family members. In the developing world, the cost of ART and health infrastructure inadequacies have made widespread implementation of treatment advances difficult, leaving millions of children and adolescents without parents and at risk for their own HIV infection and illness. Although clinical trials are underway, there is no currently available vaccine against HIV (D’Souza, Cairnes, & Plaeger, 2000).

Continued targeted prevention efforts and more equitable distribution of health care resources are essential elements in the global fight against HIV/AIDS. In the meantime, effective therapeutic interventions to address the mental health consequences of individual and familial HIV disease have an essential part to play in maximizing the outcome for children and adolescents affected by HIV/AIDS.

Mental Health in Children with Specific Sensory Impairments
Helen McConachie and Gwen Carr

Children with impairments of vision or hearing are reported to have higher rates of problems in psychosocial adjustment and of psychiatric disorder than typically developing children. However, potentially the only thing a deaf child cannot do is hear, and a blind child cannot see. In order to understand the sources of children’s vulnerability, it is necessary to consider how impairment may link to mental health outcomes. Therefore, this chapter is structured in terms of impairments, functional limitations, mediating variables and outcomes including social participation (WHO, 2004).

Our intention is to provide an overview of the issues that most affect children’s development and well-being, based on the research literature, and to offer a source of guidance for professionals on how to interpret the needs and behaviors of children appropriately. However, one of the main challenges lies in evaluating the validity of the picture presented in past literature. Currently, much received wisdom is being challenged. Therefore it is necessary to keep in mind throughout this chapter the question: To what extent have reported problems in psychosocial adjustment arisen from late identification of impairment, lack of appropriate guidance to parents and limitations in education and opportunity for children?

Sensory Impairments

Definitions and Prevalence
Prevalence figures for sensory impairments in childhood depend on the various definitions used. In the developed world, about 10–20 in 10,000 children have a severe visual impairment that has educational implications (Rahi & Dezateux, 1998; Walker, Tobin, & McKennell, 1992). Around one-quarter of these have only light perception or less, and are thus “blind” (profound visual impairment). Around 12 in 10,000 children have a severe visual impairment, i.e., children likely to have no other impairments (Dale & Sonksen, 2002). Nevertheless, where neuroimaging is available, it is clear that at least half of these children are likely to have brain lesions that may affect broader development in subtle ways (Waugh, Chong, & Sonksen, 1998).

The main types of hearing loss are conductive and sensorineural; the latter has a genetic cause in at least half of cases. In most cases the gene is recessive, and one or both parents of about 10% of deaf children are themselves deaf. The other main causes of sensorineural deafness are maternal rubella, prematurity and infections of the nervous system, all of which are more likely to result in additional impairments (Freeman & Groenveld, 2000). The main cause of conductive deafness is otitis media with effusion (OME), with a prevalence of 12–14% in preschool children (Kvaerner, Naftad, & Jaakkola, 2000). Conductive hearing loss tends to be mild to moderate, with a median of 25 dB (Klein, 2001).

For some children there are early interventions that aim to ameliorate the nature of the functional impairment. Timing may be critical, as there are sensitive periods for recovery from lack of vision (Lewis & Maurer, 2005), or for deaf children to be able to combine visual and auditory information (Schorr, Fox, van Wassenhove, & Knudsen, 2005) and thus to have more effective speech understanding and language development (Harrison, Gordon, & Mount, 2005). Thus, early cataract surgery coupled with visual training can radically improve a child’s potential for functional vision. The introduction of hearing aids and cochlear implants makes an important difference to the sounds a child can hear, although again these must be appropriately supported. A major opportunity for transformation in professional practice has occurred recently with the introduction of the universal Newborn Hearing Screening Programme (NHSP). Infants can now be fitted with hearing aids as early as 2 months after birth, rather than on average at 2.5 years of age (UK data: Davis, Bamford, Wilson et al., 1997). For those deaf infants who do not derive useful benefit from hearing aids, the age at which cochlear implantation is considered is increasingly early. With the introduction of early intervention programs, including very early support for...
communication development (orally or through sign), the prospects for deaf children are now radically improved (Davis & Hind, 2003; Yoshinaga-Itano, 2003).

The estimate for the prevalence of multisensory impairment in school-age children in developed countries is 1 in 10,000, a large proportion of whom will also have intellectual impairments (Bond, 2000; Nikolopoulos, Lioumi, Stamatakis, & O’Donoghue, 2006). Given their heterogeneity, the chapter does not attempt to include children with multisensory impairment, nor those with later-acquired sensory impairments.

Function

Before we consider how impairment in vision or hearing may affect children’s development and functional abilities, some limitations of the descriptive and experimental literature must be acknowledged. First, as there are few psychologically adequate assessment measures developed specifically for children with sensory impairments, some comparisons that suggest poorer levels of ability in children who are blind or deaf may instead reflect inappropriate questions or greater cognitive challenges for the child. Second, the circumstances of the assessment need to be considered, as young children with impairments are disproportionately disadvantaged by being asked to carry out unfamiliar tasks by an unfamiliar person (McConachie, 1995; Pérez-Pereira & Conti-Ramsden, 1999). Furthermore, most studies with deaf children who sign are presented by a hearing examiner accompanied by an interpreter, which is likely to lead to less than optimal presentation and be inhibiting for the child (Austen & Crocker, 2004; Hindley, 1997). The third limitation is the inevitable one of small numbers, given the low prevalence of severe levels of hearing and visual loss and the concentration on children without apparent evidence of additional neurological impairment.

Early Language Development

Deafness is expected to lead to delay in language development. However, considerable evidence suggests that deaf children brought up by fluent signing parents have the potential for early language development that parallels the spoken language development of hearing children (Bonvillian, Richards, & Dooley, 1997). Furthermore, for many children who have an early cochlear implant, there is evidence of speedy learning of first words (Nott, Cowan, Brown, & Wigglesworth, 2003; Spencer, 2004; Tomblin, Barker, Spencer, Zhang, & Gantz, 2003) whatever the cause of deafness (Nikolopoulos, Archbold, & O’Donoghue, 2006). There is continuing debate concerning the best approach to facilitating the early language development of deaf children, and difficulty in drawing conclusions from studies that are usually cross-sectional and underpowered. Nicholas and Geers (2003) conducted one of the better observational studies of parent-child interaction and conclude “There is clearly more than one path to successful language development in severe to profoundly deaf children” (p. 435).

Following the widespread introduction of NHSP, along with early support and intervention, evidence suggests that, on average, language outcomes for children without other impairments are within the low normal range, and correlated with the children’s non-verbal cognitive level. Yoshinaga-Itano, Sedey, Coulter, and Mehler (1998) compared 72 deaf and moderately hearing impaired children who had been identified between birth and 6 months, with 78 children identified after the age of 6 months. The early identified children had better receptive and expressive language skills by 36 months of age than later identified children (with a large effect size). As the research has expanded, the results suggest that children (without cognitive impairment) overall have an 80% probability of having language development in the normal range by 5 years (Yoshinaga-Itano, Coulter, & Thomson, 2001). What seems to matter in such studies is age of identification and early intervention, rather than socioeconomic status, the particular method of communication or degree of hearing loss (Moeller, 2000; Yoshinaga-Itano, 2003).

What about fluctuating hearing loss? A detailed prospective study from New Zealand (Chalmers, Stewart, Silva, & Mulvena, 1989) was widely accepted as confirmation of parents’ and professionals’ concerns about the consequences of chronic fluctuating conductive hearing loss, as it found reduced verbal comprehension and expression scores, and raised levels of behavior problems, in comparison with controls. However, recent systematic review of randomized clinical trials suggests none to very small negative associations of otitis media with children’s later speech and language development (Roberts, Rosenfeld, & Zeisel, 2004). Undoubtedly, there are some children with recurrent infections and hearing loss for whom language outcomes are not good, such as children in low-quality daycare (Vernon-Feagans, Hurley, & Yont, 2002) but it seems that socioeconomic indicators are predictive both of language outcome and of duration of middle ear infections (Feldman, Dollaghan, Campbell et al., 2003). Therefore, the evidence suggests that fluctuating levels of hearing loss are not in themselves predictive of poor language and other functions in the longer term.

Recent reviews (Lewis, 2003; Pérez-Pereira & Conti-Ramsden, 1999) concluded that blind children are not delayed in acquiring first words in comparison with sighted children. However, much of the evidence is from case studies (Mulford, 1988) and more representative group studies suggest some delay (McConachie & Moore, 1994). Differences in the content of the early vocabularies of blind and sighted children can be readily understood; for example, blind children’s first words include actions and tactile experience (e.g., bath, swing, poo; McConachie & Moore, 1994). Many blind children appear to learn language as “chunks” (Andersen, Dunlea, & Kekelis, 1984), which may lead to better apparent expressive language skills than their assessed level of comprehension in the first 3 years (McConachie, 1990). Although they may take atypical routes in language learning, for blind children “Language seems to have an important compensatory function, allowing the children access to the external world and social information.
that they could not obtain by other means” (Pérez-Pereira & Conti-Ramsden, 1999, p. 8).

**Emotional Development**

It is clear that sensory impairment is no barrier to the formation of attachment by infants to their parents. At the time expected in sighted babies, blind babies are likely to smile when they hear their parent’s voice (Fraiberg, 1977). Once they start to reach with their hands, they explore faces and discriminate between parent and a stranger. Protest when the parent leaves takes somewhat longer in blind babies than in sighted babies, and this may be related to delay in understanding object permanence, as blind babies cannot keep track of people easily (Tröster & Brambring, 1992).

Despite the primacy of the visual channel in the establishment of attachment (Stern, 1985), there are aspects of deaf babies’ experience that might have been expected to affect attachment. Before the introduction of NHSP, most hearing mothers would not have been aware of their infant’s hearing problem until later in the first year of life, and so would not have made adjustments in terms of touch, body postures and facial expression during interaction. However, experimental studies using the Strange Situation paradigm (Ainsworth, 1973) have not found a difference in security of attachment (Lederberg & Mobley, 1990).

How do children acquire an understanding of the perceptions of others, a key skill in emotional and social development? For deaf and for blind children, research suggests that this understanding is delayed. However, some evidence is questionable. To assess understanding of false belief in blind children, McAlpine and Moore (1995) used a hamburger box containing a sock, and Minter, Hobson, and Bishop (1998) used a warm teapot filled with sand. As Pérez-Pereira and Conti-Ramsden (2005) pointed out, these materials are inappropriately confusing; children will have been discouraged from touching a teapot (if the family even has one) and the box will not smell of hamburger. When verbal tasks involving false belief are used (Peterson, Peterson, & Webb, 2000), children are able to succeed, even though at a later age than is usual for sighted children. Given blind children’s greater cognitive challenge in following key changes in the environment, and their need for conversational language skills in order to understand how events are experienced by others, some delay seems inevitable.

The finding of delay in development of theory of mind in deaf children has been widely replicated (Peterson & Siegal, 2000). Children of parents who are fluent signers, and deaf children with moderate to severe loss who are successfully using spoken language, show less delay (Courtin & Melot, 2005; Jackson, 2001), indicating the importance of early effective communication. One factor that facilitates development of theory of mind is the extent to which mothers include talk about mental states in play with their deaf child (Moeller & Schick, 2006). Theory of mind understanding can be expected by adolescence, as shown by Rhys-Jones and Ellis (2000) in a study of the spontaneous use of mental state expressions in telling stories from pictures. These deaf adolescents also showed no difference from a hearing comparison group on a social judgment test. Nevertheless, subtle differences may persist, such as difficulties in taking account of another person’s perspective in negotiations (Terwogt & Rieffe, 2004).

**Play**

The development of symbolic play skills is closely related to the development of language. Spencer and Meadow-Orleans (1996) have shown appropriate play with toys such as a toolbox, dolls and a tea-set by deaf and hearing children at 18 months of age, although some deaf children with smaller vocabularies were not yet substituting one object for another. For blind children, understanding of objects and development of symbolic play is complicated. In the absence of vision, a doll is an irregularly shaped piece of hard plastic with strangely textured string at one end – not a “baby.” Therefore, the repeated report (Tröster & Brambring, 1994) and observation (Hughes, Dote-Kwan, & Dolendo, 1998) that blind children have limitations in symbolic play requires careful unpicking.

In some circumstances, such as having a helpful play partner, blind children do play symbolically, as was found for twin girls (one sighted, one blind) studied by Pérez-Pereira and Castro (1992). Lewis, Norgate, Collis, and Reynolds (2000) found no difference between blind and sighted children 2–7 years old on the Test of Pretend Play, except for fewer object substitutions made by the blind children. Other blind children prefer talking play, acting out pretend dialogues between themselves and others (Lewis & Collis, 2005).

Observations of blind children in nurseries suggest that they often play alone or rely on adults (Preisler, 1997; Skellenger, Rosenblum, & Jager, 1997). They have particular difficulty with outdoor play settings, where it is even more difficult to establish where other children are, and the boundaries of the space. McGaha and Farran (2001) found that blind children played more in parallel outdoors, and their initiations to other children in an inclusive preschool were less successful than indoors, in terms of number of conversational turns. Therefore, blind children clearly need skilfully planned support in order to develop successful interactions with other children in group settings at an early age (Webster & Roe, 1998).

For deaf children, successful play with others is dependent on level of communication skills. Observing social play in preschool settings, Lederberg, Ryan, and Robbins (1986) found that deaf children tended to swap play materials with hearing children but were more likely to use a variety of communication functions with other deaf children. The children with better communication skills were able to play successfully in groups, to interact with teachers and to make and receive more communicative initiations. In order to succeed in inclusive settings, deaf children may need to have superior social skills (Marschark, 1993); for example, to overcome hearing children’s lack of awareness that they have to attract the deaf child’s attention before speaking. Martin and Bat-Chava (2003) have described the parent-reported coping strategies of 35 children aged 5–11 years in inclusive education settings.
The children had either a cochlear implant or hearing aids and mostly used speech in communicating. Encouragingly, about half of the children were described as confident in socializing with hearing children, and only five children were rated as having poor relationships with others (not related to type of aid).

“Autistic Features” in Blind Children
Association between sensory impairment and diagnosis of mental health disorders, including autism, is discussed below (see p. 963). However, it is appropriate to consider at this point “autistic-like features” in the behavior of blind children, such as frequent verbal imitations and formulaic speech, reversed use of personal pronouns, difficulties with symbolic play, and repetitive behaviors such as eye-poking and rocking (Lewis, 2003; Pérez-Pereira & Conti-Ramsden, 2005; Tröster, Brambring, & Beelmann, 1991a; Wing & Wing, 1971).

Many of these behaviors have an understandable function. For example, repeated head turning and rocking can give proprioceptive feedback to the blind child. Some behaviors seem to occur more when the child is bored (Tröster, Brambring, & Beelmann, 1991a) and they decrease between the ages of 3 and 6 years (Tröster, Brambring, & Beelman, 1991b). Formulaic speech seems to be useful to blind children, repeating whole phrases in order to explore how they apply, given that they have fewer other cues (Pérez-Pereira & Conti-Ramsden, 2005). Children may use repeated questions to keep in contact with others, and adults themselves use language more repetitively when talking with blind children (Kitzinger, 1984; Pérez-Pereira & Conti-Ramsden, 1999). The reported errors in the use of personal pronouns (Dunlea, 1989) may also arise in part from blind children’s tendency to learn language in chunks. Finally, we have already examined the problems in research assumptions about blind children’s symbolic play and theory of mind. Therefore, there is a persuasive argument to be made that “autistic-like” features in the early development of blind children without other impairments show no more than a surface similarity to autism.

Ability and Achievement
There is considerable concern that deaf children have poor academic achievements: is this related to ability or to other factors? The longitudinal study of Gregory, Bishop, and Sheldon (1995) found that 46% of young deaf adults had left school with no examination qualifications. Powers (1998) documented that only 18% of deaf children obtained the higher grades in GCSE (UK school leaving exams at 16 years) compared to 45% of hearing children. A good start with communication seems to be key to later achievement (Preisser, 1999).

Long-term follow-up of 30 children with cochlear implants suggests a significantly better picture for young people’s studying and employment than previously (Beadle, McKinley, Nikolopoulos et al., 2005). The results of recent studies conducted on early identified deaf children using hearing aids and speech would point to the same possible conclusion (Yoshinaga-Itano, 2003) but longitudinal follow-up will give better indications of what deaf children in general can achieve with good educational support, and appropriate access to public examinations.

Standardized assessment of the ability of children with sensory impairments poses many difficulties in administration and interpretation of results. The limitations of assessing deaf children’s ability with only one scale of an intelligence test, such as the Wechsler Intelligence Scale for Children (WISC), are considerable given the verbal component required to understand the instructions. Tests developed specifically for deaf children include the Snijders–Oomen Non-verbal Intelligence Scale (SON-R) for ages 2–17 years (Snijders, Tellegen, & Laros, 1989; Tellegen, Winkel, Wijnberg-Williams, & Laros, 1996). The SON-R is not simply a non-verbal test as it includes abstract and concrete reasoning. The Leiter International Performance Scale–Revised (Roid & Miller, 1997) does not have deaf norms, but is presented without language and used frequently in research.

There are few instruments developed specifically to assess ability in blind children, and their norms tend to be older than would be considered valid in the assessment of sighted children. The Reynell–Zinkin Developmental Scales for Young Visually Handicapped Children (Reynell, 1979) cover social adaptation, sensorimotor understanding, exploration of the environment, verbal comprehension, expressive language structure and vocabulary, with norms for blind, severely visually impaired and sighted children aged up to 3 years. For older children, the Intelligence Test for Visually Impaired Children (Dekker, 1993) has four main factors: orientation, reasoning, spatial ability and verbal ability. Otherwise, assessors usually rely on a verbal scale of measures such as the WISC, although this may be of more use in understanding a profile of skills and difficulties rather than deducing absolute levels of ability. Some studies have suggested that blind children may be less good at tasks that involve making comparisons or relating different pieces of information, while having better than expected short-term memory (Lewis, 2003).

Mediating Variables in the Child’s Environment
Children’s developmental course is affected by their relationships, environment and experiences. In this section, we consider some of the mediating variables that affect outcome, with particular emphasis on parenting. Obviously, children’s educational environment, including the quality and frequency of support teaching, is important, but beyond the scope of this chapter.

Early Parenting
How do parents adapt to their child’s sensory impairment? Many studies have charted the impact of a child’s impairment on parents’ emotions and on levels of stress in the family (Jackson & Turnbull, 2004; Singer, 2006; Tröster, 2001), and how parents cope has been shown to be important for child outcomes (Kurtzer-White & Luterman, 2003). Parents of blind children have usually learned of their baby’s impairment early,
but with the advent of NHSP, concerns have been raised about the impact on parents of being told early that their child is deaf. Evidence so far suggests that, with appropriate intervention, mothers’ stress levels on average are low (Pipp-Siegel, Sedey, & Yoshinaga-Itano, 2002; Yoshinaga-Itano, 2001).

Sighted parents are very likely to have no prior knowledge of blindness, and have to become particularly adept at “reading” the cues; the infant becomes still when listening and leans toward an object (rather than reaching). Parents need to adapt their communication habits; for example, giving emotional feedback through vocalizing when smiling, and by mirroring the infant’s movements (Fraiberg, 1977; Preisler, 1991). After the first 6 months, interest in objects means that sighted infants spend much less time in face-to-face interaction with their parents. The challenge for parents of blind infants is to judge their child’s focus of attention (Fraiberg, 1977; Preisler, 2001). Some research with sighted parents of blind children suggests that they may use language in less than optimal ways, giving children directions, asking what they want (when the children have few words) and labeling rather than talking about objects and experiences (Andersen, Dunlea, & Kekelis, 1993; Moore & McConachie, 1994; Preisler, 1997). A style of commenting on what the child does, involving objects in rhymes and routines, providing descriptions and joining with the emotional content of the child’s behavior seems to facilitate development (Dote-Kwan, Hughes & Taylor, 1997; Norgate, Collis, & Lewis, 1998; Pérez-Pereira & Conti-Ramsden, 1999; Preisler, 1997).

Early successful interaction is vital for deaf infants and their parents. When establishing joint attention to an object, deaf parents seem well attuned and tend to wait until the infant has looked at an object of interest, and then to them, before signing its name or a comment about the object. Hearing parents who are learning signing may make more signing attempts than deaf parents do, but either these are not seen by the child or the child’s focus of attention may be interrupted by the parent (Lewis, 2003; Spencer, 2000). Luterman, Kurtzer-White, and Seewald (1999) refer to the impact of deafness on these early natural processes of interaction as causing “the system to crash” (p. 107) and cite the child’s inability to hear and respond to parents’ signals as a demotivating factor. Nevertheless, many hearing parents do adapt sensitively to their child’s needs, and this process will be aided by early identification of the infant’s impairment. The degree of emotional connectedness of mothers has been shown to be a significant predictor of deaf children’s early language gains (Moeller, 2000), even more so than for hearing children (Pressman, Pipp-Siegel, Yoshinaga-Itano, & Deas, 1999). At an early stage in language development, it may be appropriate for parents to be quite controlling in order to encourage communication from their child; but it is then important for parents not to continue with a “teaching” style but instead to have the sensitivity to hang back from asking questions and requesting clarification, so that children can take the initiative in conversation (Lewis, 2003; Luterman, Kurtzer-White, & Seewald, 1999; Power, Wood, Wood & MacDougall, 1990). In a detailed longitudinal study of 22 preschool children with cochlear implants, Preisler, Tvingstedt, and Ahlström (2002) found no clear relationship between their communicative, social and emotional development and cause of deafness, but did show the importance of a child-centered communication style by parents and teachers.

There is considerable emphasis on problematic parenting in the older literature on young deaf children. For example, in an experimental study of problem-solving with 5-year-old children (Jamieson & Pedersen, 1993), it was notable that deaf children of deaf parents (and hearing children of hearing parents) succeeded in doing the puzzle alone after a joint attempt. Hearing parents tended to intervene even when their deaf child was succeeding, and the children requested help more often, as if they had learned to rely on others. Given the challenges to be faced by children with sensory impairments in becoming independent, parents’ style in building up their self-reliance is of great importance. Some studies (Gregory, 1976; Lederberg, 1993) have also suggested that parents respond quickly to children’s demands for attention because it may be difficult to explain the need to wait; children may then not learn how to take turns in social situations. For similar reasons of difficulties in communication, parents may be more ready to resort to physical punishment (Knutson, Johnson, & Sullivan, 2004; Schlesinger & Meadow, 1972). Thus, hearing parents of deaf children may need wide-ranging support in facilitating their child’s early development.

**Support and Training for Parents**

As soon as hearing loss is identified, parents need information and support to help them make informed choices about communication options, and this requires appropriately skilled and knowledgeable staff within effective early intervention programs. The Nebraska Diagnostic Early Intervention Program and the Colorado Home Intervention Program have had the most extensive evaluations (Moeller, 2000; Yoshinaga-Itano, 2003). Research has shown the importance of family-focused services in harnessing parents’ full involvement in early intervention programs, with level of involvement a strong predictor of outcomes for children at age 5 years (Moeller, 2000). Similarly for blind children, early programs help parents to stimulate the child’s capacity for vision, as well as to develop a mutually rewarding relationship. There is generally a lack of objective evaluation, although one program (Sonksen & Stiff, 1991) has demonstrated effectiveness through a partially randomized controlled trial (Sonksen, Petrie, & Drew, 1991).

The UK government has published booklets for parents on visual impairment, on deafness and on multisensory impairment (Early Support, 2004). These are accompanied by Developmental Journals (2006), which allow parents and professionals to track developmental progress from birth to about 3 years of age, accompanied by Ideas and Activity suggestions, including sections on how to help the child who has “got stuck” in his or her development. There are many other website resources for both parents and professionals containing a wide range of materials (e.g., www.ed.arizona.
Socioemotional Interventions for Children

For both blind and deaf children, social interaction in school poses challenges. “Co-operative learning” is one approach to supporting social development that has been evaluated with both groups. Teachers are trained to set up learning activities in such a way that completion is impossible unless everyone participates. Co-operative learning strategies have been shown to promote self-esteem, socialization skills and positive interactions amongst children, including visually impaired 4-year-olds (D’Allura, 2002) and deaf 8-year-olds (Johnson & Johnson, 1986) with their peers.

The PATHS (Promoting Alternative Thinking Strategies) Curriculum for deaf children (Greenberg, 2000; Greenberg & Kusché, 1998) is built on a model of social competence that emphasizes, from a foundation of good communication, the need for skills such as anticipation, reflection and imagination, as well as tolerance for ambiguity and for frustration. Thus, the program teaches children how to develop and maintain self-control, increase awareness of their feelings and ability to communicate about feelings, and improve problem-solving skills. Controlled evaluation of the program as implemented by teachers with 6- to 12-year-olds has indicated significant and sustained improvements in socioemotional adjustment, frustration tolerance and distractibility, with additional improvement in reading comprehension (Greenberg & Kusché, 1998).

For blind children, the literature has a wealth of single case studies and small-scale descriptive interventions, which lack information about generalizability and maintenance of gains, but contain useful clinical suggestions. For example, Jindal-Snape (2005) described a behavioral program designed to improve social interaction of a blind child through self-evaluation of his facial orientation to others, and through feedback by peers. Peavey and Leff (2002) described an evaluation of “friendship groups” in school, designed to increase trust and open communication. Visually impaired students were able to talk about their difficulties and sighted students learned how to include the visually impaired student.

Deaf Culture

Within a predominantly hearing world, deafness is seen most commonly as an impairment or disability; in other words, within a “medical model.” A more general “social model” of disability, however, construes disability “as a consequence of society’s failure to make proper provisions for disabled people” (Gregory, 2002, p. 2). Members of the deaf community, who use a sign language as their preferred language, regard themselves as a linguistic minority group with a rich worldwide culture (Ladd, 2002), disabled only by a hearing-oriented society. The format “Deaf” rather than “deaf” is used in recognition of this status. Mental health professionals need to be aware of these differing models and sensitive to both the culture and the belief frameworks that exist around them and the issues raised as a consequence. For some young people there is a tension around their identity as Deaf or deaf (Skelton & Valentine, 2003).

Adjustment and Vulnerability

Having considered the effects of impairment of hearing or vision upon children’s development, and some mediating factors for development, we turn now to outcomes. For adolescents and young adults with sensory impairments do we expect to see a resolution of the different routes they may have taken through development, or is their healthy progress still at risk?

The striking impression gained from studies of adolescents is of a generally good outcome. The one available population longitudinal study painted a picture of young adults with visual impairment having few friends, with less than half employed (Freeman, Goetz, Richards, & Groenwald, 1991). However, more recent cross-sectional surveys give some indication of how well blind children are able to achieve with early intervention to families, good support in inclusive school settings and legislation to combat disability discrimination. Large-scale surveys in the USA, Finland and the Netherlands have shown no significant differences from controls in self-esteem, locus of control, happiness, physical and psychological symptoms, relationships with parents and siblings, and self-reported empathy for others (Griffin-Shirley & Nes, 2005; Huurre & Aro, 1998; Kef, 2002). Visually impaired adolescents are less likely than controls to describe themselves as having many friends (Huurre & Aro, 1998; RNIB, 2001), but the smaller social networks of visually impaired adolescents seem to provide quality support (Kef, Hox, & Habekothé, 2000; Rosenblum, 2000) and act as a helpful buffer against feeling an outsider in school. Young people who are blind still report problems with access to some leisure activities, independent travel and attitudes of others (RNIB, 2001).

For deaf adolescents, the issue of school placement may have more of a role in their social experience, maturity and self-esteem. For deaf students who sign and are at a specialist college, self-esteem is generally high (Crowe, 2003) and even higher for those who have at least one deaf parent who acts as a role model (Woolfe & Smith, 2001). However, the picture from older studies and those with mixed samples of children attending a variety of schools is more complex. Kluwin, Stinson, and Colarossi (2002) reviewed 33 studies published since 1980 and concluded that deaf students were generally less socially mature than hearing students, interacted with other deaf classmates more than with hearing ones and were only somewhat accepted by their hearing classmates. The effect of mainstream educational placement depended on the characteristics of the individual and on the support offered (Van Gurp, 2001). If children do not have adequate support to participate in the classroom then both academic achievement and social integration will suffer (Stinson & Antia, 1999). Several studies suggest that adolescents in mainstream settings have problems with loneliness, rejection and social isolation (Nunes, Pretzlik, & Olsson, 2001; Obrzut, Maddock, & Lee, 1999).
CHAPTER 59

However, a recent Australian study of adolescents educated in fully inclusive settings found no difference between hearing and hearing-impaired students in self-reported loneliness and social participation (Punch & Hyde, 2005). Qualitative analysis revealed some difficulties such as self-consciousness and feelings of awkwardness, not related to level of impairment. New technology such as text-messaging has been shown to have benefits in terms of supporting social independence of deaf adolescents (Akamatsu, Mayer, & Farrelly, 2006).

There are accumulating indications that very early intervention may have positive effects in terms of deaf children’s social outcomes. Five-year-olds identified by newborn screening have significantly higher levels of personal social skill development than later-identified children (Yoshinaga-Itano, 2003). Furthermore, children (mean age 10) using hearing aids or cochlear implants for several years have been found to have, on average, age-appropriate levels of communication and socialization skills on the Vineland Adaptive Behavior Scales (Bat-Chava, Martin & Kosciw, 2005). Such findings underline the importance of communication competence for positive adaptation.

There are perhaps unexpected findings in relation to the severity of impairment. It has long been suggested, counter-intuitively, that moderate hearing impairment is more problematic than deafness for psychosocial functioning (Myklebust, 1960). Recently, it has been shown that late identification has greater adverse implications for the personal social skills of children with mild hearing loss than for those with moderate to profound loss (Yoshinaga-Itano, 2003) and this may relate to the greater degrees of stress brought about by parent–child dysfunctional interactions found for parents of children with less severe degrees of loss (Pipp-Siegel, Sedeň, & Yoshinaga-Itano, 2002). Kurtzer-White and Luterman (2003) suggested one reason is that children with less severe loss respond inconsistently to sound, and have an ambiguous prognosis, thus increasing parents’ stress. A similar discussion can be found in literature on blind children. There is some evidence that for mothers of young children with severe visual impairment (i.e., with some form perception) stress is greater (Tröster, 2001), perhaps because they underestimate their children’s specific problems. Kef (2002) noted that adolescents with severe visual impairment had less positive adjustment than those who were blind. One specific educational issue was not being able to read print, yet not using Braille. Thus, problems may be greater for those who have more expectations put upon them to “fit in” or who try to “pass” as non-disabled (Freeman, Goetz, Richards et al., 1991).

Mental Health Disorders

For some children with sensory impairments, behavioral and emotional problems go beyond loneliness and frustration. However, a major difficulty in understanding the nature, degree and prevalence of mental health disorders is to disentangle what may arise from associated neurological damage rather than be attributable to sensory impairment (Carvill, 2001). Furthermore, there is evidence that young people with sensory impairments are at risk of emotional, physical and sexual abuse (Freeman, Goetz, Richards et al., 1991; Kvam, 2004; Sullivan, Brookhouser, & Scanlan, 2000). However, as the evidence largely comes from adults looking back, and special educational settings were noted to increase risk, protection may now be much greater.

Prevalence of Emotional and Behavioral Problems

Since 1994, there have been five studies giving estimates of the rate of mental health problems in deaf children (Hindley, Hill, McGuigan, & Kitsos, 1994; Sinkkonen, 1994, cited in Hindley, 1997; Van Eldik, Treffers, Veerman, & Verbult, 2004; Van Gent, 2003; Vostanis, Hayes, Du Feu, & Warren, 1997). Two included interviews with young people themselves, and elicited information about emotional disorders that had hitherto been underestimated. Hindley, Hill, McGuigan et al. (1994) used scales developed specifically for screening mental health problems in deaf children, the Parents’ Checklist (PCL) and Teachers’ Checklist, followed by interviews with a proportion of parents and children aged 11–16 years. The reported estimated prevalence of disorder was 43%. However, the study was not population-based, and Vostanis, Hayes, Du Feu et al. (1997) found that the PCL overestimated problems.

Studies using the Achenbach Child Behaviour Checklist (CBCL) have suggested that 27–41% of deaf children have problems in the borderline or clinical range. The highest estimate was by Van Eldik, Treffers, Veerman et al. (2004), who compared the rates of total problems in children aged 4–18 years with Dutch CBCL norms (17%); however, as three-quarters of the children attended one regional educational institute, and total problems were related to parents’ report of poor communication with the family, the results may be subject to some confounding. Only one questionnaire study had a contemporary control (Sinkkonen, 1994); in contrast to the findings of the other four studies, teacher report of behavior problems showed no significant difference between deaf children and young people aged 6–21 years (19%) and controls (16%), although low communication ability was associated with raised scores on hyperactivity. The pattern of problems in deaf children that might present to a mental health service is similar to that in hearing children (Hindley, 2000), but some of the medical causes associated with deafness (such as extreme prematurity) may also be associated with raised rates of autism spectrum disorder and attention deficit/hyperactivity disorder (ADHD; Hindley, 2005). A practitioner review by Roberts and Hindley (1999) gives useful case examples of specific mental health disorders, and the management strategies adopted.

Although most studies have demonstrated a higher rate of emotional and behavioral problems in deaf children and adolescents than in the hearing population, there remains some uncertainty about how much higher once factors such as additional impairments and validity of measures are taken into account. The evidence suggests that, where adequate
language development has been achieved, a high rate of problems may not be inevitable. In Wallis, Musselman, and MacKay’s (2004) longitudinal study of deaf adolescents’ mental health (using an adaptation of the Achenbach Youth Self-Report), the three groupings consisted of those who always used oral communication, those who had used sign from early childhood and a “sign mismatch” group who had learned to sign later or whose parent had not signed to them in early childhood. The oral group had the most positive self-report (only 20% in the borderline or clinical range), with the sign mismatch group the most problematic (63%). The total population study in Finland by Sinkkonen (1994) reported that all the mothers and almost all fathers had sign language skills. Thus, effective early communication, and community support, may underpin that study’s finding of a lack of difference in rate of behavioral problems. In this time of rapid change, only close follow-up of children given good support after NHSP will show what degree of emotional and behavioral problems are really a consequence of deafness itself.

There appear to be no recent population-based studies in blind children or adolescents. Clinic-based studies suggest that some children are particularly vulnerable. Around one-third of 102 blind children from a clinic population, who had had apparently typical development in the first 16 months of life, showed developmental setback (plateauing or regression) in their second or third year (Cass, Sonksen, & McConachie, 1994). Only one child with severe visual impairment showed a similar developmental pattern. In addition to probable neurological involvement, 60% of the children with setback had adverse social or medical histories. In some of the children, the developmental pattern was of increasingly disordered social communication and they were likely to meet criteria for a diagnosis of autism.

The only study to suggest an overall rate of disorders in blind and severely visually impaired preschool children without other disabilities is by Ophir-Cohen, Ashkenazy, Cohen, and Tirosh (2005). They considered 74 children who attended a specialist unit between 1975 and 1993, and recorded a disorder in 21%, defined when problems were still evident after 6 months in the early intervention program. How generalizable this finding might be is unclear as the authors comment that the children’s difficulties in insecurity, withdrawal, attachment problems, inattentiveness, impulsive or hyperactive oppositional-defiant behavior, and temper tantrums could not easily be classified within DSM-IV (and a validated alternative such as Zero-to-Three, 1994, was not used). Sleep problems are common in blind children, at 40–50% (Stores & Ramchandani, 1999). Nevertheless, given the picture from surveys of adaptation in adolescents, it seems possible that the developmental and social difficulties encountered early on by blind children without neurological impairment may not progress to serious emotional and behavioral disorders at school age.

**Autism**

Population-based estimates for autism in blind and in deaf children are lacking. In a large series of hearing impaired children attending audiology clinics, Juré, Rapin, and Tuchman (1991) estimated a prevalence of autism of 5.3% and noted that, with co-occurrence, both late diagnosis and inappropriate educational management can ensue. For blind children there are no comparable large-scale studies, but the co-occurrence of autism is suggested to be much higher (Pring, 2005). Hobson, Lee, and Brown (1999) carefully matched sighted children with autism to nine blind children with autism, and found some differences in the patterning of clinical features. The blind children showed more abnormality in the use of objects and in motor stereotopies, but less abnormality in the degree of engagement with others and in pretend play. Hobson (2005) speculated that long-term follow-up of blind children with autism may indicate that they have a less severe primary social incapacity than sighted children with autism, and therefore may have a better overall outcome.

**Issues in Mental Health Assessment**

When assessing a child who has severe hearing or visual impairment, a number of factors will require consideration. The child will need to take time to get used to new people and the room; a blind child will be likely to ask questions about what is happening and why, and want to touch any assessment toys. For deaf children, effective communication is vital. Clinicians cannot expect to rely on writing, as deaf children are likely to have significant reading comprehension difficulties even if their word identification is good (Wauters, van Bon, & Tellings, 2006). Where the child’s preference is for sign, clinicians with no or limited signing skills will need to work with an interpreter, which introduces several new dimensions to the assessment. First, families like to have advance notice of who is interpreting as they may know the person already. Teachers and parents are not appropriate as interpreters, both because they may inhibit what the child wants to communicate, but also because they are not trained as interpreters and may miss out important information. It is important to explain that the interpreter will abide by rules of confidentiality. Second, there must be a rule in the session that only one person speaks at once, and it is important to look at the child rather than at the interpreter. Sufficient time must be allowed, including time for the interpreter to take breaks. Third, it is unlikely that the interpreter will have had any training in child mental health or in language development. Their training has been in adult use of sign, and they may not understand child development of sign and how children express themselves. It is vital to brief the interpreter about the purpose and techniques of the session; interpreters are trained to enhance meaning, but the clinician will want at times to know if communications are unusual or disordered. It is important to distinguish grammar differences for those who use sign language from language disorder, and from thought disorder (Hindley, 2005; Roberts & Hindley, 1999).

In addition to previously mentioned socio-emotional measures validated for use with deaf children (e.g., PCL; Hindley), clinicians may use the Meadow–Kendall Social and Emotional Adjustment Inventory (Meadow, 1983) with 59 items completed.
CHAPTER 59

by school staff. Sullivan, Brookhouser, & Scanlan (2000) provide a protocol for interviewing deaf children about abuse (pp. 435–443) and include a recommendation that deaf children respond best to direct questions rather than free recall.

For blind children, fewer adaptations are required for mental health assessment. It will be important for the clinician to translate into words information that might usually be conveyed non-verbally. It will also be important not to overinterpret elements of the child’s behavior such as posture, facial orientation or expression, as well as “autistic-like” behaviors. There appear to be no recent adaptations of mental health assessment tools for blind children; as for deaf children, many research studies utilize the Achenbach CBCL and the Vineland Adaptive Behavior Scales. For sleep disorders, it is certainly the case that difficulties in light perception may lead to alteration of sleep–wake cycles. However, problems in parental inconsistency, overprotectiveness, not setting limits and not establishing routines are more of a determinant, and require assessment through interview and parent diaries (Stores & Ramchandani, 1999).

Interventions and Services for Children with Mental Health Disorders

This chapter has indicated that deaf children have been at particular risk of developing mental health problems, yet they experience significant delays in access to services (NDCS, 2005). The UK National Deaf Children’s Society recommended, in addition to early programs of structured intervention for families of deaf children: local intervention programs in schools to promote positive mental health, and build self-confidence and problem-solving skills among deaf children; school anti-bullying policies and practice; a specialist child protection service; and primary mental health care workers specifically for deaf children and young people. A national specialist service in London uses outreach with other child and adolescent mental health services, and also video-link to consult with some young people who use sign. The above recommendations and developments build on the Department of Health best practice guidance for Mental Health and Deafness published in 2005, and the Deaf Mental Health Charter produced by the Mental Health Foundation and the National Society for Mental Health and Deafness (DoH, 2005; Sign, 2005). Similar strategies and standards are being pursued by generic and specialist mental health services for deaf children and young people in other developed countries (e.g., from the Boys Town National Research Hospital, and the Laurent Clerc National Deaf Education Center, Gallaudet University, USA; from the European Society for Mental Health and Deafness).

Conclusions

The development of children with sensory impairments does not allow easy generalizations. This chapter focuses on children apparently without other neurological disorder, but even their course of development needs to be viewed in the context of the range of severity of impairment, the quality and timing (or lack) of early intervention and support to parents, and changes in technological aids, educational practice and legislation. What seems clear is the central importance of language in enabling all other areas of cognitive, emotional and social development in both deaf and blind children. Given a good start with communication and social interaction, we have many reasons to be optimistic that mental health outcomes will be better in future, and that the general picture painted by past research studies, particularly for deaf children, has been overstated. The challenge for mental health professionals is to unpick for an individual referred child who has a sensory impairment how the various risk and protective factors have interacted, and to adapt their practice to the culture and communication needs of that child and their family. Because this is what we do for any referred child, the challenge is not insurmountable. It is important to ensure that all children, including those who have sensory impairments, have access to mental health services according to need.

CHAPTER 59

Approaches to Treatment
Community-Based Interventions and Services
Christina J. Groark and Robert B. McCall

The purpose of this chapter is to summarize the process by which one can conceive, design, implement, monitor, evaluate and sustain empirically based community-operated interventions and services. The focus is on the process, not the content, of such interventions and services. As such, the discussion accepts (and does not cover) the existing literature on the problem or target behaviors as well as on approaches to preventing or treating those behaviors as the starting point of the process.

There is relatively little scholarly analysis and even less empirical validation of this process per se (see Fixsen, Naoom, Blase et al., 2005). Consequently, this chapter relies to a greater extent than is typical on the experience of the authors together with those of others and what scholarly work does exist.

Scope and Definition

The scope of this chapter can be further specified by considering the working definitions of certain key concepts.

Community-based
Community-based interventions and services are those that are implemented and operated by service professionals in the community. Often, but not always, such services are part of a demonstration and evaluation project investigating whether the intervention or service can be created, organized, implemented and produce benefits in participants. If successful, the same type of professionals will provide the service in the community on a routine basis. In contrast, innovative or experimental services conducted in a specialized environment (e.g., laboratory, school) by specialized practitioners (e.g., academic educators or social workers) do not fall in the chapter’s purview. Thus, community-based services represent the most ecologically valid version of the service and the last step in the basic–applied research continuum.

Interventions and Services
The services to be considered consist of organized supports and activities designed to promote the health, education and welfare of children, youth and families. They focus on target behaviors that tend to be public rather than strictly intrapsychic. As such, they consist of problem behaviors that come to public attention and that require public resources to prevent or treat (e.g., abuse and neglect; drug and alcohol problems; antisocial behavior and delinquency; poverty, unemployment and public assistance; poor parenting; and mental health prevention, detection, diagnosis and referral). While participants may receive services individually or in groups, the services of concern do not include traditional private or group psychotherapy (APA Presidential Task Force on Evidence-Based Practice, 2006; Weisz, Jensen-Doss, & Hawley, 2006). Instead, they are closer to services within the domains of community psychology and psychiatry, social work, public health and education.

Prevention and Treatment/Remediation

The services include both prevention and treatment/remediation, although the distinction between these categories often blurs. For example, individuals come to public attention and are referred to services because they have already displayed certain problematic behaviors or are substantially at risk of doing so; the services focus on treating/remediating the manifest behaviors, preventing additional or more extreme undesirable behaviors, and promoting more positive behavioral alternatives.

Evidence-based
Services that are evidence-based have some research supporting their potential or actual effectiveness. While some people reserve the phrase “evidence-based program” for a well-articulated service program that has been empirically shown to be effective and could be replicated, we also use the term to refer to new programs based on principles or consisting of components that have theory and evidence that support their likely effectiveness. Unfortunately, no clear standard prescribes how much or what kind of evidence is required to substantiate the claim of “evidence-based” (see p. 975) so that use of the phrase has become commonplace and less meaningful in an era in which policy-makers and practitioners value and require evidence-based practices (Groark & McCall, 2005; McCall, submitted).

Universal, Quasi-universal and Targeted Services
Strictly speaking, universal services are available to everyone. For example, public education and some form of social security
or public retirement benefits are universal in many countries. Universal programs tend to be most appropriate when everyone in society can benefit (e.g., public education, retirement benefits) or when the target group is broadly dispersed in the population (e.g., smokers, automobile drivers, obese children) or not readily identifiable and/or without clear predictive risk factors (e.g., abusive parents). They often have the advantages of reaching large numbers of people, some of whom otherwise would not be identifiable, and satisfying broad crucial social needs (e.g., education). However, only a few social needs merit the cost of very intense services (e.g., education); some are inefficient because many people are reached or served who do not need the service; and some programs benefit the educationally, financially and behaviorally advantaged members of society more than those of relative disadvantage, because such individuals are more likely to take advantage of the program and already have a head start on achieving its goals (Ceci & Papierno, 2005). Truly universal programs are not within the focus of this chapter.

Instead, we will emphasize “quasi-universal” programs, which are ones that are available to all individuals within a geographical area (e.g., neighborhood, town) or institution (e.g., an entire school, orphanage), and such programs may or may not have additional eligibility criteria, such as income level (e.g., Head Start early childhood care and education programs in the USA). These programs tend to have broad goals (e.g., improvement of family functioning, parental psychological and economic self-sufficiency; improvement of child development, school readiness, and life success), but some have more specific aims (e.g., school readiness).

Conversely, targeted programs (see chapter 61) are often restricted to participants having certain specific characteristics that may exist in relatively small percentages of the population (e.g., drug addiction, blindness, physical disabilities) and may require intense (e.g., detoxification) or extensive services (e.g., for children with severe disabilities).

Quasi-universal programs tend to be most appropriate for conditions and services in between those for truly universal and highly targeted programs; for example, when the target group is concentrated in low-income neighborhoods and when the needed service is moderately intense or extensive and clearly needs to be targeted to some extent to be cost-efficient and to benefit those most in need (e.g., Sure Start in the UK, Head Start and offered to all in low-income neighborhoods in the USA). They have the advantage of having a large percentage of participants who need the service, but they may not serve all in society who need it (e.g., low-income families who live in unserved neighborhoods).

Examples of Different Quasi-Universal Programs

We describe several examples of quasi-universal programs that illustrate some of their commonalities and differences, many of which will be discussed more fully later.

Nurse–Family Partnership (formerly Nurse Home Visitation Program)

The Nurse–Family Partnership (NFP) program (Olds, Henderson, Kitzman et al., 1999) is aimed at first time, low-income, higher risk mothers to improve pregnancy outcomes by reducing health-related adverse behaviors (e.g., smoking, alcohol consumption, drug use); improve child health and development by teaching parents to provide more responsible and competent health and behavioral care; and promote the economic self-sufficiency of families by encouraging planned pregnancies (i.e., fewer and more widely spaced) and supporting education, secure employment and linkages with other health and human services within the community. The program is being implemented in nearly half of the states of the USA and some other countries. It is quasi-universal for high-risk first-birth women located in the geographical region in which it is offered.

The program relies on nurses to visit the homes of participants, preferably during pregnancy and throughout the child’s first 2 years. The program is heavily centrally prescribed, with specific and concrete goals and activities, although some tailoring to the needs of individual families must occur. The focus on small concrete specific goals from visit to visit and throughout the program likely contributes to the ease of implementing the program and positive outcomes.

The program was evaluated in three sequential studies in three USA cities (Olds, Henderson, Kitzman et al., 1999). Pregnant women who had not previously given birth and who had at least one additional risk factor (e.g., low-income, unmarried, low education, unemployment) were randomly assigned to a treatment group (nurse home visitors, transportation to periodic health visits and home visits until the child’s second birthday) versus a variety of control conditions that included fewer or shorter services. Samples ranged from 400 to 1139 with a predominance of either White, African-American or Hispanic women in different cities. Results showed benefits to mothers and children, but these were not pervasive and tended to occur under specific experimental and non-randomized circumstances: if nurses rather than paraprofessionals did the home visiting, if home visiting lasted until the child’s second birthday and especially if the mother was at higher risk (e.g., unmarried, smoker, very low income/education). For these groups, NFP mothers were more likely to be employed and have better life skills, fewer problem behaviors, better reproductive histories, improved parenting and less abuse; their children improved in health, socioemotional, language and cognitive development as children and with reduced criminal and behavioral problems, sexual activity and substance use as teenagers. A similar but more intensive and extensive home visiting program in New Zealand produced similar (but not identical) results (Fergusson, Grant, Horwood, & Ridder, 2005, 2006).

Early Head Start

Early Head Start (EHS) is an attempt by the US government to provide health care, child care, family support and parent education to primarily low-income families. EHS is quasi-
universal in that its services are available to all low-income families with at least one child approximately from birth to 3 years of age in the geographical area in which the program is located. A small percentage of families who are not low income and others who have children with disabilities are also enrolled.

The program is a combination of a centralized set of program requirements and standards for implementation with some local flexibility to create a program that matches the needs of local participants. For example, child development services are required, but they can be provided in centers, in the homes of participants through home visiting, or in a mixture of the two.

Seventeen programs were selected from applicants to provide EHS services and to participate in a research and evaluation consortium. The total evaluation followed 3001 families who were randomly assigned to EHS or whatever other program parents chose. EHS was unusual in having local evaluation specialists at each site supervise data collection, consisting of core assessments common across the 17 sites plus additional assessments to answer specific research and evaluation questions pertinent to that site. The consortium met periodically to advise the cross-site evaluation team and participate in subsets of sites that had similar programs and similar research interests (e.g., the role of fathers).

When EHS children were 3 years old, they performed better on measures of cognition, language and socioemotional functioning than control peers, and EHS parents were more supportive of children’s emotional, cognitive and language development and more likely to be in education or job training. However, the benefits of EHS varied with non-randomized characteristics of participants and implementation. For example, benefits were greater for African-American families, families who enrolled during pregnancy versus after delivery, and families with a moderate rather than a substantial number of demographic risk factors. Further, programs with a mixed center and home visiting approach and those that more fully implemented the comprehensive performance standards had a wider range of larger benefits. Also, children who transitioned from EHS to formal early care and education programs between ages 3 and 5 had better early reading-related skills at age 5 (Administration for Children and Families, 2002; Love, Kisker, Ross et al., 2005; http://www.acf.hhs.gov/programs/OPRE/EHS/EHS_rersch/index.htm).

Comprehensive Child Development Program

The Comprehensive Child Development Program (CCDP) was a multisited demonstration project in 34 sites around the USA to provide comprehensive health, education, mental health and welfare services to low-income families with children from birth to 1 year of age at the beginning until the child reached approximately 5 years. Its purpose was to increase the financial and psychological self-sufficiency of those families and improve the children’s development. It was quasi-universal, allowing all community members to participate, but sites were targeted to low-income areas.

The program was a combination of central prescription and local innovation. Services were required to be comprehensive, because high-risk families tend to have a variety of different needs, including obtaining basic necessities (shelter, food, medical care), preparation for employment (education, training), mental health services (e.g., drug and alcohol), child care and parenting education (for further information about parent-based programs in general see chapter 64). While specific services were to be tailored to the needs of each family and thus could vary between families and sites, certain procedures, such as the frequency of contact and devising individual family plans, were specified by the federal government.

A central evaluator conducted an evaluation on 21 sites, which had randomly assigned either individuals or site locations within their area. An intent-to-treat strategy was employed. However, the government awarded separate contracts for the central evaluator and the management information system developer, and these two databases were never merged across sites so that the frequency of contact and devising individual family plans could not be related to outcomes. Results indicated that twice as many mothers in CCDP treatment sites became employed and improved their financial status as comparison mothers, but there were few other benefits for parents or children (St. Pierre, Layzer, Goodson, & Bernstein, 1997a,b). However, sites varied substantially in the nature and extent of the services they provided, families in the comparison group obtained on their own behalf almost as many services as those in the CCDP groups, families differed in their individual goals and the services they used but the intent-to-treat strategy assessed each outcome on all participants, regardless of their individual goals, nature and extent of services, or length of participation in the program (Gilliam, Ripple, Zigler, & Leiter, 2000; McCall, Ryan, & Plemons, 2003).

School Development Program

Comer’s School Development Program (SDP) seeks to improve schools, primarily in low-income neighborhoods, and student academic performance and skills by mobilizing adults to support student learning and development (Comer, 1988; Comer, Haynes, Joyner, & Ben-Avie, 1996; Joyner, Comer, & Ben-Avie, 2004). It is quasi-universal because an entire school – administrators, teachers, students, parents and local organizations – and increasingly an entire school system may be involved. SDP is operating in hundreds of schools in dozens of USA states and other countries.

The program is planned and implemented within each school or school system, rather than by some central body. The program consists of a structure and process, rather than a set of specified actions, services or directions. Three structures comprise the basic system on which the Comer process is built. The School Planning and Management Team is composed of administrators, teachers, support staff and parents. It is responsible for developing a comprehensive school plan; setting academic, social, and community relations goals; co-ordinating all school activities, including staff development programs; and monitoring the progress to identify needed changes. The Student and Staff Support Team consists of the principal and professionals in child development and mental health, such as
school counselors, social workers, psychologists and nurses. It promotes the social conditions and relationships necessary to connect all of the school’s student services; it facilitates the sharing of information and advice; and it addresses individual student needs, obtains resources outside the school and develops prevention programs. The Parent Team is composed of parents. It selects representatives to serve on the School Planning and Management Team and develops activities for the parents to support the school’s social and academic programs. Central to the process are three school operations including development of a comprehensive school plan, provision of staff development opportunities, and assessment and modification.

Evaluations conducted by SDP and independent professionals have shown that the program can improve school climate, student behavior and student achievement (e.g., Cook, Hunt, & Murphy, 1998; Haynes, 1995), but results have not been uniformly positive (Cook, Habib, Phillips et al., 2000; Neufield & LaBue, 1994). Success seems to depend on how extensively and vigorously the process is pursued and implemented. This result is concordant with research conducted years earlier (Maughan, Pickles, Rutter, & Ouston, 1990; Ouston, Maughan, & Rutter, 1991) revealing that non-experimental changes that produced better attendance and school performance in students rested heavily on the extent to which there was a clear vision of and process to guide change and a focus by all of its administrators, staff, students and parents on improving the entire school – precisely what SDP intends to guide.

**Sure Start Local Programmes**

Sure Start Local Programmes (SSLPs) is an attempt to reduce child poverty and social exclusion in the UK (the gap between rich and poor) with a quasi-universal program within certain geographical areas that are relatively disadvantaged (Rutter, 2006). It is aimed at infants or young children. Support for the program is widely available, and numerous sites have been continued, modified or created across the UK.

Programs and services were largely locally created and unspecified. The central government required five core service themes:

1. Outreach and home visiting;
2. Support for families and parents;
3. High-quality play, learning and child care;
4. Primary and community health care, including advice about child and family health; and
5. Support for children and parents with special needs.

Services within these domains were to be “evidence-based” but their nature and extent were up to local agencies. It was expected that existing services would be improved and coordinated, and that facilities for early childhood care and education would be expanded, remodeled and otherwise improved. The government’s rationale was that a minimally targeted program open to all in the area would minimize any stigma associated with using the program, and localities should have the opportunity to tailor services within the five areas to fit the needs of their local participants and existing services.

An extensive national evaluation (National Evaluation of Sure Start Team, 2005a,b) was conducted, but with at least two constraints imposed by government: first, neither families nor sites could be randomly assigned to Sure Start or a comparison condition because Sure Start was expected to be successful, and random assignment would unnecessarily deny services to certain families, and, second, that the services would not be “manufac-
tured,” which meant that no site was required to specify, and no monitoring information would be gathered on, the nature and extent of services provided. These constraints meant that there was no uniform Sure Start program, sites were extremely heterogeneous in the nature and extent of services provided, it was nearly impossible to relate any characteristics of the nature and extent of services to outcomes, and the opportunities for a comparison group were limited.

Nevertheless, the national evaluation was able to study 150 SSLP sites in which the program had been initiated for at least 3 years and 50 comparison sites that had not yet begun to implement SSLP. Extensive data were collected on participants, administrative and broad characteristics of the SSLP services, and parental report, observations and developmental assessments on a variety of family and child (9–36 months old) outcomes. The evaluation used an intent-to-treat strategy (see p. 984) in which all families eligible within an SSLP area with 9- to 36-month-old children were included in the sample regardless of the nature and extent of services received.

Given the large number of possible outcomes for parents and children, SSLP was associated with consistent benefits for very few. For example, SSLP sites operated by health agencies and other local authority agencies did better than those led by voluntary agencies. In contrast to the NFP, there were some adverse effects the more disadvantaged the family (e.g., mothers who were teenagers, single parents, unemployed parents), including slightly lower scores of children on verbal ability, social competence and more behavioral problems. Similar to EHS, there were slight benefits for families who were not so disadvantaged, including fewer behavioral problems, more social competence and less negative parenting (Belsky, Melhuish, Barnes, Leyland, & Romaniuk, 2006; National Evaluation of Sure Start Team, 2005b).

**Summary**

While not intended to be representative of quasi-universal programs, these projects varied in how specifically and concretely the program was prescribed centrally versus the amount of local flexibility allowed and in how the programs were implemented and evaluated. The remainder of this chapter focuses on these aspects of program development, implementation and evaluation.

The next section of the chapter considers various issues in bringing evidence to the creation of evidence-based programs in the community. Then, principles of collaboration are offered, because most community-based programs are or should be developed, implemented and evaluated by a collaborative team whose members are often unaccustomed to working with each other and whose values and roles may conflict.
We next consider program design, which may occur at the national, state/province or local level and be very specific and detailed or consist of broad principles or service domains. We consider how such programs may be implemented, followed by a discussion of certain issues in their monitoring and evaluation. Finally, we discuss sustainability, which includes maintaining program effectiveness year after year as well as sustaining funding.

Evidence and Evidence-Based Interventions and Services

Policy-makers and funders in many countries demand that the services they initiate or support be “evidence-based,” that is, be rooted in empirically supported principles and preferably have already been demonstrated to produce benefits for participants (for an overview of treatment evaluation see chapter 18). The simplest and presumably most expeditious and effective strategy for creating and implementing service programs is to replicate “proven programs.” Indeed, for some policy-makers, this is the only definition of an “evidence-based program.”

Requirements for Services Replication

While the rationale for service replication is straightforward, it makes certain assumptions that must be met for this strategy to be effective, and such premises are often not fulfilled (Groark & McCall, 2005; McCall, submitted; McCall, Groark, & Nelkin, 2004).

- One or more programs must have been demonstrated to have been effective. Obviously, there must be a service program that has been implemented, evaluated and found to be effective to be a candidate for replication. Such demonstrated programs exist for teenage problem behaviors including school failure, risky sexual activity, substance abuse, delinquency and violence (Weissberg & Kumpfer, 2003) and for lowering rates of abuse and improving parenting skills for high-risk mothers (Olds & Kitzman, 1993), but this is not the case for many areas needing services. For example, nearly 50 years of research on early childhood education indicates such programs are beneficial, but much less research exists on specific curricula that might be replicated.
- The service must be packaged in detail. Relatively few service programs, even demonstration programs intended to be replicated if found successful, have a “manual” describing all of the elements of the program and its implementation that practice professionals elsewhere can use to replicate the program.
- Local service providers must be willing to replicate the original service. A major tenet of good therapeutic practice is to match the treatment to the specific characteristics of the client, so it is not surprising that agencies often want to adapt a model program to fit their own specific type of clientele, local social and policy circumstances, and each individual client. Indeed, a major principle of family support programs is that each individual family specifies their strengths and needs and a program of referrals, services and supports is tailored to their individual profile. But, even for services that are comprehensively and specifically prescribed, the service program may differ substantially from one incarnation to another (Gilliam, Ripple, Zigler et al., 2000; McCall & Green, 2004), and often no research exists suggesting whether such modifications improve, harm or have no influence on program effectiveness.
- Will a replicated program also replicate the benefits of the original demonstration? Even if the program is as faithfully replicated as possible, it is not clear that it will have the same benefits for participants in its replicated incarnation as it did in its original demonstration (Green, 2001). Demonstration projects are typically implemented by professionals who are highly energized, passionate and committed to the new program and who may have substantial expertise in creating relationships with clients and motivating them to participate and persist in the service regimen. However, the practitioners who volunteer or are assigned to replicate the program may not possess the same level of motivation, commitment and interpersonal expertise. Also, the intended participants may differ from those in the original demonstration, and some services are not equally effective with all types of participants. For example, physical punishment is often discouraged in parenting improvement programs but is very common among African-American families, and research suggests that it is not as deleterious to African-American as it is to middle- and upper-class Caucasian children (Baumrind, Larzelere, & Cowan, 2002).

For these reasons, replicating proven programs may not produce replicated benefits; often the original demonstration is more effective than its replicates, which is why policy-makers and funders should evaluate replications and not assume that the program has already been shown to be effective and its replication does not need evaluation.

Nature of the Evidence

From a practical standpoint, a service program is never “proven”; rather, the evidence for its effectiveness will always be more or less “persuasive.” Further, not all research studies and demonstrations are equally persuasive; some designs and results are more compelling than others. From the perspective of a policy-maker or practitioner faced with a mounting behavioral or social problem, one picks the “best available service approach” almost regardless of the persuasiveness of evidence.

Assessing the Evidence

It would be ideal to have a simple scheme to assess the research literature on a service program, and such a scheme has been proposed (Chambless & Hollon, 1998; Mrazek & Haggerty, 1994) which literally provides a “grade” from 1 to 7 (1 is highest) for the persuasiveness of the evidence. But this particular approach seems too narrow, considers only a few types of research designs (e.g., randomized trials and replications), emphasizes internal over external validity and ignores a great deal of information (e.g., effect size, cost:benefit ratio) that
would be valuable in making policy and service program decisions (Groark & McCall, 2003; McCall & Green, 2004; McCall, Groark, & Nelkin, 2004).

Table 60.1 presents an alternative scheme (McCall, submitted) based on a broader representation of the standards of program evaluation research methodology. It has the advantages of being substantially more comprehensive, but it has the apparent disadvantages of being much more complex and not providing a simple grade for the research literature as a whole (although such a numerical rating scheme could be developed). In practice, the disadvantages may not be important, because research literatures are typically uneven and contain gaps, and they are best evaluated by academic research specialists who are capable of weighing different kinds of evidence and making judgments regarding the persuasiveness of the corpus of research.

Some groups, such as the Campbell Collaboration (C2; Co-oper, 1998) and the US Centers for Disease Control (2006),

Table 60.1 Elements of a scheme for assessing the research evidence in support of a service program.

<table>
<thead>
<tr>
<th>1 Program effectiveness (internal validity)</th>
<th>To what extent does the research demonstrate that the program per se produces its intended benefits in participants? (Generally a &gt; b &gt; c in persuasiveness).</th>
</tr>
</thead>
<tbody>
<tr>
<td>(a) Randomized experimental and quasi-randomized evidence</td>
<td>Studies using random assignment of individuals or larger units to program versus comparison conditions plus experimenter-selected units that are arbitrarily assigned to treatment versus comparison conditions</td>
</tr>
<tr>
<td>(b) Non-randomized quasi-experimental designs</td>
<td>(Cook &amp; Campbell, 1979; Rossi, Lipsey, &amp; Freeman, 2004). Studies lacking random or experimenter-controlled assignment (i.e., participants self-select to conditions) with some comparison provision (e.g., comparison groups, propensity score comparison individuals, instrumental variable estimation) that supports the inference of causality. Also, interrupted time series with three or more time points before and after the program</td>
</tr>
<tr>
<td>(c) Non-random single-group designs with a pre- and post-program assessment</td>
<td>These studies are more persuasive if they provide some additional evidence consistent with causality (e.g., dose–response effect; relations between program elements hypothesized to be causal mediators, such as fidelity of implementation or success of program implementation in individuals, and outcome benefits)</td>
</tr>
</tbody>
</table>

<td>(a) Participants varying in gender, age, education, income, race and ethnicity, severity of risk or problem condition, and other characteristics thought to be related to outcome and program effectiveness?</td>
<td></td>
</tr>
<tr>
<td>(b) Providers who vary in education, training and experience in general and specifically related to this program?</td>
<td></td>
</tr>
<tr>
<td>(c) Program characteristics that vary, such as budgets, facilities and tangible and personnel resources and other aspects that may influence outcome (e.g., size of program, number of participants per provider, hours of service per participant)?</td>
<td></td>
</tr>
</tbody>
</table>

| 6 External validity specific to the replication circumstances | To what extent has the program been shown to be effective within each of the three design categories using program characteristics as described in 5 above that are similar to those likely to characterize the replicated projects? |

| 7 Feasibility of replication | Are the program and its implementation process described comprehensively and packaged in a way that providers new to the program can faithfully replicate the program? |

Characteristics of successful programs Does the literature support one or more characteristics that may be important to producing beneficial outcomes, because they are common components of programs that were successful, especially if they are not common components of programs that were not successful (such characteristics may be participant, provider and program characteristics [see 5 above] or the characteristics listed in Table 60.2)? Is there a strong theory of change and evidence on how or why the program is effective?
provide reviews of evidence on services for a variety of physical and behavioral health programs, and governments and foundations often operate consensus groups that bring together academic authorities to review literature and make specific recommendations regarding treatment approaches and services. The scheme in Table 60.1 makes more explicit the types of evidence and to some extent the standards that might be used by such groups to evaluate the literature.

When the Evidence is Not Sufficient
Except for the most thoroughly researched service programs (e.g., NFP), the research literature is not likely to cover all of the elements necessary to decide what kind of service will be most effective and how it should be implemented and operated. There may be gaps, uncertainties and technical limitations; no specific program may have a persuasive research track record; and doubts may emerge about how a program will need to be modified to fit the local clientele, service staff and circumstances.

An alternative to prescribing a specific service program is to provide guidelines for service creation and operation that are supported by research and that permit creativity and flexibility in matching the service to local circumstances. Sure

Start was extreme in this regard, requiring only domains of services and the admonition that they be evidence-based. Fortunately, the general characteristics of successful service programs are remarkably similar across services aimed at preventing or treating a variety of different problems of children, youth and families. Table 60.2 (Groark & McCall, 2005) presents an integration across several lists of characteristics of successful programs in early childhood care and education (McCull, Larsen, & Ingram, 2003); family support (Layzer, Goodson, Bernstein, & Price, 2001; Schorr, 2003) and the prevention of adolescent problem behavior (Kumpfer & Alvarado, 2003; Nation, Crusto, Wandersman et al., 2003). This list represents the beginning of a set of general guidelines which could be supplemented with additional characteristics unique to a specific type of service and problem area.

While such characteristics are useful as guidelines to local service professionals and funders, the characteristics themselves are rarely researched directly to assess their role in contributing to service effectiveness (but see Olds, Henderson, Kitzman et al., 1999). Instead, they tend to be common characteristics of programs that have been demonstrated to produce benefits in participants. Nevertheless, coupled with other characteristics supported by research and best practices of service professionals,

Table 60.2 Characteristics of successful collaborations among diverse professionals. [Based upon Butterfoss, Goodman, & Wandersman, 1996; Grobe et al., 1993; Kegerise, 1999; Mattessich & Monsey, 1992; Wandersman & Goodman, 1993. Table originally published in Groark & McCall (2005), reproduced with permission of the publisher.]

A common purpose A collaboration is beneficial and likely to succeed if it is created to accomplish a purpose that each of the participants needs or wants but that none of the participants alone or in smaller groups can attain. The common goal is necessary so that each participant focuses on a single set of criteria, and the mutual dependency keeps the coalition together and lays the ground work for mutual respect

Clear, concrete, achievable, specific goals A collaboration must identify common, clear, achievable and specific goals, both short-term process goals and long-term outcomes, plus a plan with concrete and realistic steps and a time schedule for achieving them

Selection of participants The collaboration should bring together at the outset all individuals and/or organizations that are necessary to accomplish the goals, even though the contribution of some may not be necessary until the final stage. Collaborations may be small, consisting of a scholar and a service agency (e.g., school, hospital, early childhood center) or much larger, involving several organizations of the same or different kinds (e.g., family support centers, early childhood centers, schools, public and private funders, elected officials, media representatives). Early and continuous involvement of key players (e.g., policy-makers) creates feelings of ownership and loyalty which may be needed later

Team players Participants must be selected for the resources and influence they may bring as well as for several personal characteristics, including the ability to get along with diverse people and groups, attend every meeting, represent their organization and commit its resources to the project, listen and understand divergent points of view as well as communicate clearly and honestly their own perspective, and accept a group decision even if it conflicts with their own self-interest

Diversity The diversity of participants that is needed can present challenges. Some participants may hold stereotypic attitudes towards others, but such beliefs do not always apply to the particular individuals and organizations represented in a collaboration. Ultimately, the members of each group need to learn the skills that each participant can contribute regardless of stereotypic roles

Strong, balanced, sensitive leadership Although all of the participants of a collaboration are necessary and should share in the rights, responsibilities and credit for the collaboration’s activities and products, strong leadership is essential for any collaboration to function smoothly, efficiently and productively. The leader must be neither dictatorial nor a benign chairperson; instead, he or she must be strong enough to structure the process and activities of the collaboration, move the group in the appropriate direction, encourage participants to be appropriate to the group’s process and goals, be sensitive to the needs and characteristics of each member without unnecessary accommodation, recognize and respect the contributions of each participant, and deal in a balanced and fair manner with disagreements and even conflicts within the group. It is a tall order; few people, especially scholars, excel in these characteristics; and occasionally collaborations must change leadership if necessary to preserve the collaboration and to achieve their goals.
CHAPTER 60

such guidelines can communicate what research and professional practice have learned and permit modifications to fit local needs.

Consensus Groups
To produce such guidelines, consensus groups need to be composed not only of relevant scholars to assess the available research literature, but also service professionals, policy-makers and representatives of the intended clientele, and they need to be able to fill in the gaps in the research literature and come out with an action plan based upon the best available evidence and practice.

The Pathways Mapping Initiative (PMI) developed by Schorr (2003) represents a structured process by which such a group can create a “map” or set of recommended guidelines for the processes and characteristics that are effective in reaching the outcome under consideration. PMI recognizes that the traditional knowledge regarding a service program or a type of service is typically too limited, comes from a small number of interventions that have been adequately evaluated, and usually fails to identify all of the elements that actually make the service effective. The PMI process broadens the knowledge base by permitting reasonable judgments and plausible interpretations of a preponderance of evidence based on professional experience as well as program evaluations coupled with strong theory. The process also attempts to curb idiosyncratic opinion by insisting upon broad consensus among its diverse members. The product consists of a combination of actions needed to produce the desired outcome, the key ingredients that are likely to make those actions effective and the community contexts that will influence program effectiveness (for examples see www.PathwaysToOutcomes.org).

Proven Program or Principles?
In practice, the best solution may be somewhere between replicating a well-specified proven program (e.g., NFP) and a set of broad service domains (e.g., Sure Start), a structure and process (e.g., School Development Program) or principles of successful programs (Table 60.2). True replication of a highly specified program is likely a myth (Friesen & Koroloff, 1990; Green, Rodgers, & Johnson, 1999; McCall & Green, 2004) – it does not really take place – but vague or unspecified characteristics, such as in Sure Start, permit too much local variation and unsubstantiated program characteristics. A compromise of as much specification as research substantiates coupled with reasonable local flexibility is most desirable (and is likely to occur anyway).

Limits on the Transfer of Research and Best Practices to Communities
Whereas a set of guidelines reflecting the research literature and professional best practices may represent a necessary first step in creating and implementing effective service programs at a local level, it is not likely to be sufficient. First, simply communicating this information has not resulted in localities adopting the most effective program strategies (Ringwalt, Ennett, Vincus et al., 2002; Wandersman & Florin, 2003). For example, until recently, the DARE program to prevent drug abuse had been adopted in 80% of school districts in the USA despite a research literature that showed it to be relatively ineffective (Ennett, Tobler, Ringwalt, & Fewling, 1994; General Accounting Office, 2003).

Research-to-Practice Gap
This gap may occur for several reasons.
1 The research knowledge is generated and communicated unidirectionally from researchers to practitioners and thus may be less relevant to the policy and practice context than is necessary.
2 The research and practice knowledge may be inadequately and ineffectively communicated to local practitioners and policy-makers.
3 Factors other than research and best practice contribute to service selection and effectiveness, such as the availability of a packaged program, ease of implementation, unique characteristics of local clientele, and local personnel and financial resources.

Chinman, Hannah, Wandersman et al. (2005) identified four broad factors that influence whether communities adopt, create and implement evidence-based services.
1 Implementing high-quality service programs is a complex process that requires considerably more knowledge and skill than is needed to simply follow a program manual.
2 Systems factors pertaining to co-ordination among different agencies and community readiness to adopt and maintain new strategies need to be considered.
3 Communities must have sufficient financial, technical and personnel resources.
4 Local clienteles and other circumstances may pose unique difficulties.

Technology Transfer
One approach to building such community capacity is technology transfer (Backer, David, & Soucy, 1995), which emphasizes training and technical assistance. However, these strategies alone have been only partly successful. Chinman, Hannah, Wandersman et al. (2005) reviewed a variety of training programs in substance abuse prevention, for example, and concluded that while such programs were helpful, their content was not always appropriate to the specific local context and there were often local barriers to incorporating the information into practice. Alternatively, having an intermediate set of professionals provide direct hands-on technical assistance similarly had limited effectiveness (Chinman, Hannah, Wandersman et al., 2005). Such technical assistance, even when provided without cost, was not always welcomed at the local level; some minimal level of community capacity was required to make full use of such assistance, and community organizations seemed better able to utilize some forms of assistance (e.g., planning, implementation, organizational maintenance) than others (e.g., evaluation procedures, data analysis). While these results are based on experience with training and technical
assistance in one area—substance abuse prevention—and their generality to other areas is unknown, many funders and service professionals believe that training and technical assistance as typically provided may be necessary but are not often sufficient to improve or create service programs.

**Toward Effective Community Processes**

The ability of local communities to adopt, create and implement effective services often requires a collaborative community process (Green, 2001), not simply technology transfer or a ready-made program to be replicated. Chinman, Hannah, Wandersman *et al.* (2005) suggest that this process must have genuine community involvement and commitment: the community must possess skills in a variety of domains; resources must be identified, acquired, and managed; and there must be a collective sense of community efficacy or power to manage the skills and resources and direct them toward successful outcomes. More specifically, such a community process requires:

1. Collaboration among a variety of stakeholders;
2. A strategy for designing services that fit local needs and circumstances;
3. Effective implementation and operational strategies;
4. Appropriate monitoring and evaluation; and
5. A plan to sustain the effectiveness and financing of services. We consider each of these elements below.

**Collaboration**

While a specific service may be adopted or created by a single agency, many contemporary services are multi-sited or comprehensive, requiring collaboration across agencies and involving policy-makers, funders, academics, evaluators, the media and members of the intended clientele in their planning, implementation and operation. Such diverse collaborations have the potential benefit of converging the complementary expertise of such individuals to produce a better and more comprehensive service and to create involvement (i.e., “buy in”) of major participants and groups that are necessary for the successful funding, roll-out, operation and sustainability of the service. Conversely, collaborations may take more time, require skilled leadership and sometimes involve individuals who obstruct progress for a variety of personal and professional reasons.

**Membership**

The members of a collaboration are typically *stakeholders* in the service to be created, that is, individuals who have an interest in the project, something to gain or lose as a function of its success or failure, and can contribute in some manner to its creation, implementation, operation and sustainability. Ideally, every member of the collaboration should be necessary to its success, and no smaller subset of the collaborators would be sufficient to carry out the project. Even collaborators whose contribution occurs late in the process should nevertheless be present from the beginning so they are knowledgeable about and involved in the project. Members of a community planning and implementation collaboration could include:

- Relevant service professionals representing key agencies to be involved in the future service;
- Policy-makers and funders, who have administrative responsibility for the type of proposed service, who will or could help to fund it, and who will be necessary to overcome local political barriers the service may face;
- Academics with the research and professional knowledge behind the guidelines, who can be used to steer the creation of the service;
- Evaluators, who will work with service providers to monitor and evaluate the implementation, service delivery process and outcomes for participants;
- Potential participants in the service, who can provide the perspective of the client in designing a user-friendly service; and
- Others who may be necessary for success (e.g., the media if public awareness is needed, celebrities if a public spokesperson would be helpful, business leaders if the service is to be integrated with or benefit private enterprise, and community leaders if the service will influence the wider community or will need community support to operate).

Members should be selected for their ability to fulfill their specific roles in the project and for their personal ability to function in a collaborative group. Collaborations often leave individual members with less control over the process and product than they are accustomed to exercising and require them to make compromises with cherished values and principles (e.g., evaluators not having random assignment). They should be committed to attend every meeting, represent their organization, bring its resources to the project, listen and understand divergent points of view, communicate their perspective honestly and accept a group decision even if it conflicts with their own self-interest.

**Models of University–Community Relations**

In the past, academics and program evaluators, generally from a local college or university, have often not been part of this process, but in the era of evidence-based practices and increased emphasis on evaluation, they have become more crucial to the planning and implementation processes. While each member of the collaboration is likely to have his or her own professional values and attitudes, those of academics and program evaluators may be less similar to, even at odds with, the values and attitudes of other collaborators (Groark & McCall, 1993, 1996, 2003; Mattessich & Monsey, 1992; McCall, Green, Strauss, & Groark, 1997; Shonkoff, 2000).

Historically, academics have worked with community professionals in different ways (Denner, Cooper, Lopez, & Dunbar, 1999). Often, academics simply serve as *expert consultants*. In this case, academics provide their knowledge in a rather unidirectional fashion. Sometimes, the *community sets the agenda*. In this case, the community tends to pick the problem, the methods and the services, selectively taking what information the academic provides that is useful to its purposes. The
A better approach is the true collaboration among stakeholders, in which university and community members develop the project together, blending evidence and program evaluation with practitioner expertise and the resources and limits of the community. The interventions are developed in the community context with the community using its own resources, but research and evaluation priorities are selected collaboratively. In addition, consideration is given to broader policies and processes so that findings are relevant for general theory development. This model also requires the inclusion of various disciplines and diverse groups, thereby being more relevant to the ordinary lives of a wide variety of clientele.

One example of this collaborative approach is practiced by the University of Pittsburgh Office of Child Development (OCD; Groark & McCall, 1993, 1996, 2005; McCall, Green, Strauss et al., 1997; McCall, Green, Groark et al., 1999; McCall, Groark, & Nelkin, 2004). OCD employs:

1. Academic specialists in various aspects of child development who can bring research knowledge to the process;
2. Service professionals who are experienced in creating, implementing and managing innovative service demonstrations in collaboration with community agencies;
3. Program evaluation specialists who train service providers in monitoring and evaluation and who conduct evaluations on community-based programs in a collaborative and participatory manner with the service agency; and
4. Specialists experienced in policy and governmental service administration who work with policy-makers to create better policies and administrative services for children and families.

Some or all of these types of OCD staff may work on a specific project in collaboration with other academics, community service agencies and professionals, and administrators and policy-makers; each component of this team influences the others. The essential ingredient, however, is an attitude that emphasizes partnership – sharing of responsibility, power, control and credit among all stakeholders, who collaborate to achieve a common goal.

Characteristics of Successful Collaborations

Successful collaborations tend to have certain characteristics in common (Butterfoss, Goodman, & Wandersman, 1996; Grobe, Curnan, Melchior et al., 1993; Kegerise, 1999; Mattessich & Monsey, 1992; Wandersman & Goodman, 1993). First, they have a common purpose. Each participant must value the main common purpose of the collaboration, which focuses each participant on a single set of criteria, and the mutual dependency helps to keep the coalition together and produce mutual respect. The common purpose must be articulated early and clearly so that it becomes the touchstone that helps members focus on the reason for the collaboration during debates. Therefore, it is helpful to write down the common purpose in the manner of a vision or mission statement which can be reviewed periodically to keep members operating in the same direction and also to constitute criteria for deciding whether each major decision contributes to accomplishing the stated purpose.

Further, the collaboration should establish common, clear, achievable and specific goals; a plan with concrete and realistic steps; and a timetable for achieving them. This plan becomes the roadmap for all future activities, and a monitoring method that helps institute controls on priorities for each partner by specifying who is responsible for which tasks and how they will be measured.

Strong, balanced, sensitive leadership is required. Although all participants should share in the rights, responsibilities and credit for the collaboration’s activities and products, strong leadership is required to make the process work. The leader may be a local participant or an independent facilitator, but he or she needs to have or earn the respect and trust of all group members. The ideal leader needs to be sensitive and fair, hearing all sides of a debate, but at the same time be neither dictatorial nor benign. The leader must structure the process and move it along at an appropriate pace without restricting participation by each member and by encouraging participation by all. Further, the leader needs to deal in a balanced and fair manner with disagreements and conflicts within the group while respecting the diverse contribution of each participant. Few people have all these characteristics, yet such leadership is crucial to an effective collaboration (Groark & McCall, 2005; McCall, Green, Strauss et al., 1997).

Program Development and Design

Effective program development requires establishing and operating a successful collaboration, preparing and planning, and then conducting a logic model program development process. Many of the principles described in this section appear obvious or common sense, but in our experience they are not always followed.

Operating Successful Collaborations

Successful collaborations tend to operate in a specific way (Butterfoss, Goodman, & Wandersman, 1996; Groark & McCall, 2005; Grobe, Curnan, Melchior et al., 1993; Kegerise, 1999; Mattessich & Monsey, 1992; Wandersman & Goodman, 1993). They have regular meetings with required attendance, and they begin by identifying the values and perspectives of each participant and what they bring to the collaboration. The skills, resources, roles and responsibilities of each participant should be identified, as well as major resources and time commitments that will be needed.

If the collaboration is large and complex, written policies or even bylaws and procedures should be considered. The group should decide how decisions will be made, whether votes will be taken and how ties will be resolved. Ultimately, the collaboration should develop a “business plan” that specifies potential resources and expenses as well as goals, procedures, responsibilities, and legislative, legal and administrative needs. Finally, the collaboration itself may need to be monitored and
Planning and Preparation
An initial step in preparing to develop a new service program is to understand the current situation; namely, the nature of the intended participant group and its cultural and social values, political opportunities and constraints, and the history of the problem and previous attempts to remediate it (for service planning in general see chapter 71). For example, in the case of an intervention project to improve caregiving in the orphanages of St. Petersburg, Russian Federation Groark, Muhamedrahimov, Palmov, Nikiforova, & McCalm, 2005; Muhamedrahimov, Palmov, Nikiforova, Groark, & McCalm, 2004), this meant understanding the following:
1 How caregiving was currently provided, the rules and regulations governing the orphanage;
2 Why various practices exist (e.g., caregivers do not get socioemotionally close to children to avoid the pain of separation later);
3 That caregivers work 24-h shifts to minimize transportation expenses and to have 3 days off to be with their own children or work in other jobs; and
4 There is a long tradition of adult-directed teaching.

Next, learn what has been tried before, both locally and nationally. This step includes a review of the service literature, which may focus on the guidelines offered by a consensus group or brief reviews provided by local scholars plus knowledge of what has been tried specifically in the target locale. In the case of the orphanage project, there were few precedents, but there was a literature on early socioemotional development (e.g., attachment) and on the components of early childhood care and education programs that correlate with children’s development.

A needs assessment, conducted community-wide or specific to a particular location, agency, or program is very useful. Community needs assessments can be conducted by an independent organization with the assistance of a diverse committee of practice professionals, funders, policy-makers, scholars and service participants, or it could be the collaborative community group conducting this program development process. The needs assessment consists of reviewing the scholarly literature on the issue (e.g., after-school programming, adolescent crime prevention, comprehensive family services); determining the frequency and severity of the problems to be prevented or remediated in the target area; and specifying the short- and long-term consequences to individuals and costs to society if nothing is done or current services were continued, the nature and extent of existing services, the geographic distribution of problems versus services, available personnel and their training and preparation, and resources available or needed.

Creating the Planning Document
The program planning process should produce a written planning document. This is sometimes a grant proposal in which a government or private funder has issued a request for proposals that specifies the target population, goals and services it wants to fund. Alternatively, the diverse community-collaborative group may plan the services with or without a set of guidelines or request for proposals.

Several structured formats are available to facilitate program development. For example, the Strengths, Weaknesses, Opportunities, and Threats (SWOT) analysis (Kearns, 1992) provides an organized approach for general strategic planning, perhaps for an entire service agency. More specific to program development is the logic model. While research on the effectiveness of the logic model approach is limited, those who use it recommend it and it is widely advocated. For example, the Kellogg Foundation (1998, 2000) provided a detailed guide for conducting a generic logic model that could be applied to any service need. Benson (1997) presented an asset-based needs assessment pertaining to adolescents, and Catalano and Hawkins (1996) described risk and protective factors and suggestions for program development for preventing adolescent antisocial behavior. More recently, the logic model concept has been packaged into the Getting to Outcomes (GTO) process (Wandersman, Imm, Chinman, & Kaftarian, 1999, 2000), which is available in several formats pertinent to particular problems (Chinman, Imm, & Wandersman, 2004; Fisher, Imm, Chinman, & Wandersman, 2006; http://www.RAND.org/publications/TR/TR101). The GTO approach will soon be available in an interactive web-based technology system, iGTO.

Logic Model Approach
The logic model approach consists of a series of questions that provide a structure and logic to the program planning process. The logic model process is common sense, but not commonly conducted. It forces the collaborative to think clearly, specifically and realistically about needs, goals, participants, services, rationale, measures of process and outcome, and resources, and to make sure these components are aligned. Proponents of the logic model approach argue that it produces a clear integrated logical program that is more likely to be effective plus an evaluation that is more likely to be relevant and to contribute to program improvement and understanding how the program works (Armstrong & Barsion, 2006; Axford, Berry, & Little, 2006; W. K. Kellogg Foundation, 1998, 2000). Whereas the specific questions vary from one approach to another, generally logic models address the following questions (Groark & McCalm, 2005).

What is the Ultimate Goal of the Services?
Specifically, what is the problem or need and what should be the situation if the new intervention or services were completely successful? This is the “blue sky question” – in the ideal case, what should the intervention or services accomplish? In the case of the orphanage project, the ultimate goal was that children should develop at typical levels in all domains.

What Measures Would Indicate that this Long-term Goals has been Achieved?
Often, the goal stated is phrased in very general terms (e.g.,
children develop typically) so in this step that goal must be specified in measurable terms. For example, the measurable long-term goal for the orphanage children was for them to reach heights, weights, and developmental scores (across personal, social, communication and cognition dimensions) comparable to non-orphanage parent-reared children.

Care must be taken to ensure that the indices of success indeed reflect the long-term goal and are reasonable and potentially attainable. Some policy-makers and funders prefer aggressive goals, such as “cutting the teenage pregnancy rate by 50%.” The goal is worthwhile, but likely not attainable; should a program that cuts the rate by 25% be deemed a failure relative to such a lofty goal? Instead, determine both the minimum level of improvement that would be considered “success” as well as the maximum level likely to be attained. Thus, a goal of reducing the rate by 20–40% might be appropriate (no one will be upset if the program achieves a 45% reduction). The goal should also be well-specified – a reduction of 20–40% relative to what (e.g., current levels, a comparison group), in what length of time (e.g., 2 years, 5 years), for what ages of adolescents? Measuring instruments should also be specified when different assessment tools, reflecting different emphases, are available.

Who are the Targeted Participants?
Who do you want to help, how will they be identified, what are their characteristics and how many are there? In the orphanage project the participants were all caregivers and children in three orphanages, but in the case of Sure Start the services would be located in low-income neighborhoods and serve anyone living there. Should outreach efforts be made to recruit families, who should be employed to do this and how should it be done? For instance, should workers be hired from the neighborhood to recruit families because target families can relate to them, or would that cross the line of privacy?

What Services Can be Provided that will Produce the Long-term Goal?
First, determine a promising theory of change (Chen & Rossi, 1983, 1987), then identify services that follow from the theory that have been tried by others and found to be successful. This is the step in which theory, research evidence and best practice guidelines enter the process. What are the elements and characteristics of successful services, and what modifications need to be made to fit the local clientele and social and political circumstances? This step should have at least two major characteristics: first, there needs to be a clear rationale for why the proposed services should produce the intended outcome (i.e., theory of change), and, second, there should be some level of evidence (e.g., Table 60.1) to justify the potential effectiveness of the services, service components and characteristics. What frequency and intensity of services are sufficient to produce the intended benefits? Do the services match the risk level of participants? In the orphanage project, attachment theory provided a theoretical rationale for reducing the number of caregivers, making them more consistent in the lives of children and having them behave in a warm, caring, sensitive and responsive manner. Also, there was an empirical rationale for smaller group size, better caregiver : child ratios, age and disability integration, and child-directed caregiver–child interactions. Together, these changes should promote all aspects of children’s development.

How Will You Know that the Intended Services are Actually Delivered and Match the Plan in Character and Intensity?
This step requires a plan to monitor the delivery of services, not just how many participants receive which services but whether the nature and extent of the services are consistent with the plan (i.e., “program fidelity”). Perhaps a management information system (MIS) needs to be developed. In the case of the CCDP, did the case manager work with the family to identify their strengths, did the family identify their needs and put them into a priority sequence, did the case manager develop a relationship of trust and support with the family and did the family participate in services relevant to the family’s goals?

What are the Short-term Goals and Measures?
What should be the first beneficial outcomes of such services, and is there evidence that achieving the short-term outcomes predicts achieving the long-term outcomes? In the orphanage project, did HOME Inventory scores of caregivers’ behavior on the wards increase, because there is evidence that higher scores are related to better developmental outcomes for children? Short-term goals should be laddered from goals that are obvious and easily attained to goals that are more difficult to achieve, so that the project will have some success.

What is an Appropriate Timeline Both to Deliver Services and to Expect Outcomes?
It is important to be realistic in planning the timeline for both implementation and when short- and long-term outcomes are likely to be achieved. Sometimes, a neighborhood is not ready for a needed service, and this should be anticipated. For example, a funder may suggest establishing a family support center in a particular low-income community. To do so, there must be community “will” for such a center, a recognized and respected leader, an agency willing to administer the program and other resources. If not, program developers may need a year or more to hold town meetings to assess the community’s true interest and capacity and provide recreational services to gain trust.

What is a Reasonable Budget to Deliver These Services and Measure Their Implementation and Effectiveness?
This step begins with assigning costs to all of the elements in the previous steps, determining if the total budget is feasible and, if not, revisiting each of the above steps and making modifications to meet a specified budget. Ultimately, the group needs to decide whether a program that is likely to be effective can be operated for the amount of money available. This is
also one of several reasons why it is helpful to have policy-makers and funders at the table during this planning process.

Implementation
Implementation is as crucial a process to successful services as program development, but it is often forgotten and rarely studied. Further, implementing new services in new communities may require months or even years to build trust among potential participants, and several cohorts of participants and much trial and error may transpire before even experienced teams of providers refine procedures sufficiently to produce benefits in participants (Love, Schochet, & Meckstroth, 1996).

Community Collaborative
The same community collaborative that designs the program may also be used to oversee its implementation. Such a committee should have the characteristics of, and operate according to, the principles for, collaborations described above, and implementation should strive to have the characteristics of successful programs given in Table 60.2.

Characteristics of Good Implementation
Crucial to good implementation is to have a strong leader who relates to the diverse organizing committee plus a well-educated, trained and experienced staff who are supervised in a supportive and encouraging manner on a regular basis. Studies show that training alone is relatively ineffective unless it is accompanied by such supervision (Morrow, Townsend, & Pickering, 1991). Management needs to involve the staff in understanding the purpose of the services, their roles and the intended outcomes, perhaps by involving some of them in the logic model process described above or reviewing that process so that they can contribute modifications in the design of the services. If staff collect data, they need to understand why it is necessary and how they can use the data to guide and improve their services.

Staff also need structural supports, including reasonable work loads and the availability of resources such as technology, consultants and training necessary to do their jobs. Studies also show that teacher education and training tend not to be related to positive outcomes for children in early care and education settings, for example, unless group size and teacher : child ratios are small enough so that teachers can exercise the best practices of their training (Love, Schochet, & Meckstroth, 1996).

A management information system may be needed for large and multi-sited projects that systematizes in a uniform manner participant information, services delivered, and short- and long-term outcome measures. Directors and supervisors need to monitor such information to determine that the services are being delivered according to plan, including whether the participants are those who were originally targeted; whether services are delivered in a timely and consistent way and at an intensity or frequency sufficient to produce benefits; and whether short-term goals are being achieved.

Mid-course corrections may be necessary. For example, one program aimed at providing services and support to drug and alcohol abusing adolescent mothers found after 2 years of operation that the average age of the mothers was 26 years, not the adolescents the program was designed to target. Staff reported that drug and alcohol abusing adolescents did not perceive that they had a problem, because drug and alcohol use and abuse were rampant in their peer group; it seemed to take nearly 10 years for such mothers to recognize that they had a problem and to seek help. The project could change its target group to older mothers who were motivated to use the services and/or it could make greater efforts to recruit adolescents. It was decided to do both, using the older mothers to convince the adolescents that they needed help and enroll them in the service.

Evaluation
Most large comprehensive multi-sited services have a required monitoring and evaluation program. The funder may contract with a central and independent evaluation team, which may prescribe and conduct monitoring and evaluation for all sites, such as in Sure Start and CCDP. Smaller programs should also have a monitoring and evaluation plan, and select appropriate indices of participants, services and outcomes during the logic model process.

Program evaluation is a specialized skill, and relatively few service professionals have the appropriate training. Furthermore, simply providing local service professionals with technical assistance in evaluation does not work very well (Chinman, Hannah, Wandersman et al., 2005). Consequently, large-scale and multi-sited service projects often have a central team of independent evaluators who should be part of the diverse community planning and implementation group and contribute to the program guidelines as well as collaboratively design the monitoring and evaluation plan, specify measurements, conduct the assessments, analyze the data, and report on the process and outcome effectiveness of the project. Alternatively, some communities have local evaluation teams that work with local agencies to design and conduct local evaluations, even the evaluation of the local site of a multi-sited national intervention, such as in Early Head Start (McCall, Green, Strauss et al., 1997; McCall, Green, Groark et al., 1999).

Modern service programs, especially services that are tailored to client needs and characteristics at both the site and individual participant levels, pose several issues for traditional methods of evaluation. We consider a few such issues below.

Independent Versus Participant/Collaborative Evaluation
Historically, innovative services were often created by a university scholar who both implemented the intervention and evaluated its effectiveness. Conversely, funders feel it is a conflict of interest for the people who create and implement a service to evaluate it, so they prefer an independent evaluation team.

In the past, independent evaluators have sometimes been distant from the program and the services staff, have “done the evaluation to the project,” and sometimes issued reports that policy-makers and practitioners regarded as having missed the
point of the service program. A modern and compromise strategy is participatory or empowerment evaluation (Fetterman, 1993; Fetterman, Kaftarian, & Wandersman, 1996; McCall, Green, Strauss et al., 1997; McCall, Green, Groark et al., 1999), in which evaluators and service professionals work together from the beginning of program development to monitor and evaluate the process and outcome of the service program. Participatory evaluation is more likely to produce useful results, because the measures and design are determined collaboratively with service professionals.

Central Versus Decentralized Evaluations
Large multi-sited service programs have often had a single evaluation team that designs and collects the data for all sites (e.g., Sure Start, CCDP). Such an approach has the benefit of a uniform evaluation of all sites, and it works best when the service program is prescribed in great detail and expected to be implemented in a uniform manner at each site. However, many modern service programs permit flexibility and modification to fit local circumstances, and even programs intended to be uniform across sites nevertheless are often implemented in different ways at different sites (Gilliam, Ripple, Zigler et al., 2000; McCall, Larsen, & Ingram, 2003). A compromise strategy was used by the Early Head Start Research Consortium, which had a common core of service themes and a central evaluator, but each site had local evaluators who conducted the core assessments plus measures more pertinent to their local program emphases (Administration for Children and Families, 2002; Love Kisker, Ross et al., 2005).

The Rush to Evaluate Outcomes
Understandably, funders and policy-makers are anxious to determine the effectiveness of programs they fund, and often there is an emphasis on assessing outcomes (i.e., benefits to participants) in the first cohort of participants. But the first “outcome” of any program should be that the services were implemented as planned for the targeted participants with the frequency and intensity that are likely to produce benefits. Until the services are delivered with such “fidelity,” it is unreasonable to expect outcome benefits to participants; and it may well take two or three cohorts of participants before the program operates smoothly and according to plan. This fact prompted Campbell (1987), a patriarch of program evaluation, to admonish: “Evaluate no program before it’s proud.”

Overemphasis on Gold Standard Methodology
Scholars, policy-makers, funders and practice professionals have come to value the randomized clinical trial as the gold standard of applied research and program evaluation, so much so that often entire literatures using other methodological approaches are completely dismissed (e.g., as in review articles that only include randomized trials). While in some fields (e.g., education) there has been an avoidance of randomized trials, and some scholars (Cook, 2002) have called for greater use of this gold standard, in other fields randomized trials are overemphasized (McCall & Green, 2004).

While acknowledging the potential benefits of random assignment, McCall and Green (2004) argue that randomized trials work best in a double-blind design in which participants do not know which treatment they are being given and have relatively little influence over the success of the treatment (e.g., drug versus placebo studies). However, in behavioral interventions, participants are almost never blind to which treatment group they have been assigned, and participants’ values and perceptions of the treatment can have substantial influence on how effective the treatment is for them. As a result, some participants display “reactive disappointment” to being in the control group and acquire the treatment services for themselves, shrinking the difference between the “treatment” and the “control/comparison” groups. For example, in one evaluation of the SDP (Millsap, Chase, Obeidallah et al., 2000, reported by Datta, 2003) in which schools were assigned to treatment versus control conditions, several of the control schools implemented some or all of the Comer principles on their own. The result was that there was minimum difference between treatment and control schools in the amount of SDP “treatment” and in outcomes. However, the extent to which schools implemented the SDP principles within the control group was related to outcome. A gold standard purist would discount this finding because the beneficial outcomes were confounded with school motivation. Technically true, but a policy-maker or superintendent might be sufficiently persuaded to adopt the SDP strategy if it could be effectively implemented.

Further, after a demonstration project is completed successfully and services are offered routinely, they are never randomly assigned. So “participant bias” will always be in effect; from a practical standpoint, the “biased” demonstration sample is the group from which generalizations to future clients should be made (of course, one wants to know if such people would improve without a service program).

Also, such “bias” might be critical for program success. For example, if divorcing couples are randomly assigned to divorce mediation versus court-ordered settlements, it is possible that some couples cannot co-operate sufficiently for mediation to work whereas other couples would be dissatisfied with a divorce arrangement that was prescribed for them by a judge. The result of a strictly randomized trial might be no difference in parental satisfaction and adjustment of children between these two approaches. However, if couples were allowed to choose which approach they wanted, both strategies might be shown to be effective for those who choose them, more effective than for those who are randomly assigned to each approach. Notice that this is a case in which the randomized design produced a low effect size, contrary to those who sometimes claim that randomized designs provide a maximum effect size.

Consequently, McCall and Green (2004) advocated a greater balance of and respect for different methodological approaches which provide different kinds of information about an intervention or service. Results from a comprehensive set of approaches are more likely to provide a more complete and better understanding of the effectiveness of that service. Different research
designs and statistical strategies are described elsewhere (McCall & Green, 2004; Rossi, Lipsey, & Freeman, 2004).

**Intent-to-Treat Analyses**

Another gold standard approach to program evaluation is to conduct intent-to-treat analyses in which the outcomes are assessed on all participants who were assigned to the treatment conditions regardless of whether they actually experienced them, such as in Sure Start. This approach preserves the random assignment feature; it “avoids” the problem of selective dropouts, which is common among the high-risk populations that many services target, by including the dropouts as if they were treated participants. This strategy works well when the treatment program is uniformly delivered to all participants and the number of actual dropouts is small.

However, including dropouts inflates the error within the treatment but not the control condition; and as the number of dropouts and partially treated participants increases, detecting significant differences between treatment and comparison groups becomes less likely. Further, it is logically absurd to pretend that dropouts received the treatment when they did not. In this case, it seems reasonable to conduct both the intent-to-treat analysis as well as an analysis that is restricted to fully treated subjects (perhaps limiting the control subjects to those who were similar to the fully treated participants through propensity score analysis; Rosenbaum & Rubin, 1983).

The intent-to-treat strategy also seems limited if not inappropriate when the treatment itself is different from participant to participant. In the CCDP, families chose their goals, and only approximately 15% of the treatment families chose more education and 10% of the control families decided on their own to undertake more education. Yet the evaluation asked the percentage of all participants in both treatment and control groups who attained more education. Not surprisingly, few did (i.e., certainly less than 15–10%), and there was a very small and insignificant difference in the rates between the two groups (McCall, Ryan, & Plemons, 2003; St. Pierre, Layzer, Goodson, & Bernstein, 1994, 1997a,b). Clearly, evaluation analyses must consider different goals and services delivered within the treatment and control groups with designs and analyses that consider that modern services are often individualized (McCall & Green, 2004).

**Sustainability and Replication**

*Sustainability* refers to at least two outcomes:

1. Maintaining the quality of services and benefit to participants over time; and
2. Keeping the service funded after the initial demonstration grant expires.

*Replication* refers to attempts to reproduce the program in new sites with similar populations with the intent of replicating the original benefits and outcomes.

**Sustaining Program Benefits**

It is not uncommon for there to be unusual passion, commitment and dedication among program directors and staff during the implementation of a new service program, and such commitment often wanes over subsequent years. Also, staff turnover and changes in the participant group may also lessen the effectiveness of the services over time.

An MIS and a good plan for monitoring participants and services can provide feedback to directors regarding changes in the characteristics of participants and the manner and intensity with which services are being delivered. The director and supervisory staff need to provide continuous supervision and monitoring, even of highly experienced staff, to maintain standards and program effectiveness. Supervision must be formative and reflective (Johnson & Tittnich, 2004) so that continuing improvements are made in services with staff input and enthusiasm for the program is maintained.

It also helps to design the original demonstration in such a way that the intervention can be maintained. Building intellectual and skill capacity in the community is essential in sustaining the quality of services. For example, the St. Petersburg (Russia) orphanage project (Groark, Muhamedrahimov, Palmov et al., 2005; Muhamedrahimov, Palmov, Nikiforova et al., 2004) used a train-the-trainer approach in which a written curriculum was produced and a specialist trained the professionals in each orphanage. Those professionals were able to train new caregivers who replaced those who left and thus keep the level of performance high in the orphanage over time.

**Sustaining Funding**

Many interventions and services are initiated with a demonstration project, which is often funded at relatively generous levels. However, once the demonstration is completed, it can be much more difficult to obtain funding to continue the program, even when the evaluation has clearly demonstrated program benefits to participants. Also, when governments assume funding after demonstration programs, it is often at substantially lower levels but with the same expectations for success – it is the government’s penchant to expect champagne benefits on a beer budget.

Programs that must be trimmed to fit smaller budgets need to analyze and break down the program into its components, including personnel, participants, the types and extent of services provided, as well as the costs involved. The research literature on this type of service and characteristics of successful programs should be used as the criteria for determining which aspects of the service are likely to be crucial and which aspects appear less important and are likely candidates for trimming. Sometimes, the number of participants may need to be reduced to maintain program quality within the available budget. This is always a very difficult choice for service professionals, but it seems obvious that it is better to be effective with fewer participants than to be ineffective with many.

One strategy in sustaining programs after their initial demonstration is to invite potential long-term funders (e.g., the director of children and youth services for the geographical area in which the service program resides) to be on the community collaborative committee that designs, implements and
oversights the management of the demonstration program. By involving such funders at the beginning, they are more likely to be committed and to feel a sense of ownership of the program after the initial demonstration and therefore more likely to provide funds to sustain it.

The results of a successful evaluation should be disseminated widely and specifically to potential funders. Further, results need to be packaged differently for different audiences, from detailed technical reports for scholarly journals to one-page summaries for policy-makers.

It is also helpful to have cultivated one or more “champions,” who may be policy-makers, funders, influential citizens, celebrities or media professionals. They also should be part of the community collaborative that designs and oversees the project from the beginning, so they are fully informed and feel partial ownership of the service. Eventually, their job is to “sell” the program to policy-makers, funders and the general public.

Sometimes, successful participants can be the most powerful advocates for sustaining a service. Consider a drug and alcohol abusing mother of two young children who is assisted by a family support program to become substance free, develop marketable skills, become employed, and whose children wind up in honors classes. If she is willing to tell her story publicly, she can do more to sell a program than all the carefully collected evaluation results. It is difficult for legislators to see such a success story and then vote against funds to offer the same opportunities to others.

Repliation
Repliycing a program in a new locale with new staff and clientele requires the same planning process and ingredients for successful implementation as for the original (i.e., leadership, committed staff, perceived need for change, program development with the logic model process). Does the new director have sufficient commitment, energy and confidence to “pull this off”? Is the staff capable and receptive to change? Are the local social, cultural and economic conditions conducive to change? If not, these elements need to be resolved before or during the program planning process.

Conclusions

There is no “silver bullet” or step-by-step manual that will guarantee that community-based interventions services will be successful. However, there are principles and strategies suggested by research that help to create highly effective programs. They start with a thorough process of planning that customizes the service and its delivery to the clientele and context. It includes developing a solid collaboration of diverse but relevant stakeholders who become knowledgeable loyal partners. Together these stakeholders develop a common purpose, goals, and clearly agreed-upon rules, and are led by a fair, balanced and respected leader. They employ a structured planning process that designs a program founded on theoretical and practice evidence and based on characteristics that work, while always being sensitive to future sustainability and replication issues. The program is continuously monitored for service improvement and evaluated for interim and long-term outcomes. Moreover, all steps are documented and frequently reviewed by senior management and the diverse oversight group for “lessons learned.” Finally, outcomes and lessons learned are disseminated to policy-makers and practitioners for sustainability in the current sites and replications to improve services and lives elsewhere.

Clarifying and Maximizing the Usefulness of Targeted Preventive Interventions

Frank Vitaro and Richard E. Tremblay

Objectives and Overview

This chapter covers targeted preventive interventions as applied to the psychosocial domain and is divided into three parts. In the first part, we examine who should be the focus of preventive interventions. In doing so, we critically review past and current classification systems of prevention programs in light of the Science of Prevention concepts (Coie, Miller-Johnson, & Bagwell, 2000; Coie, Watt, West et al., 1993) as well as new knowledge accumulated over the last decade in the area of developmental psychopathology (Cicchetti & Cohen, 2006; Masten, Burt, & Coatsworth, 2006). The second part focuses on what should be targeted for change, how such targeting should be accomplished and when such targeting should occur. Finally, we review practical and clinical issues related to recruitment and retention of participants, timing and components of preventive interventions, assessment of results, cost-effectiveness and dissemination. Throughout the chapter, we refer to past or ongoing preventive interventions to illustrate our points. We assume that most readers are aware of the theoretical and practical advantages of preventive interventions over treatment. These are well described by Coie, Miller-Johnson, & Bagwell (2000) and Offord and Bennett (2002) (see also chapter 60).

Who Should be Targeted?

Based on the Science of Prevention concept, preventive interventions are a series of organized, theoretically driven efforts to break the developmental pathways linking early risk factors to later adjustment problems. As illustrated in Fig. 61.1, the disruption of this psychopathological process can be achieved by:

1 Eliminating the initial risk factors or their subsequent mediators;
2 Adding beneficial factors to the developmental chain to compensate for risk factors; or
3 Putting in place protective factors (i.e., moderators) that mitigate the links between risk factors and their associated outcomes (for the distinction between risk factors, mediators and moderators see Kraemer, 2003).

In this context, developmental psychopathology provides a comprehensive framework for constructing “theories of the emerging problem,” whereas the Science of Prevention can be seen as a comprehensive framework to construct “theories of the appropriate solutions” to prevent problems from emerging.

Brief Historical Overview

The first conceptualization of prevention into primary, secondary and tertiary interventions was proposed by Caplan (1964). Caplan’s conceptualization emphasized the timing of intervention relative to the problem to be prevented: before onset (i.e., primary prevention), during early or preclinical manifestations (i.e., secondary prevention) or after the full-blown clinical establishment to prevent relapse or further complications (i.e., tertiary prevention). Caplan’s model has been criticized on the basis that it is problematic to assume that the development of a problem follows three easily identifiable and conceptually distinct phases (Kraemer, Stice, Kazdin, Offord, & Kupfer, 2001). Indeed, for most psychopathological problems, frequency and severity of symptoms occur on a continuum, even though specific clusters can be identified (Maughan, 2005; Offord & Bennett, 2002).
A new classification system was proposed in the 1990s which remains in vogue (Mrazek & Haggerty, 1994; Offord & Bennett, 2002). In the current two-level classification system, prevention initiatives are classified according to who is offered the intervention (Gordon, 1983; Institute of Medicine, 1994; Offord, Kraemer, Kazdin, Jensen, & Harrington, 1998). At the first level are universal preventive interventions (UPI) in which all members of a geographical unit (e.g., a residential area, a school) or a social unit (e.g., kindergarten classes, adolescents) are offered new activities or new services aimed at helping them overcome current or future challenges, but without targeting anyone in particular (see chapter 60). According to some authors, UPI encompasses the notion of health promotion (Cowen, 1991), although others do not agree with this view (Institute of Medicine, 1994). In UPI, intervention can occur in the absence of any sign of the problem to be prevented or any visible (i.e., quantifiable) risk, although risk for some individuals is suspected. UPI can also occur in the presence of identified risk factors as long as these factors might affect the entire population (e.g., the availability and acceptability of drugs that seem to be linked to an elevated rate of substance use in the entire adolescent population; Bachman, Johnson, & O’Malley, 1998).

The second level includes targeted preventive interventions (TPI). In the case of TPI, only individuals at risk for a problem are targeted. If the individuals are at risk for environmental reasons, as in the case of children born from teenage mothers, then the TPI is called selective. If, instead, the children are at risk on the basis of personal dispositions such as early signs of persisting physical aggression, then the TPI is termed indicated. TPI is deployed in the context of risk factors or early precursors of the problem to be prevented. These risk factors or early precursors need to occur at the level of the individual or his or her immediate environment (i.e., family), not at the level of the entire community as in the case of UPI. This distinction may explain in part why TPI-oriented researchers and practitioners usually deploy their efforts at the level of the individual and his or her immediate social environment (i.e., family, teacher, peers). In contrast, UPI-oriented colleagues attempt to establish services and resources at the level of the community. More details about the distinctions between universal, selective and indicated preventive interventions can be found in Mrazek and Brown (2002).

Who is At Risk and to What Extent are They At Risk?

Traditionally, TPI involves a dichotomous view of those at risk (who should get the full TPI) and those not at risk (who do not need any preventive intervention). In most cases, risk is not a binary category but a continuum of probabilities, although this continuum may not be normally distributed (Meehl, 1992). Hence, it is inaccurate to think of individuals as being either at risk (and thus deserving TPI) or not at risk or not yet at risk. Given the multifactorial and developmental determination of most psychosocial problems, individual variation with respect to risk is most often a variation in degree, not in kind. In consequence, we advocate a continuous approach towards risk. This continuous approach also needs to be multivariate.

Three strategies can be used to help determine the degree of risk according to a continuous multivariate perspective. The first strategy was proposed by Burgess (1928). It is a cumulative strategy in which the total number of risk factors is calculated after establishing their individual presence (or absence) using a dichotomous approach. This approach is based on the traditional 2 × 2 epidemiology tables that are used to establish risk status based on its relationship with ulterior psychopathology status (Kraemer, Kazdin, Offord et al., 1999; Offord, 1996; Rice & Harris, 1995). A second strategy is to use the results of a multivariate regression, either linear or logistic, to determine the weights of each risk factor before summing them. This method is known as the weighted additive approach. Some authors have claimed that the weighted additive and the cumulative methods are equally effective in determining the degree of risk (Farrington, 1985). However, others report divergent results. For example, Deater-Deckard, Dodge, Bates, and Pettit (1998) showed that a cumulative risk index based on four childhood risk factors (i.e., child characteristics, sociocultural level, parenting and caregiving, and peer victimization/rejection) correlated only modestly with later externalizing problems (i.e., 0.32–0.39 depending on whether parent, teacher or peer reports were used). In contrast, the predictive coefficients between the four risk factors and the outcome varied between 0.60 and 0.67 when using a weighted additive approach.

One important advantage of the regression approach on which the weighted additive method rests is that it can be expanded into the interactive approach, which is our favored strategy. Most developmental models include not only risk factors with main effects (either direct or indirect, via mediators), but also moderators that qualify these main effects, sometimes in dramatic ways (Coe, Watt, West et al., 1993; Rutter, Giller, & Hagell, 1998). For example, child maltreatment leads to violent behavior, more so in children with the short allele of a variant in the gene coding for the neurotransmitter metabolizing enzyme monoamine oxidase A (MAOA; Caspi, McClay, Moffitt et al., 2002). These findings correspond to a person × environment interaction model which is now becoming generally accepted in developmental psychopathology research (see chapter 23; Plomin & Crabbé, 2000; Sameroff & Mackenzie, 2003). This interactive model allows for the integration of moderating factors to determine the degree of risk. These moderators can reflect either protection or vulnerability. Contrary to resource (or compensatory) factors that have main effects opposite to risk factors, protection factors mitigate the relationship between risk factors and later outcomes. Conversely, vulnerability factors exacerbate the link between risk factors and later outcome; they can also reduce the link between resource factors and later outcomes (Fergusson, Vitaro, Wanner, & Brendgen, 2007; Luthar, Cicchetti, & Becker, 2000; Rutter, Giller, & Hagell, 1998).
It follows that the identification of at-risk individuals should result from a combination of environmental and personal factors that can operate additively or interactively, and not only on background factors or on personal vulnerabilities. An important consequence of such a multivariate interactive strategy is to minimize the distinction between selective and indicated TPI because this distinction requires that participants be selected on the basis of either background or personal factors. Already, some prevention programs target at-risk individuals on the basis of both personal and background characteristics. For example, the promoters of Fast Track, one of the major TPIs in the USA (Conduct Problems Prevention Research Group, 1999a, b), selected the participating children on the basis of neighborhood crime and poverty level and teacher-rated disruptiveness scores.

To summarize, a risk score can be derived for each individual or each community by combining risk/resource factors and vulnerability/protective factors derived from multivariate analyses. Of course, one should not rely on only one study to establish which risk and protective factors are relevant. Meta-analyses and averaged effect sizes of the r type (i.e., beta weights or odds ratios) can also be used in this context (Lipsey, 1995; McCartney & Rosenthal, 2000). However, the value of the risk score may need to be adjusted depending on cultural or geographical variations (seen here as additional putative moderators). For example, children’s anxiety may not be linked to depressive feelings in China as much as in Canada because anxious Chinese children are not ostracized by their peers as much as their anxious Canadian counterparts, a consequence of the differences in the ways anxiety is perceived in the two cultures (Chen, Rubin, & Sun, 1992). One must also be aware of possible non-linear relationships between risk factors and developmental outcomes. In addition, the risk score should be based on risk factors that are easy to measure, reducing the cost of the screening process and increasing its chance for widespread use. If necessary, the continuous risk score can be split into segments to reflect the degree of risk and possibly the nature of the risk faced by the individuals and the communities from each segment. The cut-off scores used to identify the different segments as well as their respective sets of risk and protective factors can take advantage of traditional or recent clustering techniques (Nagin, 2003; Pickles & Angold, 2003).

Note that this segmentation approach is different from the traditional epidemiological approach because: (i) it is based on the full information derived from additive and interactive statistical models; and (ii) in most cases, it generates more than the traditional two segments (i.e., one at risk and one not at risk). Ideally, each segment would receive a program with content and dosage tailored to its specific constellation and level of risk/resource and vulnerability/protective factors. This suggestion is in line with the adaptive preventive intervention approach proposed by Collins, Murphy, and Bierman (2004).

According to this approach, different dosages of certain program components, including zero dosages, are assigned across individuals and/or within individuals across time in accordance with the individuals’ needs or response to the program. Clear and well-informed decision rules help link specific levels and types of program components to the characteristics of the individuals in each segment. The latter are called tailored variables. Tailored variables refer essentially to pretest variables that might exert a moderating effect on the impact of a preventive intervention and/or participants’ progress toward a prespecified threshold representing a successful outcome. To illustrate, in the Fast Track multicomponent program (see pp. 993–4), the number of home visits during the first years of the program (i.e., monthly, biweekly, weekly) was determined based upon ratings of parental functioning, which included empirically validated risk factors. A similar approach was used for the reading tutoring component; only the children whose academic performance was below the 33rd percentile received that component. Parental functioning and academic performance were selected because they were hypothesized to moderate the impact of the core elements of the Fast Track program, although they can also be seen as proximal outcomes and putative mediators. Given that the appropriate dosage depends on the tailored variables, these variables should be selected and measured with care. It is also important that they are stringently operationalized according to well-documented decision rules, which also help in the evaluation of these adaptive preventive interventions.

**What? When? and How?**

Now that we have clarified who should be targeted in preventive interventions, we turn to what should be targeted and when, and how preventive interventions should take place.

**What Should be Targeted and When Should They be Targeted?**

Not all risk/resource factors and not all vulnerability/protective factors are equally important or relevant for TPI. The risk/resource factors and the vulnerability/protective factors that should be targeted by TPI are those that are:

1. Theoretically relevant and empirically active;  
2. High in predictive power and in causal plausibility;  
3. Potent and generative;  
4. Chronologically, culturally and geographically relevant; and  
5. Modifiable in a cost-effective way.

Indeed, only variables and processes that have an active role as main effects or moderators in the developmental pathways leading to the emergence of maladaptation should be targeted by TPI (Felner, Yates Felner, & Silverman, 2000; Rutter, 2003). Hence, risk indicators such as factor B, in Fig. 61.2 (also called markers, proxies or incidental correlates) need to be distinguished from risk factors with unique main effects such as factors A, and mediators such as factors B, and moderators such as factors B, and C. As acknowledged by Rutter (2003), this is not an easy task given that most knowledge about risk factors is derived from correlational studies. However, it is an important task if we want TPI to impact on factors that make an active and possibly causal contribution.
to the complex chain of events leading to maladaptation. Causal plausibility is increased further when the probable mechanisms of these active factors are well documented.

Some risk/resource and vulnerability/protective factors may have an active role in a developmental pathway and their operating mode may be well documented, but their effect size may be small in terms of partial correlations and odds ratios resulting from multivariate analyses. These are not potent risk factors and may not be worth targeting through preventive efforts. Instead, priority should be given to risk/resource factors that are more potent in terms of their effect size relative to the outcome to be prevented. Similarly, priority should be given to protective and vulnerability factors that have a high multiplicative power with respect to the link between risk or resource factors and the outcome (Kraemer, Stice, Kazdin et al., 2001). Protective factors with buffering effects should be the primary target of prevention efforts, especially if risk factors are difficult to modify.

Generativity of risk/resource factors and of vulnerability/protective factors is also important in determining which factors deserve to be targeted by TPI. The notion of generativity refers to the number of mediators with potentially additional unique effects of their own that are triggered by a single risk/resource factor according to a cascade model (i.e., such as factor B2 in Fig. 61.2; Masten, Burt, & Coatworth, 2006). It also refers to the number of risk factors that can be moderated by a single protective factor (such as factor C3 in Fig. 61.2) or the number of adjustment problems resulting from a single risk factor according to the principle of multifinality described by developmental psychopathologists (Cicchetti & Hinshaw, 2002; i.e., such as factor C1 in Fig. 61.2). Hence, cost-effective TPI would target generic risk factors in order to “kill several birds with a few stones.” Many, if not most, of these generic risk factors may be found early in life. As a result, early TPI during the prenatal and preschool periods may be the most (cost) effective, as results from preventive interventions during the prenatal and preschool years indicate (Aos, Lieb, Mayfield, Miller, & Pennucci, 2004; Carneiro, & Heckman, 2003; Olds, Henderson, Kitzman, & Eckenrode, 1998; Schweinhart, 2006). Interventions targeting these periods may also receive public and government support more easily because it makes common sense to try to prevent the complex chain of events that leads to later maladjustment in children by targeting the initial elements of the chain (that have a high generic power). Of course, these early risk factors must be ethically modifiable.

They should also be easily modifiable. For example, low socioeconomic status (SES) and tobacco exposure during pregnancy are independent risk factors for later disruptive behavior (Maughan, Taylor, Taylor, Butler, & Byrner, 2001; Wakschlag & Hans, 2002). Low SES may be modifiable (Leventhal & Brooks-Gunn, 2004), but not by health professionals, at least not directly. In contrast, prenatal exposure to nicotine is easily modifiable, at least in principle. However, modifying prenatal nicotine exposure requires the right timing; after the first months of pregnancy, it may be too late to effect change. Other risk factors, although modifiable, may not be relevant because of the participants’ characteristics such as age, sex, ethnicity or cultural background.

To conclude, trying to change factors that cannot be changed or, when changed, do not affect the incidence of the outcome because the factors are markers and not causal antecedents is a waste of time and valuable resources. Trying to change factors that, although causal, are not potent, not generic, not well-timed or not culturally relevant will also prove to be a waste of resources. In designing preventive interventions, the emphasis should be placed on active, independent, causal, generic, early, modifiable and culturally approved or important risk/resource and vulnerability/protective factors.

**How do we Achieve the Maximum Impact of TPI?**

One first step toward answering this question is to identify effective prevention strategies with respect to a specific problem. Narrative (e.g., Greenberg, Domitrovich, & Bumbarger, 2001) and quantitative (LeMarquand, Tremblay, & Vitaro, 2001) reviews of existing prevention programs are a good starting point. Meta-analyses are particularly useful because of the comparative statistics they generate in the form of effect sizes. As illustrated in Table 61.1, several meta-analyses of effective and ineffective prevention programs in different areas of adjustment have become available over the past decade. Above and beyond summary statistics such as the effect size, the usefulness of meta-analyses is to categorize original studies according to their theoretical background, methodological rigor, intervention components or participants’ characteristics.

Also useful in the identification of the most effective programs are the hit lists of best preventive programs prepared by different groups of researchers. One such list was prepared by the Center for the Study and Prevention of Violence (http://www.colorado.edu/cspv/blueprints). The first part of this list
includes 12 prevention programs considered “blueprints” according to a series of well-defined criteria. These programs mainly target substance abuse, aggression and delinquency. The second part of the list contains 16 programs that are considered promising.

In addition to narrative and meta-analytic reviews of prevention programs in one problem outcome area, some authors compared the results of several prevention programs across different problem outcome areas in order to identify key characteristics associated with successful programs that might transcend specific content areas. Nation, Crusto, Wandersman et al. (2003) identified nine principles after reviewing 35, mostly narrative, reviews of universal and selective prevention programs that targeted five problem areas: substance use, risky sexual behavior, delinquency, violence and school failure. Nation, Crusto, Wandersman et al. concluded that effective programs are:

1. Theory driven;
2. Appropriately timed;
3. Comprehensive;
4. Oriented towards opportunities for positive relationships;
5. Open to varied teaching methods;
6. Sufficiently potent with respect to dosage and duration;
7. Well integrated in delivery services;
8. Socioculturally relevant; and
These principles are illustrated and discussed further through the examination of a number of targeted prevention programs.

**Theory Driven**

Prevention programs need to rest on clear theoretical grounds and strong empirical evidence. To illustrate, promoters of Fast Track, a multicomponent multitarget TPI for low SES disruptive children and their caregivers, elaborated a clear theoretical rationale for every component of their program and attached each component to specific objectives with regard to risk and protective factors (Conduct Problems Prevention Research Group, 1992, 2004). Hence, each component was first justified by the important part played by that component in the etiology of conduct disorder (the distal outcome in this study). Each component was also justified by its evidence-based effectiveness. The six components were as follows:

1. Group parent training aimed at improving parenting skills and parent–child interactions;
CHAPTER 61

2 Home visits designed to ensure that parenting skills were implemented and to inspire feelings of confidence in parents;
3 Group-based social skills training with the children aimed at improving their social-cognitive skills;
4 Peer-pairing, in which a target child and a no-risk peer participated in guided play sessions designed to capitalize on positive modeling from the no-risk peer and to change the no-risk peer’s likely negative perception of the target child;
5 Academic tutoring designed to prevent academic problems; and
6 Teacher support for effective management designed to help reduce the general level of disruptive behaviors in the classroom. Despite the theoretical and empirical “cutting edge” nature of Fast Track, the evaluation results are at best moderate, with effects sizes varying between 0.2 and 0.5 for the children most at risk (i.e., above the 90th percentile on the disruptiveness screening scores) after the first 3 years. After 5 years (by age 11 or grade 5), 37% of the randomly assigned Fast Track children had no conduct problem dysfunction compared with 27% of control children (Conduct Problems Prevention Research Group, 2002). Interestingly, and importantly, mediation analyses indicated that these results were partially explained by gains in the domains targeted by the program (i.e., parenting, peer relations and social-cognitive skills). The most recent data available show that the children above the 90th percentile were significantly better off with respect to important outcomes such as a DSM diagnosis for conduct disorder, index criminal offenses and interpersonal violence, although the effect sizes remain moderate (Conduct Problems Prevention Research Group, 2005). To illustrate, 72% of the control children had committed an index crime by grade 10 compared to 28% of the intervention children (the percentages for conduct disorder and interpersonal violence were 14 and 43% in the control group versus 6 and 20% in the intervention group, respectively). However, for the lower-risk children (i.e., those between the 70th and the 90th percentiles), the differences between the two groups were non-significant.

 Appropriately Timed and Developmentally Sensitive
Preventive interventions should be initiated early enough to have an impact on the development of the problem behavior to be prevented. There is empirical evidence to suggest that the timing of a preventive intervention may be as important as its content. To illustrate, the Metropolitan Area Child Study Research Group (2002) randomly assigned schools to one of four conditions: a universal 2-year general classroom enhancement program, a universal general enhancement plus small-group peer skills training program, a universal general enhancement plus small-group peer skills plus family intervention, and a care-as-usual control condition. The authors also examined whether the results pertaining to aggressive behaviors and school achievement differed according to the timing of implementation (i.e., grades 2 and 3 only, grades 5 and 6 only, or grades 2, 3, 5 and 6). Globally, the results of this complex factorial study with the high-risk children (defined according to their baseline aggression scores) revealed that the most comprehensive condition produced the best results when aggression scores were examined. Specifically, the improvement in the behavior doubled when the initial 2-year intervention in grades 2 and 3 was followed by a second 2-year intervention in grades 5 and 6. Perhaps even more important, however, were the findings that none of the interventions were effective in preventing aggression when implemented only in grades 5 and 6. In fact, an iatrogenic effect was found whereby children in the control condition decreased in aggression whereas the intervention participants, particularly those in the small-group peer-skills training condition, did not.

Comprehensive
Because risk is multifactorial, prevention programs must include several components that address as many risk and protective factors in as many systems as possible in order to maximally influence development and the behaviors to be prevented. This rationale guided several of the most recent prevention programs described here (e.g., Fast Track and the Metropolitan Area Child Study) as well as older TPIs (e.g., the Cambridge Somerville Youth Study; McCord, 1978). The evidence in support of this intuitively logical principle, however, is inconsistent. Reid, Webster-Stratton, and Hammond (2003) and Webster-Stratton and Hammond (1997) compared different combinations of their Incredible Years Parent Training Program, their Incredible Years Teacher Program and their Child Training Program within a sample of 159, 4- to 7-year-old children with oppositional-defiant disorder (in order to prevent later conduct disorder, substance abuse and school dropout, which represent more serious outcomes than ODD) (for further material on parenting programs see chapter 64). More specifically, the authors randomly assigned the children to one of the following conditions: the parent program only, the child program only, the parent and teacher programs, the child and teacher programs, and the child, parent and teacher programs. These five conditions were compared to a waitlist control condition.

In the parent program only condition, the parents watched a series of 17 videotapes depicting ways parents can effectively manage problematic behaviors or situations with their children. The rationale, efficacy and content of these weekly 2-h group training sessions at the clinic are described in detail by Webster-Stratton, Mihalic, Fagan et al. (2001a).

The child program consisted of 18–19 weekly 2-h sessions with two therapists and 6–7 target children. Through the use of puppets, the therapists illustrated a series of interpersonal skills that are usually absent or in excess in ODD children’s repertoires. These included conflict resolution skills, negative attributions, perspective taking and empathy, complying with teacher or parent requests, and communicating and co-operatively playing with other children. In addition, parents and teachers were asked to reinforce the targeted skills (e.g., sharing, teamwork, friendly talk, listening, compliance with requests, feeling talk and problem-solving) whenever they noticed the child using them in the home or the school. Children were also given weekly homework assignments to complete with their parents. A more complete description of the videotape training curriculum and leader manuals is provided by Webster-Stratton (1990).
TARGETED PREVENTIVE INTERVENTIONS

The teacher program comprised 4 full days group training sequenced throughout the school year. Through illustrations and discussion, the teacher program promoted the use of praise and encouragement for positive behaviors, proactive teaching, using of incentives to motivate children, techniques to decrease disruptive behavior and collaborative strategies with parents. The teacher workshops also included topics such as prevention of peer rejection, acknowledgment of individual differences and strategies to prevent playground aggression. Two individual appointments with each teacher were scheduled to develop an individual behavior plan for the targeted child.

At the end of the 6-month intervention period, children manifested improvements in comparison to controls that were consistent with the treatment condition. Hence, children in the three conditions with the child program showed more prosocial skills with peers than the children in the control condition. No difference between treatment and control was observed for children in the two conditions without the child program. Similarly, parents in the three parent program conditions manifested less negative and more positive parenting and reported fewer child behavior problems than parents in the control condition and parents in the two conditions without parent training. Children’s behavior problems at school were reduced for those whose teacher participated in the teacher program relative to the control children. Overall, the conditions that included all three programs produced the best results after 6 months.

However, at 2-year follow-up the results were less clear-cut. Teachers reported an equal proportion of children with behavior problems across all five treatment conditions (i.e., around 50%). Parents in the parent + teacher programs reported fewer cases of behaviorally disordered children relative to only one other condition – the parent program only condition. Unfortunately, the waitlist control group was not available for comparison at the 2-year follow-up.

Results from the Early Risers program (August, Egan, Realmuto, & Hektner, 2003; August, Realmuto, Hektner, & Bloomquist, 2001) further illustrate the lack of evidence in support of the notion that more is necessarily better in the context of a TPI. In their first study, August, Realmuto, Hektner et al. (2001), August, Hektner, Egan et al. (2002) implemented a 2-year program aimed at altering the developmental trajectories of young children with early-onset aggressive behavior. The Early Risers multicomponent program included five CORE components: a child social skills group training that used Webster-Stratton, Mihalic, Fagan et al.’s (2001a) protocol, a parent education and skills training program that also used the parent training protocol of Webster-Stratton et al., a teacher behavior management program, a student mentoring program focused on academic learning and an annual 6-week summer school program that included non-targeted children. In addition, it also included a FLEX family support component tailored to address the unique needs of families. Intent-to-treat analyses revealed that, compared to controls, program participants showed greater gains in academic functioning. The most severely aggressive children, but not the others, also progressed on measures of self-regulation.

In a second study, August, Egan, Realmuto et al. (2003) tested whether the FLEX component increased the impact of their program as expected. The authors randomly assigned a new group of aggressive children and their families to three groups. One group received both the CORE (applied in the same manner to all participants and their families) and the FLEX (tailored to families’ specific needs) components of their Early Risers program. The second group received the CORE component only. The third group received care as usual. Implementation results showed that CORE + FLEX participants attended more program sessions than their CORE-only counterparts. However, the two experimental conditions did not differ from each other in reducing children’s disruptive behaviors and parents’ levels of stress, although both were superior to the care-as-usual condition; these results suggest that the FLEX component, although intuitively appealing, did not seem to improve upon the basic CORE program.

Consistent with the idea of creating a synergy between different prevention components, one strategy that might optimize the effects of a TPI is to combine targeted and universal components within the same program. Fast Track illustrates how such a combination of targeted and universal components can be achieved (Conduct Problems Prevention Research Group, 1999b). In addition to the six targeted components already described, a series of socioemotional skills training sessions (i.e., the Promoting Alternative Thinking Strategies or PATHS curriculum; Greenberg, Kusche, Cook, & Quamma, 1995) were implemented in the classrooms of participating children. The PATHS lessons were intended to teach all the classroom children such social and personal skills as self-regulation, emotional awareness and social problem-solving.

Combining universal and targeted prevention components in a single program may be more likely to mobilize and prepare the child’s whole social environment, changing the local norms for appropriate behavior. These positive changes in social norms may support the positive changes that the targeted components can achieve with the at-risk children, promoting their maintenance and generalization to other contexts. Combining universal and targeted prevention also ensures that the “false negative” cases (i.e., children not considered at-risk who will nevertheless develop a problem) receive minimal preventive help through the universal component. Similarly, combined programs minimize the “Matthew effect” (Ceci & Papierno, 2005). The term “Matthew effect” refers to the possible outcome of a universal intervention in which children who are not at risk benefit more from the intervention than do those at risk, thus increasing the gap between the two groups. However, these are only speculations because to our knowledge no author has compared the results of a combined program with a TPI only or UPI only program.

Sufficient Dosage and Intensity
A related issue is the necessary and sufficient dosage and intensity of a TPI. Dosage and intensity refer to aspects of a TPI
CHAPTER 61

such as length and number of sessions, spacing of sessions and the duration of the total program. Most prevention programs offer all-or-none packages in which some children receive every component of an intervention and other children receive no treatment or treatment-as-usual. However, we believe that dosage of a program should be gauged to the level of risk faced by the targeted individuals or groups and program content should match the nature of the risk factors faced by those individuals or groups. Hence, different groups of at-risk individuals may require different combinations of program components. Ideally, preventionists should develop programs with different modules that address specific risk/protective factors. For example, a child at high risk for a certain problem outcome may receive modules A, B, C and D whereas another child at a lower risk level may receive only modules A and B. Alternatively, as in the Early Risers program, a basic package can be complemented with supplementary activities tailored to the participants’ needs. Another strategy is to train to criterion (i.e., until a desired threshold is reached).

Also of concern are the questions of when to start a TPI and for how long the TPI should last. These are important questions at the clinical, practical and financial levels that have not been addressed adequately until now. As a result, a wide variety of prevention programs of varying lengths have been devised to target the same risky outcomes. Among the prevention programs that start at birth and target children from disadvantaged families, some last for a period of 2 years (e.g., home visiting program; Olds, Eckenrode, Henderson et al., 1997) and some for periods of 4 years (e.g., Sure Start, a large-scale preventive program currently deployed in the UK for young children in disadvantaged areas and their families; National Evaluation of the Sure Start Team, 2004). Similarly, among prevention programs that advocate high-quality child-care during the preschool period for at-risk children, some cover a period of 2 years (e.g., from age 3 to age 5 in the Perry Preschool Project; Schweinhart, Barnes, & Weikart, 1993), whereas others cover periods twice as long (e.g., from age 1 to age 5 in the Abecedarian Project; Campbell & Ramey, 1995). Finally, programs targeting schoolchildren or early adolescents with behavior problems vary from 12 weeks (Dishon & Andrews, 1995) to 6 months (Webster-Stratton, Reid, & Hammond, 2001b), 1–2 years (e.g., Early Risers; August, Realmuto, Hektner et al., 2001) or a decade (e.g., Fast Track; Conduct Problems Prevention Research Group, 2002). Some programs include booster sessions at transition periods (e.g., Early Alliance; Dumas, Prinz, Smith, & Laughlin, 1999), others do not.

More importantly, the reasoning behind the prevention researchers’ choice of program duration and timing is often missing or unsubstantiated. Indeed, the only way to identify the most effective length and timing of a prevention program is through studies that compare different durations and different starting points with similarly at-risk children. Very few studies of this type are currently under way. Meta-analytical reviews that examine intervention dosage or timing as potential moderators of the impact of a prevention program offer a temporary alternative to clarify this question. The results of such reviews are not always in accordance with what one might expect. For example, a meta-analysis of the impact of 70 attachment-based interventions designed to improve maternal sensitivity (a known risk factor for later adjustment problems) concluded that the most effective interventions last between 5 and 16 sessions and are applied during the second half of the first year of life, when problems become visible but problematic child–parent relationships are not yet firmly established (Bakermans-Kranenburg, van IJzendoorn, & Juffer, 2003). Thus, effective interventions need not last many years — but they do need to be intensive and well timed.

Until experimental manipulations of timing and duration through factorial designs become available (i.e., experimental conditions × dosage or duration), some interventionists rely on dosage–effect analyses or instrumental variables to extract as much information as possible from their studies (Angrist, Imbens, & Rubin, 1996). It is important to keep in mind that these strategies use quasi-experimental designs and their results should be interpreted with caution. This comment also applies to results from meta-analyses.

Modes of Intervention and Teaching Methods

The necessary dosage and intensity of a TPI to achieve a goal can depend on the quality, effectiveness and appropriateness of the modalities used to implement the desired changes. Tobler, Roona, Ochshorn et al. (2000) concluded their meta-analysis on school-based drug use prevention programs by stressing that interactive programs were more effective than non-interactive lecture-oriented programs. Actually, non-interactive programs were ineffective, with average effect sizes of about 0.10. This finding suggests that effective prevention programs involve interactive teaching methods, such as role-playing, corrective feedback, instructions and modeling, and active learning of the desired skills. Such a strategy seems more likely to ensure that actual behaviors are learned — in addition to changes in knowledge and perceptions — by facilitating generalization from the training sessions to the real world.

Other researchers have found that teaching methods and modalities for change significantly impact a program’s ability to achieve the desired objectives. For example, in their meta-analytical review of programs designed to prevent delinquency, Farrington and Welsh (2003) noted that the programs that use behavioral parent training (similar to Webster-Stratton’s parent program) are the most effective, with a mean effect size of 0.40. The least effective types — with a mean effect size of 0.07 — are based solely in schools. These authors also found that home visiting, day care/preschool, home/community and multisystemic therapy programs tended to be modestly effective, with mean effect sizes in the mid 0.20s.

Ensure Potent Causal Mediators Are Set in Motion

It is indeed important that by the end of a program, mediating processes have been triggered that will ensure the maintenance, and possibly the progress, of behavior change. The Urban Institute’s Children at Risk program (Harrell, Cavanagh,
TARGETED PREVENTIVE INTERVENTIONS

Harmon, Koper, & Sridharan, 1997; Harrell, Cavanagh, & Sridharan, 1999) serves to illustrate this point. Children at Risk targeted high-risk early adolescents from poor neighborhoods in five cities across the USA in an effort to prevent delinquency. The program included case management and family counseling, family skills training, academic tutoring, adult mentoring, after-school activities and community policing. In addition, the components of the program could be adjusted depending on the specific risk factors in each neighborhood in accordance with the adaptive prevention approach described earlier (Collins, Murphy, & Bierman, 2004). To explain the weak and inconsistent results reported at both post-intervention and at a 1-year follow-up with respect to delinquent behavior, the authors noted that few individual, family and community factors were changed, although some peer-related factors were (i.e., program youth affiliated with less delinquent peers and had more positive peer support). If affiliation with deviant peers were the only causal risk factor or mediator of risk factors for delinquency (i.e., both necessary and sufficient), then the Urban Institute’s Children at Risk program should have been successful at preventing delinquency even if it failed to influence other important risk factors. As suggested by most prominent theoretical models of delinquency, deviant peer affiliation is not likely to be the only causal risk factor for this outcome (for the possible role of deviant peers in delinquency see Vitaro, Tremblay, & Bukowski, 2001b). Therefore, it may prove important to trigger the necessary (i.e., potent and causal) and sufficient mediators identified in prominent developmental models in order to impact on an outcome at the endpoint of a long developmental chain formed by a series of mediators. Vitaro, Brendgen, and Tremblay (2001a) showed that delinquent behaviors could be prevented in their high-risk sample of low SES, disruptive boys provided that several mediators – each of which corresponded to the proximal objectives of their targeted preventive program – were changed. These mediators included the child’s disruptiveness, parental supervision, academic performance and deviant peer affiliation.

The difficulty of triggering the important mediators (which often correspond to the proximal objectives of a TPI) may explain some of the so-called “sleeper effects” that seem to characterize some TPIs. One TPI in which sleeper effects were observed was the Queensland Early Intervention and Prevention of Anxiety Project. This program targeted anxious schoolchildren who did not yet reach the threshold for a clinical disorder (Dadds, Spence, Holland, Barrett, & Laurens, 1997). The program included 10 weekly group training sessions at school. Through modeling and behavioral rehearsal, the children were taught cognitive–behavioral coping strategies to overcome anxiety-arousing situations. They were also taught relaxation techniques to counteract their physiological discomfort. The parents of the anxious children were also taught how to support their child in the use of the coping strategies and how to use similar coping strategies to face their own anxiety. This short-term TPI, which also involved homework for both children and parents, may have required prolonged practice of the new coping skills by both parents and children before producing its optimal effects. Indeed, the experimental children differed from their control counterparts on a series of child- and parent-rated measures not at the immediate posttest but only at later follow-ups. At the 6-month follow-up, only 16% of the experimental group manifested anxiety problems, compared to 54% of the control group. Significant differences were again observed at the 1- and 2-year follow-ups (Dadds, Holland, Laurens et al., 1999).

Well-Coordinated and Integrated Prevention Services

To ensure effective change on as many potent causal risk or protective factors as possible, comprehensive multimodal prevention programs rely on different categories of prevention agents (e.g., school personnel, childcare workers, physical and mental health professionals, nurses, community leaders, policymakers). As a result, the programs should rest on a well-coordinated and integrated prevention delivery infrastructure. The Nurse Home Visitation program, first developed for the Elmira project (Olds, Henderson, Tatelbaum et al., 1986; Olds, Henderson, Kitzman et al., 1998), is a good example of a program with such an infrastructure. In this program, a nurse visits primiparous pregnant women who have a high-risk profile. Specifically, the pregnant women are young, unmarried and poor. Nurses visit the women approximately 32 times between 24 weeks’ gestation and the child’s second birthday. Nurses give support to the mothers in three areas of their life:

1. Personal development, including education, workforce integration and family planning;
2. Health-related behavior, including smoking prevention and adequate nutrition for the mother and child; and
3. Competent care of the child.

The nurses also link mother and child with community services. This program has been shown to reduce child abuse and neglect (Olds, Henderson, Tatelbaum et al., 1986) as well as maternal and child delinquency. This program has also revealed the importance of a well-trained clinician to the effectiveness of a prevention effort. In a randomized controlled trial, nurses were found to have significantly greater impact on most of the outcomes studied than trained paraprofessionals. The outcomes ranged from reduced smoking in pregnancy and increased workforce integration among the mothers, to improved emotional and cognitive development among the children (Olds, Henderson, Kitzman et al., 1999).

Socioculturally Relevant and Engaging

Prevention programs need to be tailored to the cultural norms of the participants and the community (for a violence prevention program that specifically addresses cultural diversity see Alkon, Tschan, Ruane, Wolff, & Hittner, 2001). Community representatives should be consulted when planning the objectives and the implementation of a prevention program. The content of the program and the strategies used to ensure implementation may also need to be adjusted to the local norms. Interestingly, models and methods for cultural adaptation of empirically based prevention programs are available (Martinez, 2006).
Social Acceptability and Cost-Effectiveness

Finally, to ensure that prevention programs become part of standard practice and are disseminated, they need to be acceptable to – or even desired by – potential recipients and practitioners. They should also be cost-effective. These last two issues are discussed next.

Practical and Sociopolitical Issues

Strategies to Mobilize Program Recipients, Program Deliverers and Decision-makers

The most effective prevention program is useless if it is not attractive to program recipients or if it is not adopted into everyday practice by program deliverers (for a discussion of these topics in relation to treatment see chapter 18). Indeed, one challenge of preventive interventions, compared to curative interventions, is to engage eligible participants not just during an evaluation trial but also during widespread implementation. Several groups of researchers have noted that, in general, recruitment and retention rates for targeted preventive intervention trials are low, often below 50% (Coe, Underwood, & Lochman, 1991; Fontana, Fleishman, McCarton, Meltzer, & Ruff, 1988; Garvey, Wrenetha, Fogg, Kratovil, & Gross, 2006). Low participation has important consequences for efficacy and effectiveness demonstration trials. First, low participation is a threat to external validity because little or no information is usually available on non-participants. Second, low participation can result in a Matthews effect in which the less at-risk cases benefit more from the program than those at higher risk because the former tend to participate more than the latter (Ceci & Papierno, 2005). Third, low engagement may result in a highly selective sample of participants. This decreased diversity in the sample makes it more difficult to identify participant characteristics that amplify or attenuate the impact of a preventive intervention (i.e., moderators). Fourth, low participation can seriously limit the statistical significance of program effect size in the context of an intention-to-treat analysis. Such an analysis includes all of the assigned participants, regardless of level of participation. Finally, low participation rates (often compounded by low retention rates) may threaten the utility of the program as a tool for social change because sustained funding may not be achieved without a critical mass of participants. Therefore, as stated by Mrazek and Haggerty (1994), “A plan to successfully engage and retain targeted participants is needed.”

Because of their key role in most prevention programs targeting child behavior, either as active participants or legal guardians of their children, parents should be at the center of this plan to engage participants. The key role of parents has been acknowledged by many of the successful or promising TPIs reviewed here. Indeed, almost all TPIs that target the prevention of externalized (i.e., violence, delinquency, conduct disorder, school dropout) or internalized (i.e., anxiety) problems include a parent-targeted program component, which is considered the most effective strategy to date (Kazdin, 1985).

In contrast, few TPIs that target children and adolescents at risk for major depression (either because of their preclinical levels of depressive symptoms or their experience with divorce or death of a family member) include a parent-targeted component. Most TPIs for major depression adopt a cognitive–behavioral approach to teach youths coping strategies in 10–15 group sessions (e.g., Coping with Depression Course for Adolescents: Clarke, Hawkins, Murphy, & Sheeber, 1995; Penn Prevention/Resiliency program: Cardemil, Reivich, Beavers, Seligman, & James, 2007; Jaycox, Reivich, Gillham, & Seligman, 1994; Cognitive Psychoeducational Intervention program: Beardslee, Salt, Porterfield et al., 1993). The few depression prevention programs that target parents tend to devote only a few sessions to this program component (e.g., three information meetings with the parents in the Clarke, Hornbrook, Lyn et al., 2001, study). Not surprisingly, the effect sizes observed in most depression prevention programs are considered modest by current standards (with values in the low 0.30s at the immediate post-test and in the low 0.20s at follow-up). Similarly, the few TPIs intended to prevent suicide in at-risk individuals also rarely incorporate a parental or family component (Eggett, Thompson, Herting, & Nicholas, 1995; LaFromboise & Howard-Pitney, 1995). The results of these studies are even more mixed and inconclusive than in the case of TPIs to prevent depression.

Still, programs that include a parent component are not always successful in actually engaging parents. Hence, given that a parent component seems desirable, knowledge of how to successfully engage parents is needed. This knowledge can be derived from three sources:

1. Studies that examine the factors predicting engagement and perseverance in a prevention program;
2. Narrative or meta-analytical reviews that compare studies that address similar problems but result in different recruitment or retention rates; and
3. Studies that experimentally manipulate factors in order to directly examine the causal impact of those factors on recruitment and retention rates.

A combination of efforts in these three areas has revealed a number of factors that predict engagement and retention. These factors can be grouped into five categories. The first category is comprised of sociodemographic factors. The empirical evidence regarding this category is mixed. Some studies report that ethnicity, socioeconomic adversity and child age influence recruitment and retention whereas other studies do not (Holden, Lavigne, & Cameron, 1990; Prinz & Miller, 1994).

Still, and although sociodemographic factors cannot be manipulated directly, these factors can have a key role through careful and strategic matching of participants’ and trainers’ characteristics. For example, using nurses to recruit young parents with a history of conduct disorder into a prevention program may be less threatening to the parents than using social care workers.

The second category of predictors includes parents’ beliefs about child behavior problems and about the benefits the child will derive from participating in a prevention program. More
specifically, the parents’ perception of the benefits the child will receive from a prevention program is influenced by the parents’ perception of the prevalence of the targeted problem and the likelihood that their child might experience that problem. These perceived benefits, in turn, predict the parents’ enrollment in the program (Spoth & Redmond, 1995). Therefore, focusing a prevention program too narrowly on one specific problem may not attract many parents. First, the parents may think that their child is not at risk (even if they acknowledge that prevalence rates are high). Second, parents may think that they can deal with the problem themselves. Without alarming them unnecessarily, parents may need to be informed of their child’s level of risk (if that child is facing many or more severe risk factors) and that the prevention program may help the parents with their own preventive efforts. In order to maximize parents’ motivation to participate in a prevention program, some authors offer a self-screening questionnaire with respect to risk and protective factors. Dishion, Nelson, and Kavanagh (2003) use a “Family Check-up” assessment to enhance parents’ motivation by providing them with feedback about the strengths and the weaknesses of their parent–child relational strategies and their child’s functioning as well as a menu of intervention strategies from which to choose.

Once a child and his or her parents are involved in a prevention program, retention is predicted by the extent to which the participants benefit from the program. Improvement in the child’s behavioral repertoire during the first months of a multimodal prevention program for disruptive boys predicted which families would remain involved in a 3-year prevention program and which families would drop out before the end of the first year (Charlebois, Vitaro, Normandeau, & Rondeau, 2001).

Another aspect to consider with respect to parents’ beliefs is whether the parents deem the prevention strategies and targeted behaviors to be appropriate. Spoth, Ball, Klose, and Redmond (1996) used “conjoint analysis” (i.e., a marketing data collection strategy designed to tap into consumer choices and needs) to examine parents’ preferences for different intervention strategies (e.g., child-only, family-only or combined child–family skills training) and different practical arrangements (i.e., home visits vs. group meetings, weekdays evening sessions vs. weekend sessions). Interestingly, Spoth, Ball, Klose et al. found that different clusters of parents preferred different arrangements and different strategies. Notably, some parents were open to address personal and sociofamilial issues whereas others were focused mainly on the child’s problems.

Using an experimental approach, Miller and Prinz (2003) also found that assignment to a treatment condition that did not match parents’ motivations and expectations was predictive of premature termination. More specifically, premature termination was higher in a parent-only treatment condition than in child-only and combined parent–child conditions. Prinz and Miller (1999) have also shown that adding supportive discussions not directly related to child behavior to a series of parent training sessions targeting children’s disruptiveness resulted in less attrition than focusing exclusively on parenting and parent–child interactions during the sessions.

The third category of factors affecting engagement and retention of participants represents practical barriers to participation, including the scheduling of program activities. In general, flexibility in program delivery has been found to be related to retention rates (Prinz & Miller, 1996; Weiss, Weiss, Allice, & Klotz, 1987). Of special interest is whether home delivery of services produces better engagement and recruitment than flexible out-of-home services. Unfortunately, no study has directly compared the two strategies. However, the relative effectiveness of these two strategies in enhancing participation and retention may vary depending on the child’s age (e.g., newborns vs. early adolescents) and parent characteristics. Facilitating participation by offering transportation, daycare services for the target child and any siblings, or supplementing training sessions for the target child with fun activities may help overcome resistance if the out-of-home delivery service is chosen.

Another critical element with respect to participation and retention is the temporal spacing of the prevention activities. If program activities are spaced too far apart, participants may lose interest in the program. Activities spaced too close together may lead participants to feel overloaded. For example, during the Fast Track trial, parents “rebelled” during the third year when session spacing was changed to once every 3 months from once a week during the first year and twice a month during the second year. Based on parents’ reactions, the Fast Track researchers reinstituted more frequent sessions of once a month. In addition, potential recipients who feel that they do not need some program components may refuse participation or become bored and withdraw from the study. In this situation, a differential approach to the spacing and number of sessions – similar to the adaptive approach described above (Collins, Murphy, & Bierman, 2004) – may increase compliance and retention of participants.

Parents’ characteristics are another important category of factors that may affect participation in prevention programs. There is empirical evidence showing that fathers are less inclined to participate in prevention programs than mothers (Spoth, Ball, Klose et al., 1996). In consequence, some authors tried to compensate for parents’ low motivation by offering incentives in the form of tangible rewards, such as money and meals (Conduct Problems Prevention Research Group, 2002; St. Pierre, Mark, Kaltreider, & Aikin, 1997; Webster-Stratton, Mihalic, Fagan et al., 2001a), or social rewards, including giving parents a role as co-therapists or co-trainers (Conduct Problems Prevention Research Group, 2002; Cunningham, Bremner, & Boyle, 1995; St. Pierre, Mark, Kaltreider et al., 1997).

The final category of factors that might affect participation refers to the manner in which and the moment at which parental participation is requested. Personalized recruitment seems more effective than a generic and impersonal approach (Schlerntzauer, Bierhals, Geary et al., 1998). Even the manner in which the initial invitation to participate is formulated may affect participation. Spoth and Redmond (1994) compared two different letter solicitation strategies for recruiting families
CHAPTER 61

of early adolescents to participate in a family-based drug prevention program. In one strategy, families were invited first to participate in an assessment session and next to the full program. In the other strategy, the families were offered full participation right away. Not surprisingly, the first strategy produced higher retention rates. Linking the program to an official and respected institution may also increase its credibility and, consequently, enhance participation rates of parents as well as of prevention service deliverers (i.e., teachers and mental health professionals). Promotion of the program by esteemed persons or the media may also help increase the participation of key stakeholders. Finally, the description of the program's objectives is also important. Because most prevention programs, including the targeted ones, focus at least as much on promoting skills and opportunities as on reducing risk factors, the objectives should emphasize health and competence promotion.

The timing of the offer to become involved in a prevention program may also affect participation. Transition periods may be particularly good points of entry because of the anxiety and the uncertainty experienced by many parents and children at these times of change. Some transition periods at which interventions are commonly directed include the birth of the child, beginning of preschool, transition to high school and transition to adulthood. Other, less normative experiences may also be considered important transitions (e.g., divorce of parents). Finally, it is essential that the recruiters and trainers possess appropriate skills and knowledge of the targeted families' cultural and linguistic backgrounds. The recruiters and trainers should also establish a positive bond with the families. Low staff turnover may help ensure such a positive bond (Prinz, Smith, Dumas et al., 2001).

In sum, many of the factors reviewed here are controlled or influenced by the individuals responsible for the prevention program. However, although participation rates may be dramatically affected by such factors, the experimental studies that have assessed the impact of these factors on participation remain scarce. Indeed, rates of engagement and retention should be included among the outcomes assessed in any prevention program.

How to Optimize Cost-Effectiveness

One important argument often used in support of prevention is its cost-effectiveness in comparison to treatment (for a description of cost-effectiveness analysis see chapter 10; Chatterji, Cafray, Jones, Lillie-Blanton, & Werthamer, 2001). However, effective prevention programs addressing psychoemotional problems are not cheap. Indeed, most prevention programs for high-risk individuals or communities need to target several domains of functioning (i.e., different systems) and deploy different intervention strategies over several years to hope for more than modest effect sizes (for an overall consideration of issues of service planning see chapter 71; Greenberg, Domitrovich, & Bumbarger, 2001; Yoshikawa, 1994).

One way to reduce the cost of a prevention program is to deliver as many components as possible, such as parent and child training sessions, in a group format. Such a strategy has resulted in at least one cost-effective program – a prevention program for adolescents at risk for major depression (Clarke, Hornbrook, Lynch et al., 2001; Lynch, Hornbrook, Clarke et al., 2005). Notably, the cost-effectiveness of this TPI was comparable to most treatments for adult depression.

Still, there is a risk that the economy of scale that results from group sessions may impact adversely on the program’s effectiveness. Ang and Hugues (2002) concluded their meta-analysis by showing that individual social skills-training sessions are more effective in teaching social skills to children than group sessions, probably because of the additional attention a child receives and the additional opportunities to practice the learned skills. Moreover, prevention programs that aggregate at-risk children, such as those with externalizing problems, appear less effective than programs that mix at-risk children with prosocial peers. Group interventions that aggregate only at-risk children may even result in iatrogenic effects through a process known as deviancy training (Boxer, Guerra, Huesmann, & Morales, 2005; Dishion, McCord, & Poulin, 1999; Dodge, Dishion, & Lansford, 2006). However, iatrogenic effects do not invariably result from aggregating at-risk individuals because deviancy training depends on a host of circumstances, including the children’s age and trainer’s competence (Gifford-Smith, Dodge, Dishion, & McCord, 2005).

Another strategy to reduce costs during the training and the implementation phases of a prevention program is to manualize the program components as much as possible (van de Wiel, Matthys, Cohen-Kettenis, & van England, 2003). However, it is important that the staff do not lose track of the theoretical principles behind the intervention, as was the case in an unsuccessful dissemination effort of the Prenatal/Infancy Project (Olds, Henderson, Tatelbaum et al., 1986), which had been found to reduce abuse and promote health in children on many previous occasions.

If costs cannot be reduced without negative consequences, then either efficiency or effectiveness – or possibly both – need to be improved. Efficiency refers to the ability to produce optimal effects with the available resources and time. The adaptive approach is one promising strategy to increase efficiency. The resources saved when less at-risk participants receive fewer program components can be transferred to those who have greater need. This increases the potential for optimal impact with the available resources – and may even reduce costs relative to a fixed approach in which all participants receive all components (Collins, Murphy, & Bierman, 2004). There are no studies manipulating dosage or comparing an adaptive approach to a fixed approach.

Effectiveness may be increased in at least two ways. First, effectiveness may be enhanced by adding new innovative intervention strategies (such as Fast Track’s peer pairing and academic tutoring components) to more traditional prevention strategies (such as parent training and social-cognitive skills training). Second, combining a universal with a targeted approach may also improve the targeted program’s effectiveness. Adding new prevention components, such as the innovative
components or a universal component, makes sense only if they target risk or protective factors not already targeted by the more traditional components. In other words, it is important to avoid redundancy and increase coverage of new targets such that enough – and the most potent – risk and protective factors are modified. This, in turn, increases the probability of enhanced effect sizes and notable and durable benefits.

Another aspect to consider in cost-effectiveness analysis is whether a prevention program is capable of helping the most at-risk and most costly cases. In the area of disruptive behavior, longitudinal studies have found that 3–10% of the children displaying conduct problems account for at least half of all adolescent and adult crimes (Moffitt, 1990; Nagin & Tremblay, 1999; Stattin & Magnusson, 1991). Each individual persistently involved in crime represents a $2 million lifetime cost (in today’s dollars) to society (Cohen, 1998). This cost does not even include the expenses related to the collateral problems – such as a failure to complete high school and pathological dependence on substances – for which this small group of children is also at higher risk. To develop a full and accurate picture of the cost-effectiveness of a prevention program, investigators should include the cost of all possible problems that the program could prevent. Costly but moderately effective (i.e., effects size of 0.20–0.50 in the short term) prevention programs that impact on the most extreme cases, such as Fast Track, then seem particularly cost-effective (Foster & Jones, 2006). Cost-effectiveness analysis of a number of other targeted prevention programs, such as the Coping Power Program for aggressive children (van de Wiel, Matthys, Cohen-Kettenis et al., 2003) or the Perry Preschool program for disadvantaged children and their families (Barnett, 1985; Schweinhart, Barnes, & Weikart, 1993) shows that these also appear to be cost-effective.

Importance of Dissemination, its Challenges, and Some Possible Solutions

Large-scale dissemination of evidence-based and cost-effective targeted prevention programs is important. The essential prerequisite before dissemination is a strong test of the program’s validity and efficacy. Lists of model programs that are ready for large-scale implementation are available. However, given the diversity of prevention programs, even among programs targeting the same outcome, direct comparisons between competing prevention programs are needed in order to determine which is most cost-effective. Second, it is essential to replicate the original (effective) prevention programs in different socio-economic contexts and different cultures in order to identify the program’s limits. Such replications may also explain why the results of evidence-based interventions are often not as strong when disseminated to real-world settings (i.e., the so-called “effect erosion” problem; Lochman, 2001). To address the problem of “effect erosion” when going to scale, preventionists should conduct both efficacy and effectiveness trials for any given program. Contrary to efficacy trials, in which the “maximum” impact of a prevention program is assessed under optimal conditions, an effectiveness trial evaluates the “true” or actual impact of a prevention program under real-world conditions. Both are important preliminary steps that should be taken before large-scale implementation occurs. Only when both efficacy and effectiveness are assessed is it possible to understand the conditions that produce the maximum impact of the program.

Performing both efficacy and effectiveness trials may reduce – but not necessarily eliminate – the risk of inadequate dissemination. In order to further reduce or eliminate this risk, researchers need to turn their attention to what Dodge (2001) referred to as the science of dissemination towards practitioners and policy-makers. Elliott and Mihalic (2004) listed a six-step process for achieving successful dissemination of a prevention program: select the sites that are ready, train the practitioners, provide them with technical assistance, monitor and reflect on program fidelity, and assure sustainability through continuous funding and permanent changes in the service delivery system. Other researchers examined the ways to make scientific knowledge more usable and used more frequently by policy-makers and practitioners (Dodge, 2006; Huston, 2005). Among the proposed strategies is the use of the media through press releases or public briefings presenting research findings that are likely to be of interest to the public. Another interesting strategy is to create two-way communication forums in which policy-makers, practitioners and researchers share and debate their research questions, methodologies, cost-benefit analyses and conclusions. Research questions should be framed in such a way that evaluation results will clearly inform about:

1. The chain of factors that lead to change in at-risk individuals or communities;
2. The most cost-effective intervention strategies; and
3. Moderators of program effectiveness.

Conversely, preventive intervention evaluation results may also aid researchers in refining the theoretical models that served as the foundation for that intervention.

How Preventive Interventions can Inform Theory

TPIs can help to clarify the role of the risk and protective factors and processes that were initially selected as proximal outcomes or putative mediators of the intervention effects. They can also help to identify new factors that, although not targeted initially, may have an important role with respect to the program’s impact. Finally, TPIs can help to validate the principles for change that were used to guide the development of the intervention strategies. Hence, a TPI evaluation can illuminate the theory behind the development of the problem to be prevented and the theory behind the process leading to more positive outcomes (Cicchetti & Hinshaw, 2002).

To illustrate, Vitaro, Brendgen, & Tremblay (2001a) showed that the Montreal longitudinal prevention program targeting young low SES disruptive boys achieved its impact on later delinquency in two ways. First, the program improved children’s behavioral repertoire and parental supervision (i.e., proximal effects). Second, the program reduced affiliation with deviant peers and school problems (i.e., intermediate effects).
More specifically, improved social competence and parental supervision and reduced affiliation with deviant friends and school problems mediated, in a two-step sequential process, the impact of the prevention program on later delinquency. These findings enhance the plausibility that these mediators have a causal role in the chain of events leading disruptive boys to become involved in delinquency. They also point to the importance of targeting these mediators through booster sessions if necessary. However, most TPIs cannot clearly establish the causal role of risk factors because more than the putative mediators may have been triggered by the prevention program (Howe, Reiss, & Yuh, 2002). One solution to this problem would be to specify and measure all relevant mediators and control for their effects, a task rarely achieved or even achievable.

TPIs can also contribute to developmental models of psychopathology in other ways. Prevention programs can help uncover or verify mechanisms of influence, even when the programs result in iatrogenic effects. Dishion, Spracklen, Andrews, and Patterson (1996) used an experimental design to determine that a group-based social skills prevention program resulted in iatrogenic effects. Dishion, Spracklen, & Andrews et al. were able to confirm the causal role of deviancy training (discovered earlier through the coding of the interactions between the participating at-risk adolescents and their friends in the context of a correlational study). Deviancy training results from positive reinforcement through laughter or positive nonverbal feedback of rule-breaking talk and deviant acts as well as from ignoring or punishing normative behaviors through principles of operant conditioning.

**Conclusions and Future Directions**

To conclude, we offer suggestions for the next generation of TPIs.

Through narrative or quantitative reviews (i.e., meta-analysis) of prospective longitudinal studies, we need to establish more clearly which risk and protective factors should be used to identify individual levels of risk and categories of at-risk individuals. We favor an interactional approach over a cumulative approach. We also believe that more than two groups exist (i.e., more than simply the at-risk and the low-risk groups), although the number of relevant groups may depend on the type of outcome considered and a host of other factors.

Through narrative and quantitative reviews, we need to identify the best prevention practices and program models that match the evolving criteria for efficacy, effectiveness and dissemination. The Society for Prevention Research (2004) proposed a series of clear criteria with respect to each of these three elements that can serve as guidelines, although these criteria are likely to evolve over the coming years. The Institute of Medicine Committee on Prevention of Mental Disorders (Mracek & Haggerty, 1994) has also issued a seven-level scale to judge the quality of a prevention program from the characteristics of that program’s evaluation protocol.

Studies that compare different versions of the same program are needed (i.e., programs that differ with respect to the number of components or duration of the intervention). After experimenting with single or bimodal prevention programs during the 1980s (often social skills and/or family-based programs), prevention scientists started experimenting with multimodal comprehensive programs during the 1990s (e.g., Fast Track). These programs were often compared only with a control condition, a strategy that was well-justified at the time (Coie, Miller-Johnson, & Bagwell, 2000). However, we believe the time has come for factorial designs in which different sets of components, different durations or different programs are compared, taking into account their possible interactions with participants’ characteristics and contextual factors (i.e., moderators). This factorial approach would help refine and possibly increase the power of current and future prevention programs in an optimal cost-effective manner by identifying necessary and sufficient components or important new elements of those programs. Indeed, it would be interesting to see whether targeted prevention programs that are embedded in universal prevention programs bring the multiplicative effects expected in comparison to targeted-only or universal-only programs. It would also be interesting to compare an adaptive approach (Collins, Murphy, & Bierman, 2004) to a fixed approach. Such a comparison could be achieved by comparing two randomly assigned groups of participants: one receiving a fixed dosage of a preventive package and one receiving different combinations and different dosages of the same package. However, costs and resources should be kept equivalent across the two conditions or be taken into account when comparing effect sizes. A randomly assigned no-intervention/care-as-usual control group could also be included. Small-scale experimental studies that compare the efficacy of different modes of intervention or teaching methods to achieve specific desired goals, both with respect to process variables and with respect to outcomes, are also needed. These experimental studies will advance our knowledge about effective strategies for change and their underlying theoretical principles.

Programmatic comparative studies are also needed to explore the most effective strategies to engage and retain potential participants, practitioners and decision-makers. The science of prevention took form during the past decade. Currently, a science of dissemination and social policy-making is taking form (Huston, 2005). In order to ensure that the best programs are disseminated and form the basis for social policy, valid and convincing cost-effectiveness studies need to be conducted. Luckily, more and more such studies are available (Foster & Jones, 2006; Lynch, Hornbrook, Clarke et al., 2005; van de Wiel, Matthys, Cohen-Kettenis et al., 2003; see also Cuijpers, 2003; Romeo, Byford, & Knapp, 2005). Business models can also contribute to the promotion and dissemination of the best prevention programs (Rotheram-Borus & Duan, 2003).

We need more process-oriented prevention research that documents mediators of change both during and after the prevention trial. This type of prevention research can have both
targeted and practical implications. Understanding mediating factors and processes can help to clarify and validate theoretical models. A greater understanding of the role of mediators can also enhance the intervention process by guiding program content and program duration until the potent, pertinent and plausibly causal mediators are sufficiently modified to ensure that the distal outcomes are affected. In the case of an unsuccessful prevention program, being able to pinpoint unchanged important mediators will inform the next wave of prevention programs so that they can target these mediators more effectively.

We also need to verify which preventive intervention program works best under which conditions and for which population. Interesting suggestions and examples of context-specific preventive interventions have been described by a number of researchers (Allen & Philliber, 2001; Beauchaine, Webster-Stratton, & Reid, 2005; Gillham, Shatté, & Reivich, 2001). It is particularly important to document the conditions under which a program previously observed to be effective may fail when applied to new populations (MacMillan, Thomas, Jamieson et al., 2005).

The impact of TPIs should be assessed with respect to the distal outcomes they are designed to prevent. Short- and mid-term effects on important mediators, although promising, do not always guarantee the final result. In addition to including randomly assigned control participants to guard against spurious results or iatrogenic effects, a group of normative children should also be included to probe the clinical significance of the effects of the TPI (Kendall, Marrs-Garcia, Nath, & Sheldrick, 1999). Despite the statistically significant improvements demonstrated by program children on a number of measures, it is rarely the case that these children function “normally” (i.e., within 0.5 SD of the normative mean or without any clinical symptoms) even after the intervention. Only a few TPIs reviewed in this chapter included a normative group (e.g., Early Risers, Fast Track, the Montreal longitudinal prevention program). Short-term results produced by these three high-intensity multicomponent preventive interventions show that none of them was able to move the targeted high-risk children into a normative range on important measures, despite significant overall differences between them and their counterparts in the control condition. In addition, long-term follow-ups show that many targeted children manifest serious adjustment problems, although proportionately less than their control counterparts (Boisjoli, Vitaro, Lacourse, & Tremblay, 2007; Conduct Problems Prevention Research Group, 2002, 2005). This finding alone calls for a renewed strategy with respect to our current prevention efforts.

We believe that the diverse and often competing prevention programs targeting different outcomes at different periods in development should become the building blocks of an integrated prevention system. These different programs should be linked to each other at three levels in addition to being delivered in accordance with an adaptive approach at each level. First, at the chronological level, the perinatal programs would be the first to be deployed. If the proximal results are satisfactory, these perinatal programs would be sufficient, as will undoubtedly be the case for some participants and problems. Participants still at risk for problems left unchanged by a perinatal program would be exposed to a second wave of prevention strategies during the preschool years. These may take place in the daycare setting, for example. This cumulative modular strategy would be repeated until the risk factors are dissipated or the protective factors are solid enough to ensure a highly probable positive trajectory. The early prevention programs should target as many potent generic causal factors as possible to achieve an optimal impact. However, because new risk factors may appear with development, booster programs might be needed at later transition periods to address these new and often specific risk factors. These booster programs would also capitalize on the malleability of participants’ behavior during periods of transition. Periods of transition often correspond to the changing phase between two developmental stages which are particularly sensitive to new learning because of the disequilibrium created both at the cognitive and the emotional levels and the new opportunities that become available (Dahlberg & Potter, 2001; Pickles & Angold, 2003).

Second, at the service delivery level, different services which often involve different personnel in different contexts need to be integrated into a coherent prevention system. Finally, at the outcome level, it is important to acknowledge that many prevention programs target the same risk factors and use similar strategies to achieve change even though their stated intention is to prevent different adjustment problems (e.g., school dropout vs. delinquency). As a result, programs with different stated goals may also have an important impact on other aspects of development – a probable consequence of their many common risk factors. Hence, most TPIs should assess several types of outcome, independent of their initial goals. This is particularly true for TPIs that adopt a generic perspective. This strategy might help increase the cost-effectiveness of TPIs. In addition, assessing change in different types of problem makes sense given the surprising similarities in the components and strategies used in TPIs targeting children at risk for different types of outcome (e.g., conduct disorder, substance use and depression).

Despite our enthusiasm for prevention, we nevertheless wish to conclude by raising concern about several iatrogenic effects that have been reported sporadically in the literature and may represent only the tip of the iceberg (Dishion, McCord, & Poulin, 1999; Dodge, Dishion, & Lansford, 2006; Werch & Owen, 2001). One well-known TPI that produced spectacular iatrogenic effects is the Cambridge Somerville Youth Study (Dishion, McCord, & Poulin, 1999; McCord, 1978). After 30 years, boys who participated in a multimodal program throughout early adolescence which included academic tutoring, family counseling, medical attention, summer camps and contact with community organizations had worse outcomes in several domains of functioning (i.e., criminal behavior, alcoholism, mental and physical problems, death) than matched controls who did not participate in the program. We believe that the planners and the disseminators of prevention programs...
CHAPTER 61

should be extremely sensitive and responsive to this issue. We need to learn about the conditions and the processes that are responsible for such iatrogenic effects as much as we need to learn about the conditions and processes responsible for positive and hopefully long-term effects of current and future targeted prevention programs.

Complementary References and Websites

Because the focus of this chapter is on the underlying principles, the number of prevention programs that were used for illustration purposes is necessarily limited. The reader can find a more complete and detailed list of targeted preventive programs in narrative reviews mentioned below. The reviews by Greenberg, Domitrovich, & Bumbarger (2001) and by Mazzeck and Brown (2002) cover most programs targeting children aged 5–18 or 0–6 years, respectively. The reader can also consult the meta-analytical reviews reported in Table 61.1 and several of the other chapters in this volume for a more complete overview of preventive interventions targeting different areas of functioning.

Finally, some universal preventive interventions document their results for the most at-risk children in addition to the whole population of children. These findings may be relevant for targeted preventionists even if they are derived from universal programs. One such program is the Good Behavior Game (Kellam, Rebok, Ialongo, & Mayer, 1994), a team-based classroom program that uses group reinforcement and competition to promote appropriate behavior in first grade. At 6-year follow-up, experimental boys who were the most aggressive in first grade manifested less aggression according to teachers than their control counterparts, whereas the other children did not.

Behavioral Therapies
Stephen Scott and William Yule

Background
Origins
Behaviorism began to take hold as a major influence in psychology in the early 20th century. John B. Watson finished his doctoral thesis on the behavior of the white rat in 1903, in which he acknowledged the powerful effects of innate capabilities, but showed that early experience, in a way that could be carefully measured, had a clear strong effect on current behavior. In 1913, in his article “Psychology as the behaviorist sees it,” he drew attention to the limitations of psychological theories current at the time and proposed behaviorism as an objective natural science with a progressive pragmatic agenda that could be applied to humans as well as animals. The article has a lengthy footnote on the nature of thinking, and Watson believed that complex emotional reactions in humans were derived from the newborn’s unlearned reactions of fear, rage and love. Thus, contrary to some current concerns, from the outset, major mainstream behaviorists recognized the importance of innate inherited traits, accepted the existence of complex emotional states and had theories about the role of cognitions. However, while recognizing these influences, behaviorists showed that for a given individual, many particular behaviors could be substantially altered by changing the immediately preceding events, and those that immediately followed.

Watson’s ideas were developed by Skinner, who gave more emphasis to the influence of events subsequent to a given behavior than to antecedent stimuli. Skinner was especially skeptical of psychological explanations for behavior based on introspection, which he called “mental fictions.” Skinner expanded his approach beyond the individual level to suggest a model society based on behavioral principles for returning US war veterans in Walden Two (Skinner, 1948), and applied behaviorist principles to language, in his classic Verbal Behavior (Skinner, 1957). However, the limitations of a behaviorist approach to language were set out by the young Chomsky (1959), who was scathing of Skinner’s approach, pointing out that language learning occurs independently of external rewards.

Soon there were clinical applications, and in 1952 Eysenck coined the term “behavior therapy” to capture the application of behavioral principles to treatment of patients, and Wolpe began developing treatments based on classic conditioning theory. The 1960s saw the heyday of pure behaviorism, with the founding of several journals such as the Journal for the Experimental Analysis of Behavior, Journal of Applied Behavioral Analysis, Behavior Therapy and Behavior Research and Therapy, in which a plethora of articles explored the application of behavioral principles to a wide range of situations, from animal behavior to business management. Many clinical applications were developed for adults. In the 1970s, many treatments were developed for children and adolescents. These covered all the main disorder groupings, with, for example, exposure treatments with relaxation for fears and anxiety, contingency management through parent training for disruptive disorders and functional analysis for challenging behaviors in children with intellectual disability. In this era, evaluations showed that the new treatments were generally notably effective; typically, they used relatively small numbers (4–10 cases) in single-case designs, plus some group trials, typically with 15–40 participants.

In the last 25 years behavioral therapies have continued to be refined, and large-scale randomized controlled trials comparing behavioral therapy with controls or in combination with medications with 100–800 participants have generally attested to their effectiveness (Conduct Problems Research Group, 1999; MTA Cooperative Group, 1999). In addition to the many new treatments, other therapies have grafted different approaches onto a behavioral base. Cognitive–behavioral therapies (CBT; see chapter 63) address thoughts as well as actions, but not in a loose introspective way, instead applying to cognitions the same concepts espoused by behaviorists of precise measurement, pragmatic individual formulation of phenomena in the present time and experimental trying out of what works with each patient and modifying it according to its effectiveness. A number of family systems approaches have taken up behavioral ideas and methods; for example, Functional Family Therapy (Alexander, Pugh, Parsons, & Sexton, 2000) and Multisystemic Therapy (Henggeler, Schoenwald, Liao, Letourneau, & Edwards, 2002). Problem-solving and social skills therapies use behavioral methods within the context of impaired relationships (see chapter 63). Therapies for those with post-traumatic stress disorder (PTSD) in the context of wider personal violations such as war or sexual abuse...
have broadened behavioral therapies to include addressing the profound impact on the patient’s sense of self and identity (e.g., using narrative approaches; Schauer, Neuner, Elbert et al., 2004). In the last 10 years, a “third generation” of behaviorally-based cognitive therapies has emerged following traditional behavior therapy and CBT. Examples include Acceptance and Commitment Therapy (ACT; Hayes, Luoma, Bond, Masuda, & Lillis, 2006), Dialectical Behavior Therapy (DBT; Linehan, 1993) and Mindfulness-Based Cognitive Therapy (MBCT; Segal, Williams, & Teasdale, 2001). Although based on behavioral principles, these therapies take cognitive issues further, by acknowledging that sometimes unpleasant thoughts and feelings cannot be changed, but can be accepted as less concerning; to date child and adolescent versions are only just emerging.

**Basic Tenets**

**Classic Conditioning**

Pavlov described classic conditioning, whereby unconditioned stimuli (e.g., food) that lead to unconditioned responses (salivation) could be presented at the same time with other (conditioned) stimuli (e.g., a bell), which then led to similar, but not identical, conditioned responses. Watson showed that classic conditioning had wide applicability. Understanding this mechanism has led to several applications; for example, dogs given food as they smell explosives learn to associate the smell of explosives with a reward, and can be trained to sniff airline luggage. A clinical application was developed by Wolpe (1958) when he suggested that in phobias the unconditioned response of overwhelming fear to a stimulus could be replaced by a competing conditioned response of relaxation through sufficient exposure, so that habituation occurred, a process he named systematic desensitization. This mechanism continues to underpin many current treatments for anxiety, phobias and PTSD.

**Operant Conditioning**

Skinner was concerned that most everyday behaviors were not related to simple unconditioned responses such as fear or hunger, but rather were often emitted spontaneously, and if they were followed by rewards or punishment then their form and frequency were adapted. Thus, children starting school soon learn that speaking to their friends in class may be punished by disapproval and a consequence such as detention, but that putting their hands up to answer a teacher’s question may be rewarded by approval. Skinner termed behaviors that led to rewards or punishments operants because they operated to change the environment for the individual. Others have argued that this description of events is the wrong way round, because it is the events subsequent to the original behavior that control its future emission.

Both classic and operant approaches do not concern themselves with the inner motives of the individual, but instead address the antecedent stimuli and consequent responses. This is in contrast to psychotherapies that primarily aim to change the inner world. Some of the differences between behavioral therapies and traditional psychotherapies are outlined in Table 62.1. Private thoughts and feelings are not ignored by behavior therapists, but they take a very different approach to them from traditional therapists, because they believe the same principles can be applied to them as to behavior (e.g., precise operational definition, quantifiable measurement, modification through learning principles). In short, thoughts and feelings are not seen as belonging to a different world (Phillips, 1981).

**Methods**

**Behavioral Assessment**

A core tool is behavioral assessment. This can vary in intensity, from a behaviorally-based interview, supplemented with a chart or diary if necessary, using a reliable and valid rating scale, to adding direct observation, additionally carrying out a full functional analysis which includes experimental manipulation of key variables, where possible.

**Interview**

In the interview, a thorough and detailed description of the behavior in question is elicited, including its frequency, duration and severity. Usually, the account is from the parents or the teacher, who may need help in moving from a generalized concern such as “He’s a rude boy” to specifics such as “He shouts at me in a loud voice for 3−4 minutes every day.” The general setting should be explored, such as “He’s only started doing it since his Dad left me 3 months ago,” moving on to clarify the antecedents, “It’s when I’m on the telephone,” and the consequences, “I have to stop chatting to my friend and tell him off.”

**Diary**

Where the picture is unclear, parents can be asked to keep a diary and note each day what happens over, say, a 2-week period. This may reveal exceptions, when the problem behavior is not shown; then the clinician will work closely with the parents to elucidate what else differed on those days.

**Rating Scales**

A standardized rating scale is helpful in ensuring that a systematic approach is taken to measuring the extent and severity of the problem domain. It can provide a useful talking point when an item has been checked, and can act as a baseline measurement of severity, to be given at different points of treatment to monitor progress. It is preferable to have at least two informants (e.g., parent and teacher for attention deficit/hyperactivity disorder [ADHD] symptoms, or parent and child for obsessive-compulsive disorder [OCD]). Some useful examples include the Conner’s rating scales for ADHD symptoms, the Eyberg Inventory for conduct problems, the Mood and Feelings Questionnaire for depression, the Child Impact of Traumatic Events Scale Revised for PTSD, and the Yale−Brown Obsessive-Compulsive Scale for OCD (more details of rating scales are given in chapter 20).
Direct Observation

Direct observation, preferably “live” in the context where the behavior occurs, is often revealing. For example, the same complaint “hits other children in school” might in one child be observed only to occur when other children speak to him while he is engrossed in schoolwork, and in another when she is taunted about her weight and told by her peers to go away. The first case might be triggered by too close proximity of others, in a child who is fairly solitary and wants to be left alone; the second by anger at being belittled and excluded by “friends.”
CHAPTER 62

Functional Analysis
Functional analysis goes a step further so that after generating hypotheses, they are tested experimentally. Thus, in the first example above, children might be asked to approach the boy and see whether indeed he then lashes out; it might emerge that he does so when boys approach and not girls. The hypothesis might be refined to state that the behavior has the function of keeping boys at a distance. In this way of thinking, causation in the pure sense is eschewed for practical functions, so that the hypothesized “cause”:

1 Covaries with the behavior;
2 Is in principle changeable; and
3 When changed, leads to an alteration in behavior.

In many cases, interview and diary keeping are sufficient to formulate an effective plan. However, in secondary referrals for complex cases, observation is invaluable. Functional analysis is especially useful when children have intellectual disabilities with challenging behavior that is hard to make sense of, such as head banging.

Case Formulation
This should go considerably further than behavioral assessment to incorporate all relevant psychiatric factors. As well as determining triggering and maintaining factors, defining positive behaviors to train up is usually more important than simply eliminating negative behaviors in one context (Herbert, 1987).

Intervention Techniques to Increase Behavior
What follows is a broad account of techniques. Readers seeking a detailed manual are referred to Herbert (1987) and to Hersen (2005).

Positive Reinforcement
This should be used when a new behavior is to be incorporated into the child’s repertoire, or when an existing behavior is desired more frequently or across more situations. It can also be used to increase the strength of an existing behavior so that an undesirable incompatible response diminishes. The method is to identify what is desired, and arrange matters so an immediate reward follows the performance of the behavior; in the words of one adage “Catch them being good” (and then reward them).

Social Rewards
Reinforcers may be social or tangible. In the social domain, attention is most powerful with younger children, but it is often also very effective for adolescents. It is often enough to say a few words showing that the behavior has been appreciated (e.g., describing what they did). To add power, it may be combined with words of praise or physical expressions of affection such as a hug. Positive attention is a two-way process in that children’s positive behavior reinforces adults; a happy relationship results from many mutually reinforcing interactions. As the child grows up, attention from peers, when present, may be far more influential than attention from parents. Attention that is associated with criticism or punishment will usually not be reinforcing; however, there is an exception. For children raised with very little attention, negative attention (such as being told off in a disapproving tone of voice) may be more reinforcing than being ignored completely. In this way, a parent who mainly ignores their child and then only scolds them may unwittingly be reinforcing bad behavior.

Tangible Rewards
These include items such as food (from single sweets to a trip to a restaurant), leisure activities (time on the computer or the telephone, going swimming) and privileges (staying up late, having a friend over). For more frequently occurring behaviors, tokens such as stars on a chart, or points can be given and later exchanged for a tangible reward; money can be given too.

Application of Rewards
Reinforcers can be provided by adults such as parents and teachers, other children such as siblings or peers, or the child themselves. The person doing the reinforcing will need coaching in each case – one cannot automatically assume that a parent or teacher has a large repertoire of praising comments that they use freely and warmly; and a child may need to rehearse congratulating themselves for, say, doing their homework or not losing their temper. Praise in front of others (e.g., peers and siblings) can have a particularly strong effect. Reinforcers should be given for trying and for steps in the right direction – not withheld until a perfect performance is given. Praise is given for the behavior, and so needs to be labeled – it is not for the child in general. Rewards should be given often, and not mixed with criticism. “Well done for getting two A grades – if you hadn’t been lazy, you’d have got three” is going to completely undo the effect of the praise element.

In practice, rules for rewards must be clear and simple; the therapist must check with the child that they understand them, and check that the parent implements them fairly and consistently. Rewards need to be changed every week or so to avoid satiation. Non-contingent general praise will not improve specific behaviors and can lead the child to be “spoiled” (i.e., believe they are approved of whatever they do). Reinforcers need to be carefully selected for the individual – they need to be something that the child wants.

Differential attention is where appropriate behavior is attended to, whereas inappropriate behavior is ignored (e.g., minor irritations, whining; hitting and destruction cannot be ignored). In practice, the difficulty here is to get the parent to switch back to attending to the desirable behavior after ignoring the undesirable behavior, because by now the parent is often irritated. Application of differential attention takes practice, and often some reattributions may need to be rehearsed with the parent (e.g., “He’s only doing it for attention, I shan’t give in!”). If assessment fails to show any relationship between attention and the behavior in question, it may not be appropriate to use this technique.

Schedules of Reinforcement
These may be continuous (i.e., after each behavior) or variable,
either by time (interval) or after a certain number of behaviors (ratio). Rewards set up expectancies within the individual, and help them predict their world. Their effects will depend on what the child is previously used to; if they already receive a great deal of praise then adding more may not be a powerful reinforcer and a tangible reward may be more effective. Conversely, where there has previously been little or no praising, some children may take a while to accept it – parents may need to persist for a few weeks to be believed. Variable schedules establish behaviors that are hard to extinguish (the individual’s experience is that reward may still come, even after a long time without).

Negative Reinforcement
This refers to the removal of something unpleasant, with the consequence that the procedure is reinforcing (the term is sometimes mistakenly used to refer to receiving reinforcement for negative behavior; e.g., through attention). Negative reinforcement can be used to increase wanted behavior through removing a mildly aversive situation after the child behaves as desired (e.g., a parent may threaten to turn off the TV unless the child takes his feet off the table, and remove the threat after he does). Inappropriate negative reinforcement may unwittingly lead parents to encourage antisocial behavior (e.g., by giving in). Thus, if a parent tells a child to go to bed (when the child wants to continue playing a video game), the child responds by whining and being defiant and the parent then backs off for 5 min, the child is learning that if they are defiant the aversive stimulus is removed.

Positive and negative reinforcement can be further divided into:

1. **Reward training**: “If you make the response, you will get a reward”;
2. **Privation training**: “If you don’t make the response, I will withdraw a reward”;
3. **Escape training**: “If you make the response I will withdraw a punishment”;
4. **Avoidance training**: “If you don’t make the response you will be punished.”

All serve to increase the frequency of a desired behavior.

In practice, parents need to be very clear about which behavior is to be rewarded and to ensure the child is also clear. This can be achieved by the parent devising a chart with the child, and placing it in a prominent position such as above the child’s bed or on the refrigerator door.

Token Systems
These allow instant rewards to be given, and so maintain performance over a time when reward cannot be given without delay. Later, they can be exchanged for substantive rewards such as a special meal, going to the park or having a friend round. Useful applications apply in classrooms and in foster homes. Token systems can be helpful where adult social rewards such as attention or praise are for some reason less effective. An example would be in classrooms where peer pressures compete with adult attention. The Good Behavior Game is an evidence-based token system that makes use of peer influences, rather than fighting against them. Groups of children in a classroom earn points for good behavior, and the winning group gets rewarded; children monitor and control their peer group’s behavior to ensure their group wins. This has proven effective in trials (Kellam, Rebok, Ialongo, & Mayer, 1994). A second example would be promoting peer friendship behaviors, for example by giving tokens for good gamesmanship such as praising a team-mate’s efforts, which has also been proven effective in randomized controlled trials (RCTs; Frankel & Myatt, 2003). Some children are not responsive to social rewards because they have been abused and so do not trust adults. The Multidimensional Treatment Foster Care program uses token systems to improve behavior in the home and at school; it too is supported by RCT evidence (Chamberlain & Reid, 1998). Like other behavioral techniques, token systems are not a magical solution to be applied in a mechanical way, but require thought and skill.

Shaping
Here one reinforces small steps in the right direction of a behavior the individual has not done before. It is a popular technique with animal trainers, who can train two naïve pigeons to play ping-pong in half an hour! Shaping is especially helpful for children if they cannot imagine what is required, the behavior cannot be modeled for them or they will not understand it. Shaping is especially useful with children with intellectual disability.

The Premack Principle
Premack (1965) was concerned to identify effective reinforcers where obvious ones did not appear to work. He suggested that observing what an individual liked to do with high frequency when left to their own devices would be a good reinforcer for a targeted low-frequency behavior – thus, actually it is a response that is rewarding. This can be especially helpful for children with severe learning disability (e.g., one might let them suck a favorite toy for 2 min after they have learned a step towards a new behavior).

Modeling
This technique is useful for learning new complex behaviors or for learning more appropriate responses (e.g., a fearless response to a dog). It assumes the child can observe the model and internalize it, and that externally (or through internal motivation) one can reward it. If the model has characteristics the child respects or desires, this will aid effectiveness. One can use filmed modeling for children (e.g., of other children being brave when confronted by feared situations) or to show parents other ways of responding to their children (Webster-Stratton, Hibbs, & Jenson, 2005).

Prompting
A prompt is a stimulus that may help a behavior pattern be initiated, and is especially useful at the beginning of a program. When giving a command it may help to hold up the reward...
(say, a token) to the child to prompt him or her. For prompting to work, it is crucial to have rewarding consequences in place – parents and teachers often use multiple prompts ineffectively (nagging) without setting up the consequences likely to ensure that the desired behavior occurs. Written prompts are prevalent in everyday life (“Drive slowly!” “Now wash your hands”).

**Intervention Techniques to Decrease Behavior**

**Extinction**

This refers to the withholding of reinforcements for behavior so that it is eliminated from the child’s repertoire. It requires careful analysis of all possible reinforcers (e.g., attention from parents, siblings and peers) and then ensuring no source of reinforcement is available – in this example, asking all parties not to respond to the behavior in question. As ever, to succeed one has to be very clear and specific about the behavior to target, and rehearse with parents and teachers how to avoid responding. This may be hard; if the behavior in question is rude remarks from the child, the adult has to learn to withhold responding. Initially, the child may “strive” even harder to elicit the reinforcer and so behave more badly than ever, the so-called “extinction burst”; one needs to persevere to overcome this. For extinction to work, the behavior in question has actually to occur and the link with reward be weakened, so the procedure is not suitable for behaviors that are dangerous or seriously disruptive of others. In these cases, other strategies such as punishment may be necessary. The cutting out of reinforcers needs to be almost total, because if intermittent reinforcement is available, the behavior may be maintained indefinitely.

Extinction can work well in the classroom, although teachers may find it hard to ignore or only attend briefly to poor behavior. Thus, Walker and Buckley (1974) found that 18% of teachers’ attention to non-problem children was for inappropriate behavior, whereas 89% of that paid to children with behavioral difficulties was for undesirable classroom behavior. Overall, 77% of all teachers’ individual attention was directed at children with problem behavior. This state of affairs is likely to maintain difficult behavior. To extinguish it, teachers can be taught to give very brief, quiet warnings that are rapidly followed by a consequence if the behavior is repeated (Webster-Stratton, 2003). Extinction works especially well when combined with differential reinforcement of other behavior (DRO), so the teacher ignores the child looking out of the window but praises her when she is doing her bookwork.

**Stimulus Control**

Here the aim is to remove a stimulus that leads to a difficult behavior, rather than changing the consequences. Turning off the TV may help a child get to bed by removing the competing stimulus of the program; removing a boy from a place in class beside his chatty neighbor may stop him talking in class; halting access visits of a maltreated child to her abusive father may prevent the episodes of self-harm that used to follow. Older children can learn to self-regulate stimuli (e.g., avoiding going to parts of town where they are likely to be tempted by the offer of drugs).

**Punishment**

This can be the withdrawal of something reinforcing (i.e., extinction), or the contingent application of something aversive; at times one may shade into the other. Hitting and hurting are types of punishment that have been associated with more traditional cultures and families. Apart from the inhumanity and potential for abuse of such methods of discipline, they tend to suppress or inhibit behavior through fear, pain or humiliation, without necessarily extinguishing it or teaching a mutually incompatible constructive alternative. Punishment alone reduces the chance of the child learning prosocial alternatives. Excessive painful punishment may have undesirable side effects such as inducing general fearfulness of the parent or teacher, the promotion of aggressive responding to frustrating situations through modeling by the adult and the induction of resentment in the child, thus leading to cycles of retaliation, withdrawal and non-cooperation.

Punishment can be popular with parents and teachers because of its reinforcing characteristics for them – prompt cessation of the unwanted behavior by the child, even though it may recur relatively soon – and, for some, the feeling of having given the child their just desserts and “taught them a lesson.” Even if it is not effective in the long term, these short-term reinforcers for the adult may help make it a frequently-used strategy unless other alternatives are taught. Studies suggest that punishing children is especially harmful when given in a painful, humiliating way that is ill-timed, irregular, inconsistent and retaliatory, with no accompanying choices for the child, or encouragement of more positive behaviors (Kazdin & Benjet, 2003). To be effective, punishment does not need to be intense or physical, but it does need to be applied quickly and consistently when the inappropriate behavior is displayed (Kazdin & Benjet, 2003). Time out is a good example of an appropriate way to administer punishment.

**Time Out**

The full term is time out from positive reinforcement. To be effective, before the punishment is given, the child has to be in a context that is positively reinforcing. Typically, the child is sent to a boring place such as the end of the corridor, a toilet or the bottom of the stairs. In time out there is general removal from a wide range of stimuli, as well as the reinforcing ones and removal from the context where undesirable behavior took place, so preventing further harm or damage to the surroundings or other people. In both these characteristics it differs from extinction, which is removal from specific, previously identified reinforcers. If the context around the child is not reinforcing – say, a boring lesson or a harsh parent – then being sent to time out will not be a punishment but may be a relief, and so will not be effective in reducing inappropriate behavior. As for other techniques, time out is less likely to work on its own than if combined with reinforcement of desired behaviors and extinction procedures.
The technique provides a useful alternative to smacking or spanking. It also has an advantage in terms of emotional control, because it provides a time for both the young person and the parent to cool down. It is especially useful for teachers as it removes the child from being an aggravating stimulus to other pupils, and to teachers and parents too. Adults need to be taught how to implement time out effectively; the time should not be longer than a maximum of around 5 min, with the proviso that the child has to be quiet for the last minute of the time (so a complaining child may need to be in time out for 40 min on the first occasion if it takes him that long to quieten down). The space used must be cleared of breakable objects as far as possible (e.g., perfume bottles in toilets) as the child may continue an angry tantrum and try escalating behavior before calming down. It is suitable for children aged around 3–10 years; older children may be too strong to be made to go, in which case a back-up strategy should be used, such as response cost strategies (e.g., “Because you have refused to go to time out, you will not be going to the football game tomorrow”).

Response Cost
This refers to the withdrawal of specified amounts of reinforcement (e.g., points, tokens, money, privileges) immediately following a previously defined unwanted behavior. Thus, for responding in a way that violates rules, the child promptly loses out. Response cost tends to be used with tangible, rather than social rewards, and consequently is especially helpful when social rewards are not likely to work: for example, in the context of a relationship that the child does not particularly care about, say a disliked teacher whose disapproval would not matter; for children for whom social rewards are generally less effective (e.g., abused children); looked after children who have had several sets of carers and become mistrustful; or children with psychopathic traits.

There are a number of practice points to bear in mind when setting up a response cost regime:
1. By definition, there has to be some level of positive rewards (e.g., points or money) or else there is nothing to withdraw.
2. The value of points or tokens has to be agreed in advance and be individually tailored to the child.
3. As for any consequence, the cost has to be applied immediately and consistently; giving feedback to child so they learn to make the connection helps.
4. It is important to avoid making the costs too high (the child may give up out of frustration).
5. Wherever possible, after removal of points, it helps to arrange for the child to be able to earn them back soon through a reparative positive behavior.

In contrast to time out, immediately after losing points, the child can gain positive reinforcement. He also remains in the presence of the stimulus that triggered the unwanted behavior, which can help learning towards self-control, or provoke the inappropriate behavior again, depending on the circumstances. Response cost is easier to implement than time out, as there is no need to take the child physically to another place; in school, the child continues to be exposed to class learning material. Because there are set rules, response cost is helpful in situations where it is important to avoid lengthy emotional interchanges and nagging, for example with oppositional teenagers in a foster home (Chamberlain & Reid, 1998).

Overcorrection
Here the child is subjected not only to a response cost, but also to an additional penalty to “overcorrect” for their misbehavior; the idea being to make the child especially aware of the punishment that will follow the unwanted behavior. Thus, a child who throws down litter may be made not only to tidy up his or her own rubbish, but to clear up a whole field.

Differential Reinforcement of Other Behavior or Incompatible Behavior
DRO refers to reinforcement of any other behavior; incompatible behavior takes the principle further by selecting a behavior that is specifically impossible to perform at the same time as the undesirable behavior. Both strategies are enormously helpful in reducing undesirable behavior. A noisy child can be given tokens for keeping quiet, an obsessive child rewarded for not enacting rituals, and so on.

Graded Exposure/Systematic Desensitization
This procedure is typically used where there is avoidance (e.g., because of phobias or anxiety states, or events experienced as traumatic). It can be combined with other techniques such as participant modeling (see p. 1013; e.g., the child watches the therapist stroke a frightening dog). The method is to make a hierarchy of the feared stimuli, starting with imagined ones, moving up systematically to reproductions such as pictures, to being at a distance from the real stimulus and finally to being close to the frightening object. The child defines the hierarchy, with help from the therapist. The child is trained in incompatible responses – typically relatively pleasant ones, for example imagining a favorite place, or training the child in relaxation techniques, or simply reassuring the child, or another pleasant activity such as eating or playing. When the child is comfortable, he is exposed to the stimuli, for long enough to overcome an anxious or fearful response so that this is replaced with a relaxed one. Over a number of sessions, the stimulus strength is increased by ascending the hierarchy, and supports are withdrawn. Encouraging active participation by the child enhances the procedure. During exposure, the child can rank their fear response on, say, a 1–100 scale; as the level of fear goes up, they practice the techniques. In this way the procedure effectively includes a coping element, with the child achieving mastery. It is crucial not to stop too soon during the procedure, because adequate exposure for long enough is key to getting anxiety levels eventually to subside. A variation of exposure is response prevention, whereby steps are taken to stop the child responding to the feared stimulus by acting inappropriately, as occurs in obsessive-compulsive disorder.

Flooding
This is an extreme form of exposure, whereby the child is
CHAPTER 62

brought into contact with the most feared item on the inventory, and kept in contact with it until the fear is extinguished. Because it is initially very frightening, this procedure is seldom used with children; it could be seen as abusive, especially in maltreated children, and adds little to graded exposure.

Modelling
Here a model is exposed to the feared stimuli while the child watches – thus it is a form of exposure whereby the child can identify and learn from the model that the stimuli are in fact safe and can be coped with. For example, a child can be shown a film of medical procedures, or a teddy bear can be given a blood test. Such procedures have been shown to reduce fear and anxiety (Melamed & Siegal, 1975). Live modeling is generally more effective than symbolic modeling. If anxiety is severe, it can be combined with relaxation, and repeated several times in a graded way. Modeling can be used to develop a whole range of prosocial skills, and is especially effective if combined with other techniques such as role play. It is more effective if the model gets rewarded for the new (e.g., prosocial) behavior. Complex behaviors may need to be broken down into component steps, as in problem-solving (see chapter 63).

Role Playing
By enacting behaviors rather than just talking about them, the child gets to practice the new responses in a favorable environment with fewer distracting stimuli than in real life. This is particularly helpful when emotional reactions may supervene (e.g., when a child with anger management problems is trying to stay calm while being provoked). For parents who cannot imagine the impact of their harsh practices on a child, it can be helpful to set up a role play with the parent playing the child, and another person behaving the way the parent usually does.

Fading and Generalization
After setting up a relatively intense reinforcement program, assuming it works, then the issues of generalization and withdrawal arise. Too abrupt a withdrawal of the reinforcement schedule is equivalent to introducing an extinction program for the new desired behavior. Fading procedures gradually change the environmental stimuli so they approximate, as far as possible, the natural conditions that will prevail following treatment. Methods include reducing reinforcement to an intermittent schedule, arranging for the artificial rewards such as tokens to be replaced by social ones such as praise from close adults – in real life these rewards are likely to be given only intermittently. If during fading the desired behavior diminishes or the undesired one recurs, then one should go back to the preceding reinforcement schedule for longer. Another approach is to widen the rewards and the people giving them, thus increasing generalization. Overlearning is a useful approach for more chaotic, conduct problem families where parents find it difficult to maintain consistency. Promoting the child to self-direct is a powerful way to promote generalization, whereby the child evaluates and directs their own behavior.

Application and Effectiveness in Specific Conditions

Emotional disorders
Anxiety Disorders
Anxiety disorders respond well to behavioral approaches, which are a mainstay of treatment, although medication can be effective too, at least in the short term (see chapter 39). The underlying principle is to expose the child to the feared stimulus and teach an alternative conditioned response characterized by calm and relaxation. Graded exposure and systematic desensitization are used as described above. Nowadays, the child’s cognitions will be worked on as well, with an element teaching them to monitor their thoughts and challenge their erroneous beliefs (“Maybe I’m dying,” “Everyone can see I’m going to faint”). These interventions would therefore be classified as cognitive-behavioral, but there is a strong behavioral element and cognitions are addressed using behavioral principles. The treatments work well, but then the question arises as to what is the active ingredient. Three studies have addressed this, using control groups that received various forms of non-specific supportive counseling or psychoeducation (Beidel, Turner, & Morris, 2000; Last, Hansen, & Franco, 1998; Silverman, Kurtines, Ginsburg et al., 1999). Only the last of these showed CBT was more effective than active control. Further studies are needed to determine what mediated a good treatment response – for example, it may be that in the control conditions educating children about fears and supporting them about their anxieties gave sufficient mental exposure to allow them to learn more adaptive behavioral, cognitive and emotional responses. Additionally, trials are needed with long-term follow-up that directly compare medication with behavioral treatments.

Earlier trials of behavioral therapy for anxiety took an adult model of treatment, with the therapist seeing the child only. However, there are several reasons for involving parents in treatment. First, from the earliest months, infants look to their mothers to “read” whether situation are dangerous and anxiety provoking, as shown in Gibson’s experiment where infants looked to their mothers to see if it was safe to walk across a glass plate with a drop beneath it (the “visual cliff”; Gibson & Walk, 1960). Therefore, helping parents to show a calm response rather than colluding with anxious responses should help to reduce child anxiety. Second, parents can support the therapeutic endeavor by ensuring that the child gets exposed to feared situations, and by helping with coping responses. The effectiveness of adding family involvement was tested by Barrett, Dadds, and Rapee (1996), who found it gave a significant advantage in reducing child anxiety, which was maintained at 1-year follow-up.

Obsessive-Compulsive Disorder
In childhood OCD, anxiety is a major feature, and the behavioral treatment is based on similar graded exposure to the feared object or context (say, dirt). During exposure (E) to the phobic stimulus, it is important to prevent the child from
carrying out the obsessive response, which acts as a negative reinforcer for the child by reducing anxiety. Response prevention (RP) involves stopping the child carrying out rituals; for example, they must touch “germy things” but refrain from washing until their anxiety is reduced. A third element in addition to E and RP is stopping parental reassurance, to ensure full exposure effects (March, Franklin, & Foa, 2005). The efficacy of E and RP has been demonstrated in multiple open studies and two RCTs (Barrett, Healey-Farrell, & March, 2004; POTS, 2004). Cognitive components may be added if there are substantial obsessive thoughts, but these are absent in up to half of cases (Swedo, Rapoport, Leonard, Lenane, & Cheslow, 1989), and to date there have been no studies comparing the effectiveness of adding cognitive components with none.

As for other anxiety therapies, studies are now beginning to examine different parameters of delivery of E and RP. Involving families is now standard practice, but an RCT demonstrated that it is equally efficacious when conducted in a group setting as with individual families, an important consideration for cost-effective service delivery (Barrett, Healey-Farrell, & March, 2004). Furthermore, in adults, computer-based E and RP delivery with minimal therapist contact time is effective (Kenwright, Marks, Graham, Franses, & Mataix-Cols, 2005); a similar study with children is now needed. The necessary “dose” of behavior therapy for children has been studied by Franklin, Kozak, Cashman et al. (1998), who compared once weekly with daily therapy; no significant difference in outcome was found, although the study was not randomized, so conclusions now need confirmation in an RCT. The meta-analysis by the UK National Institute of Clinical Excellence (NICE, 2005) suggested that while more therapist-intensive approaches were more efficacious, even those involving relatively little therapist contact time (less than 10 h) were also effective (NICE, 2005).

Behavioral and pharmacological treatments were directly compared in the Pediatric OCD Treatment (POTS) multicenter study that randomized children to sertraline, CBT, both treatments combined, or pill placebo for 12 weeks (POTS, 2004). All active treatments were superior to pill placebo, and CBT alone was as efficacious as sertraline, but combined treatment was more effective than either alone. This finding of the superiority of combined psychological treatment and medication was also found in a small study (Neziroglu, Yaryhura-Tobias, Walz, & McKay, 2000); a direct comparison of behavior therapy with clomipramine found a non-significant advantage for psychotherapy (de Haan, Hoogduin, Buitelaar, & Keijers, 1998), suggesting the POTS study findings broadly agreed with others.

Post-Traumatic Stress Disorder
As for other anxiety-related conditions, the core of behavioral treatment for PTSD is exposure, in this case to vivid recollection of the traumatic event. In a non-randomized design, Goenjian, Karayan, Pynoos et al. (1997) reported that a seven-session school-based CBT intervention for young people with PTSD over a year after an earthquake resulted in symptom reduction, whereas an untreated control group showed no such improvement. March, Biederman, Wolkow et al. (1998) used a single-case design and several measures to evaluate an 18-session group CBT intervention for 17 young people who had developed PTSD following a variety of traumas (road traffic accidents, accidental injury, gunshot injury and fires). After treatment, there were significant reductions in PTSD symptoms and associated psychopathology (anxiety, depression and anger).

Three RCTs of psychological interventions with children who developed PTSD symptoms as a result of single-event traumas have been reported. Chemtob, Nakashima, and Hamada (2002) randomly assigned 248 children at high risk of PTSD after a hurricane hit Hawaii to four sessions of CBT delivered individually, or in groups; or to a control group. Both individual and group treatment had equally good results compared to controls by an effect size of 0.76; more children dropped out of individual than group treatment. Stein, Jaycox, Kataoka et al. (2003) randomized 126 children who had been exposed to violence to 10 sessions of group CBT or a waitlist control. Three months post-treatment, the treated group had significantly lower scores on PTSD, depression and psychosocial dysfunction measures, although teacher-rated behavioral difficulties did not reflect improvement.

Using Ehlers and Clark’s (2000) more cognitive model of PTSD, Smith, Yule, Perrin et al. (2007) randomized 24 clinically referred children with a diagnosis of PTSD (rather than a population-based sample screened for symptoms) following assault or a road traffic accident to trauma-focused CBT or waitlist control. After treatment, 92% of the CBT group no longer met criteria for PTSD, compared to 42% on the waitlist; treated children also showed significant reductions in symptoms of depression and anxiety. The effect size was 2.2 on the self-report measure and 1.6 on the clinician-rated instrument. The differences remained at 6-month follow-up. This study was innovative because it measured a potential mediator, maladaptive cognitions, which did indeed turn out to mediate treatment effectiveness.

Finally, the question arises whether a cognitive element adds anything to imaginal exposure. Tarrier and Sommerfield (2004) found no difference at 1-year follow-up in a trial comparing the two approaches in adults, but at 3-year follow-up 29% of the imaginal exposure group still had PTSD whereas none of the cognitive group did. Similar trials for children are now called for.

PTSD and Child Sexual Abuse
In recent years, some of the reactions some children develop after sexual abuse have been recognized as fulfilling some or all criteria for PTSD. This has resulted in a number of therapeutic trials of CBT to treat these reactions, including full PTSD. There are many other sequelae of abuse, and only PTSD-type outcomes in trials of CBT are reviewed here. Generally speaking, studies favor CBT. Thus, Deblinger, Stauffer, and Steer (2001) randomized 67 children aged 2–8 years to group
CBT or a support group; the CBT group had better outcomes. Cohen, Deblinger, Mannarino, and Steer’s (2004) multi-site RCT also favored CBT, but Celano, Hazzard, Webb, and McCall (1996) compared 15 girls in an abuse-specific program with 17 given a parallel set of eight non-directive supportive sessions and found no differences in outcomes. To investigate different approaches to delivery, King, Tonge, Mullen et al. (2000) allocated 36 sexually abused children aged 5–17 years who met criteria for PTSD to CBT with child and family, CBT with child alone, or waitlist control. Both ways of delivering CBT (which lasted 20 sessions) were equally effective in reducing PTSD and anxiety more than in controls.

**Disruptive Disorders**

**Conduct Disorders**

Behavioral methods and the social learning approach revolutionized the treatment of conduct problems. In the late 1960s and through the 1970s, clinical researchers such as Patterson at the Oregon Social Learning Center, Wahler in Tennessee, Forehand in Georgia and Eyberg in Washington State tested and refined methods for parents to apply to disruptive children. By reducing attention for inappropriate behavior, giving it for desired responses and combining this with calm consistent discipline, antisocial behavior was considerably reduced. Over 100 trials attest to their effectiveness (Kazdin, 2005), and meta-analyses show mean effect sizes of around 0.4–1.0 standard deviations (SD; Barlow, 1999). More recent developments include similar programs for teachers to apply at school, because generalization of parenting programs to that setting is unreliable (Scott, 2002). Anger management programs working directly with children and adolescents are also based on behavioral theory, to which a self-control cognitive element has been added (see chapters 35 and 63). They are a useful adjunct to parent and teacher programs, helping temper control not only at home and in school, but also out in the community with peers (see chapters 35 and 63). The question arises whether parent, teacher and child interventions should ideally all be given.

Kazdin, Siegel, and Bass (1992) compared parent training alone with child social skills training alone, and both combined. All groups improved substantially, with improvements seen not only by parents at home, but also by teachers at school and self-reported offending by the young people. However, the combined treatment had greater effectiveness on nearly all measures, notably 0.5–1.1 SD greater effect than parent training alone on antisocial behavior. Webster-Stratton and Hammond (1997) used a group format with videotapes to compare parent training only with child training only, both parent training plus child training, and a waitlist control group. A total of 97 children aged 4–8 years specifically referred to a parenting clinic were studied with a thorough set of measures including direct observation at home and observation of interaction with a friend. The intervention was relatively long (22 weekly sessions of 2 h) and attendance was excellent, with all cases attending at least half of the sessions and most attending nearly all. There were no dropouts. There were several important findings. On parent questionnaire, children in all three intervention conditions did considerably better than waitlist controls, who did not improve significantly. The fact that child training alone led to improvements in child behavior is important practically because there will always be some parents who are unable or unwilling to attend for intervention. All interventions had an effect in reducing observed directive parenting behavior. From a theoretical standpoint, it is interesting that child training led to less coercive parenting behavior, confirming the hypothesis that for children with clinically significant antisocial behavior (as for non-clinical children) child as well as parent factors are involved in driving parenting style; it shows that the coercive cycle of negative parenting and child defiance can be interrupted from either end.

Parent training led to greater changes in parent-reported child behavior problems than child training, whereas child training led to better improvements in the ratio of positive to negative strategies used by children when interacting with a friend on direct observation, and on laboratory tests of social problem-solving. The combined parent–child intervention led to similar effect sizes as one would predict from either intervention alone in the domain in which they were most effective, but did not act synergistically. Thus, parent-rated child behavior was no more improved in the combined condition than for child training alone, and observed child–peer behavior was no more improved in the combined condition than with parent training alone. The exception was observed antisocial behavior in the home at 1-year follow-up, where the combined condition had a greater effect than either alone. Unfortunately, although in all intervention conditions there was a good effect compared to controls for observed reduction in child behavior at home (ES 0.7–0.8), total deviant behavior reduced to half original levels whereas controls did not change, the variance was large (standard deviations greater than means in all cases), so none was statistically significant.

All gains were maintained at 1-year follow-up, suggesting that the reduction in antisocial behavior is lasting. Unfortunately, further follow-up to test longer-term persistence of benefits will not be possible from this study as the control group were treated after the waiting period for ethical reasons. No intervention made any difference to teacher-rated child behavior in either the short or longer term. This was partly because some of the children had no significant problems at school, but nonetheless it suggests that child behavior may be fairly context specific, and supports adding a teacher element.

**Attention Deficit/Hyperactivity Disorder**

Behavior therapy for ADHD has tended to be similar to that for conduct disorders, with parents and teachers giving rewards for prosocial behavior and punishments for rule infringements and antisocial behavior. This is not unreasonable, given that it is often the comorbid conduct problems that are more troublesome than inattention and hyperactivity per se. Laboratory studies indicate that children with ADHD respond better to immediate rewards – delays beyond a few seconds lead to diminished responses; but, like other children, they will work
to maximize the total reward on offer (Scheres, Dijkstra, Ainslie et al., 2006). Modifications to standard behavioral programs should include giving rewards more rapidly and frequently, changing them more often to avoid boredom, and giving directions more clearly. Generally speaking, core symptoms of ADHD change less in behavioral programs than do conduct symptoms. Generalization outside the immediate situation where the reward system is being operated may be limited (e.g., in the playground when there is a teacher-administered reward system only in class); nonetheless, even after regimes are faded, there are some enduring effects (Arnold, Chuang, Davies et al., 2004). The presence of ADHD does not prevent specific methods being effective. For example, Fabiano, Pelham, Manos et al. (2004) compared the effectiveness of short (5 min) and long (15 min) time out sessions versus none in a cross-over design with 71 6- to 12-year-olds with ADHD. Both time out regimes were more effective than none in reducing aggression, destructiveness and repeated non-compliance, with an effect size of 0.32 SD; longer time out was no more effective, confirming other findings that 5 min is sufficient.

In the MTA Cooperative Group trial (1999), behavioral therapy was compared to medication and both in combination; there was also a treatment-as-usual arm (which was mainly lower doses of medication). In the behavioral-treatment-only arm, ADHD symptoms improved only modestly but conduct symptoms more so; the mechanism here appears to be child insensitivity to the changed contingencies, because direct observation of the parents showed that they did indeed change their responses to the children (Wells, Chi, Hinshaw et al., 2006). Behavioral treatment worked equally well irrespective of potential moderators, whereas in the medication arm, parental depression and more severe child ADHD symptoms moderated a poorer response (Owens, Hinshaw, Kraemer et al., 2003). The question arises whether medication potentiates the effects of behavior therapy – it might be expected that because there is a central nervous system deficit in ADHD, correcting this through medication would then enable the behavior therapy to work much better. However, this was not found to be a large tendency in the MTA trial, where once medication had been given, adding behavior therapy did not improve outcomes much further – the main improvements in core ADHD symptoms came from the drug. However, adding behavior therapy increased the proportion of children brought into the normal range, and improved aggression at home (MTA Cooperative Group, 1999). Also, in the arm with both behavior therapy and medication, substantially lower doses of medication were used while getting similar overall results – thus, behavior therapy allowed less medication to be used.

A final point to remember is that reasonably well-conducted intervention studies from 20–30 years ago that used relaxation training procedures alone or in combination with other treatments generated larger effect sizes than did CBT interventions (Benson, Beary, & Carol, 1974; Budzynski & Stovay, 1969; Kratter, 1983). More studies are needed that directly compare different treatments while measuring potential mediators.

**Developmental Disorders**

**Nocturnal Enuresis**

This is a good example of the great success behavioral methods can bring. Mowrer (1980) recounts how, despite being a professor at Yale, during the great depression in the 1930s to supplement his salary he and his wife took a job in a residential home for misfit boys, most of whom wet the bed every night. Based on classic conditioning, they devised an aversive conditioned response triggered by the stimulus of wetness in pads worn in underpants. Initially, the aversive response was provided by a spring-loaded metal bed that catapulted the child across the room, but soon a loud bell was used instead (Mowrer & Mowrer, 1938). This has repeatedly been shown to be effective in simple nocturnal enuresis (von Gontard, 2005). The Cochrane review of alarm interventions for nocturnal enuresis (Glazener, Evans, & Peto, 2005) found 55 trials involving 3152 children. Immediately after treatment, two-thirds were dry at night, with half remaining so in the long term (compared to no untreated controls ever becoming dry). Adding overlearning (e.g., by increasing fluid intake at night – for details see Houts’ 2003 account) reduced the long-term relapse rate further to around 20%, but adding penalties for wet beds was positively counterproductive. Alarms were better than tricycles during treatment, and while desmopressin achieved dryness in most cases while it was taken, a meta-analysis of studies has shown that almost all cases relapsed after it was stopped (Glazener & Evans, 2007).

The mechanism of action of alarms has been debated. Mowrer was clear that classic conditioning was involved as outlined above. Subsequent physiological studies (Norgaard, 1989) suggest that bladder detrusor muscle contractions that lead to urination are inhibited by pelvic floor muscle contractions. The alarm promotes these, and then the child does not wake up. However, nocturnal enuretics have learned to habituate to the aversive stimulus of a wet bed, and have relaxed pelvic floors during nocturnal micturition. The classic aversion account was challenged by Azrin, Sneed, and Foxx (1973), who claimed that the mechanism of effective treatment was that the child was operantly rewarded by dryness. He developed so-called “dry-bed” procedures with the parents waking up the child at regular intervals in the night and taking them to the toilet so they remained dry; no alarm was used. This procedure is demanding on parents, but results showed it was indeed as effective as simple alarm training (61% vs. 59% success at 2 years in the trial by Bollard, 1982). It seems therefore that both accounts of the mechanism of action of each treatment may hold true; at times it is a fine line between “classic” learning of conditioned responses to clearly identifiable stimuli, and “operant” learning whereby the individual responds because certain apparently spontaneous actions are rewarding.

**Pervasive Developmental Disorders**

Behavioral methods can help some specific problems in autistic spectrum disorders (ASD), but should only be part of an overall package. This should aim to stimulate, as far as possible, normal development of language and socialization, and to
reduce the particular maladaptive behaviors such as rigidity, stereotypies and inflexibility as well as general ones such as hyperactivity and tantrums. Behavior therapy needs to be adapted to this client group in a number of ways. First, changes need to be introduced gradually, within a framework that is predictable and structured in terms of daily routines – otherwise anxiety, social isolation and rigidities may emerge rapidly. Second, instructions need to be concrete, specific and calmly delivered, because metaphorical expressions and using tone of voice to convey meanings may lead to misunderstandings. Third, the intensity of social stimulation will need to be titrated to the level that can be handled, which may be quite low in some cases. Fourth, training and interventions should be performed as much as possible in daily-life situations, to overcome the problems in the transfer of skills mastered in one setting to another.

There is a modest amount of research suggesting intensive early interventions for children with ASD are more likely to be successful than low-intensity treatment later on. A well-known approach is that taken by Lovaas and Smith (2003) in the Young Autism Project at the University of California in Los Angeles. This is a comprehensive teaching and rearing program, rather than just treatment for particular problems. There is an introductory phase of establishing a teaching relationship where basic directions such as “sit” or “come here” are established and interfering behaviors such as tantrums reduced. This is followed by several months of developing communication and social skills, culminating in peer relationship training; depending on the rate of progress, the program may take 1–3 years or longer, terminating when the child goes to elementary school. Lovaas (1987) and McEachin, Smith, and Lovaas (1993) published a comparison of 59 children non-randomly allocated to intensive treatment, minimal treatment or special education. By age 7 the mean IQ of the intensive-treatment group was 83 while those of the two comparison groups were 52 and 59; by age 12 the percent with an IQ over 85 who were in a normal school was 42% in the intensive-treatment group and 0% in the minimal-treatment group. An independent replication (Smith, Groen, & Wynn, 2000) that was less intensive (25 h per week rather than 40) but fully randomized found at follow-up that the intensive-intervention group had an IQ 16 points higher than controls. Other replications have yielded comparable results (Smith, 1999); thus, Eikeseth, Smith, Jahr, and Eldevik (2002) tried the method with older children (4 years and above) but still obtained good results, including an IQ gain of 13 points. Since then, reviews of more recent evaluations indicate that although this approach is certainly effective, the overall results are neither as marked nor as universal as initially claimed (Shea, 2004).

Is such intensive intervention by fully qualified professionals necessary, or can parents be taught to deliver it as effectively? Bibby, Eikeseth, Martin, Mudford, and Reeves (2001) studied 66 children treated through their parents using consultants, but the results were disappointing – although there were gains of 9 points on an adaptive behavior scale, there were no intelligence or language gains. Kabot, Masi, and Segal (2003) have suggested that for maximal gains, both intensive professional daycare and high-quality parent training are needed. Such a model is incorporated in the school-based Treatment and Education of Autistic and Communication Handicapped Children program (TEACCH; Mesibov, Shea, & Schopeler, 2005). This uses parents as co-therapists to ensure that the same principles are enacted at home; to date there has not been an RCT evaluation, although a small-scale study (Panerai, Ferrante, & Zingale, 2002) reported significant gains in educational and adaptive behaviors compared to progress in an integrated classroom.

More specific interventions are available (e.g., social skills training programs, delivered on an individual or on a group basis), and are increasingly being offered to children and adolescents with ASD (Bauminger, 2002). However, the merits on a long-term basis are often disappointing because of a lack of generalization of skills.

**Intellectual Disability (Mental Retardation)**

Behavioral methods are a major part of treatment regimes in children with intellectual disability. While children with IQs above 60 or so may be able to participate to some extent in using cognitive techniques (Turk, 2005), this is seldom the case for those with lower IQs, for whom behavioral approaches are key. Challenging behaviors such as tantrums and self-injury are especially common in this group, and a thorough functional analysis should be carried out. Depending on what this shows, a range of techniques may be applied (Ball, Bush, & Emerson, 2004). Stimulus control and manipulation of antecedent variables are often especially helpful. These can include changing routines so the child is in a better biological state (e.g., less hungry, tired, or constipated); changing activities that precede the challenging behavior (e.g., by providing more varied activities and curricula to avert boredom and frustration); and changing triggers that in the functional analysis appear to lead immediately to the behavior (e.g., transition points in the daily routine, too close facial contact).

Teaching alternative responses can also be very effective. Functional communication training is a form of functional displacement, whereby a child is taught a more appropriate alternative. For example, if a child’s aggression in class serves the function of enabling them to escape disliked activities, they can be taught to request an alternative activity instead. This will work so long as the child finds it is effective in getting the result, and is easy for the child to implement (Carr, Levin, McConachie et al., 1994). More generally, DRO, which is often a very effective technique in typically developing children, is often less effective in children with intellectual disability, who may find it hard to learn relatively complex alternatives (Didden, Duker, & Korzilius, 1997). Punishments such as time out can be effective, but should not be used frequently in this group as they could become abusive.
General Issues

Indications and Limitations
As the above review has shown, behavioral therapies have offered mainstream interventions for many conditions. However, they may not be especially helpful where the primary problem is an inner mood or belief state without pressing behavioral manifestations. Thus, there is no purely behavioral method for the treatment of the core symptoms of depression, although the approach can be used to tackle some of the manifestations (e.g., lack of physical activity), and some of the postulated maintaining factors (e.g., low self-esteem because of a lack of friends arising from poor social skills). In contrast, behavioral approaches offer unique strengths for conditions where the child’s problems cannot easily be changed effectively by a cognitive approach, for example in babies and young infants (e.g., feeding and sleeping problems), in children with severe learning disabilities (e.g., challenging behavior) and more generally where the behavior is not very amenable to conscious control (e.g., hyperactivity and aggression). More widely, behavioral techniques are helpful for any condition where changes in the external environment can make a difference, and behavioral analysis can reveal where this is the case. Even where little can be done to change externally the main features of the environment such as a hostile family or a dangerous neighborhood, often children can be instructed in techniques that will enable them to mitigate its worst aspects or select better contexts (e.g., by learning what leads parents to become hostile, or learning to avoid bullies).

The absence of any theory about what is happening in the child’s inner world and the failure to address it directly inevitably bring with them some limitations. While learning is expected to occur in an unconscious way, in certain conditions this does not always hold. Thus, there is the issue of generalization, which requires the individual to be able to extract the rules regarding both the context when they behave a certain way and the rewards. Many children learn new habits from the rewards, and these will persist after the rewards are withdrawn. If no lasting connection is made, then extinction will occur as the rewards are withdrawn. This can occur if material rewards such as sweets are given and then withdrawn, and particularly for children who may be poor at generalizing and so need ongoing rewards, such as those with autism. Rewards that can always be easily given such as social rewards (smiles, praise) may lead to better control in these cases. Likewise, newly learned behaviors may not persist in antisocial children once the context is changed – thus, delinquents may behave very well while in controlled settings such as “boot camps” but the rate of relapse is over 80% after they are released back into the community (Stinchcomb, 2005). The issue here is to change the contingencies in the child’s natural environment (e.g., praise at home and close supervision in the community).

A further criticism of behavioral approaches arises from the apparent failure to take the individual’s past or personal vulnerabilities and liabilities to a condition into account. While it is true that certain individuals may be more at risk than others, there is abundant evidence that for many problems and disorders, the dynamic interplay between the context and the individual is crucial in determining the expression of the difficulty in any particular case (e.g., life events in depression, or coercive parenting in antisocial behavior). A good therapist will take a very detailed history of the predicament of the child and check carefully what the triggers are for them – so that the resulting program will be entirely individualized and will not fit another child. Arguably, this is a much more personalized approach than, say, prescribing medication.

Has Adding Cognitive Elements to Behavior Therapy Improved Outcomes?
More trials are needed to explore this issue, in addition to the few reviewed above. Certainly, clinically there are often scenarios where the beliefs seem to prevent behavior change; for example, the parent who thinks it is militaristic to set limits, or who cannot bear to ignore a child crying at night. Adding cognitive components would be worth evaluating in these contexts. In the adult literature, CBT techniques have produced impressive outcomes in many areas but it is not clear how much of this is brought about by what was added to traditional behavior therapy. Component analysis studies have often failed to find support for the importance of direct cognitive change strategies, which was the common sense lynchpin of CBT (Jacobson, Dobson, Truax et al., 1996). The response to traditional cognitive therapy often occurs before cognitive change techniques have been implemented (Ilandi & Craighead, 1994), and support for the hypothesized mediators of change in CBT is often weak (Burns & Spangler, 2001; Morgenstein & Longabaugh, 2000). Well-known cognitive therapists have been forced to conclude that in some important areas there is “no additive benefit to providing cognitive interventions in cognitive therapy” (Dobson & Khatri, 2000, p. 913).

This overall picture presents an anomaly. On the one hand, most empirical clinicians agree that traditional behavior therapy was simply not adequate and that better methods of dealing with thoughts and feelings were needed. CBT is widely understood to have been a step forward in freeing up the behavior therapy tradition to work directly with cognition, and the outcomes for CBT protocols are generally quite good compared to work outside of behavior therapy writ large. On the other hand, the core concept of traditional cognitive and CBT – that direct cognitive change is necessary for clinical improvement – is still only partially supported.

Therapist variables
Does it matter how well behavioral therapies are delivered? Therapist variables can be divided into:
1. The alliance, which, put simply, refers to how well therapist and client get on together, including sharing of goals of treatment;
2. Fidelity or adherence, which refers to whether the therapist carried out specific procedures; and
CHAPTER 62

3 The skill or competence with which the therapy was carried out.

The Alliance
A meta-analysis of studies of the alliance over a range of treatment modalities with children found an effect size of 0.21 for the effect of the alliance, and found it was important across treatment types (including giving medication), and across child, parent or family treatment approaches (Shirk & Karver, 2003). Kazdin, Whitley, and Marciano (2006) found about 7% of the variance in outcome of treatment for antisocial children was related to the alliance, although findings varied by informant.

Fidelity or Adherence
Fidelity or adherence concerns the extent to which the therapist follows the actions prescribed in the manual. Studies of child therapies have found equivocal effects. In a study of multisystemic therapy for delinquency, Henggeler, Melton, Brondino, Scherer, and Hanley (1997) compared a total of 15 parent, therapist and youth-rated fidelity scales with 7 youth outcomes, and found significant effects for only 7 out of 42 parent-rated associations, 4 out of 35 therapist-rated and 1 out of 28 adolescent-rated; moreover, some effects went the “wrong” way, with better fidelity leading to worse outcomes. The same group (Huey, Henggeler, Brondino, & Pickrel, 2000) found that when they used a latent variable approach, therapist-rated fidelity improved family functioning and parent monitoring, both of which in turn reduced youth delinquency, but that parent- and youth-rated fidelity had no effect. These somewhat modest findings for the role of adherence or fidelity raise the question of whether applying the treatment according to the manual is necessary or sufficient to bring about change.

Skill or Competence
It is possible that a more important and relevant influence on effectiveness is the skill or competence with which tasks are carried out; put simply, skill concerns how well the therapist performs the actions. Thus, two behavior therapists might each carry out a functional assessment, set up a behavioral program, choose targets and rewards, and issue homework. However, the more skilled one might do this in a more sensitive way with greater complexity, and so characterize the child’s problems more accurately and be more proficient in overcoming barriers to doing homework, thus leading to more change.

Researchers from the Treatment of Depression Collaborative Research Program (TDCRP) reported that therapist variables had substantial effects on a clinician-rated outcome of depression (Shaw, Elkin, Yamaguchi et al., 1999). The quality of the alliance accounted for 5% of outcome variability, but therapist adherence had no effect. Competence added a further 15%, although when this was decomposed into how well the sessions were structured and how skillfully the sessions were run, skill had no effect if structure was entered first in a multiple regression. Amongst childhood studies, Forgatch, Patterson, and DeGarmo (2005) developed an observer-based instrument to assess therapist variables that included skill in a parenting program for recently divorced parents. They measured knowledge, structure, teaching skill, clinical skill and overall effectiveness. The outcome they assessed was the proximal one of observed parenting practices, rather than child behavior; greater therapist skill led to more change in parenting. Finally, Scott, Carby, and Rendu (unpublished data) examined the effect of therapist skill in a multi-site trial of parent training for children with severe conduct problems. Skill correlated 0.7 with improvement in child antisocial behavior. The practitioners in the top third level of skill achieved twice the change of the bottom third, and the lowest level of skill actually made the children slightly worse. If further research supports these findings, then it will provide evidence for the need for more high-quality training.

Service Issues
In some countries and in some professions, behavioral approaches are poorly understood and poorly taught. They may be seen as mechanical and not addressing feelings and relationships, which some practitioners feel is core to their work. Further, there are still many practitioners in education, social work and mental health professions who pay scant attention to the evidence of what treatments work. In fact, the effectiveness of behavioral therapies means they often have a powerful effect on children’s happiness, and the children have more fulfilling relationships with their families, friends and teachers. Behavioral methods can be combined well with other therapeutic modalities (e.g., with family therapy in disruptive disorders, with medication as reviewed above, or with life story and other work in war-affected refugees who have PTSD). Delivery may need to be commissioned at different levels of skill, with self-administered behavioral therapy being tried first for less severe cases with families judged to be able to handle this, ranging up to deployment of highly skilled therapists for complex cases.

Conclusions
In the last 40 years or so, behavioral therapies have revolutionized the treatment of emotional and behavioral disorders in children, and have offered effective interventions to improve social and intellectual functioning. Purely behavioral treatments have continued to be refined and expanded, in content, mode of application and large-scale evaluations. Behavioral approaches based on the same method of empirical scientific enquiry and experimental testing have strongly influenced the development of cognitive elements in CBT, in a manner that is entirely consistent with the thinking of the founders of behaviorism. Future research needs to clarify mechanisms of action and modes of delivery, and to compare behavioral therapies with plausible alternatives. Wider training is required in what behavioral techniques have to offer, and how to deliver them.

CHAPTER 62

Cognitive–behavioral therapies represent a large portion of empirically supported treatments for child and adolescent psychiatric disorders (Kazdin & Weisz, 1998). Cognitive–behavioral therapy (CBT) is based on the premise that cognitions or thoughts can influence emotions and behaviors across a variety of situations, and thus altering maladaptive, distorted or deficient cognitions can be effective in treating various forms of psychopathology. While the widespread application of CBT to emotional and behavioral problems in youth began in the mid 1980s (Graham, 2005), often using problem-solving interventions, the theoretical and empirical underpinnings of these treatments began as early as the 1950s. In this chapter we provide an overview of the development of cognitive–behavioral interventions, as well as their current application in treating various disorders in childhood and adolescence.

Historical Cognitive Processing Models

Social Learning Theory

The application of CBT to the treatment of child and adolescent disorders is based upon social and cognitive learning theories proposed over 40 years ago. Rotter (1954) developed one of the first social learning models of early child development and psychological disorders, drawing on studies of animal learning (Hull, 1943) and conceptualizations of personality development as a dynamic process (Jones & Burks, 1936). Rotter noted that behavioral theories that focused on innate drives and reinforcement contingencies were insufficient for understanding individual differences in human behavior. He stressed that behavior was also influenced by cognitive processes, such as the subjective value individuals placed on reinforcers and their expectations that specific behaviors would result in rewards. Whereas these expectancy contingencies were influenced by previous experiences, they were not necessarily equivalent to objective probabilities (Rotter, Seeman, & Liverant, 1962), and were believed to impact on behavior across a wide variety of social situations (Jessor, 1954). As a result, this model expanded upon existing behavioral theories by introducing cognitive representations of social information and reinforcement contingencies as mediating processes.

Observational Learning

Early observation learning theories also stressed the importance of cognitions by recognizing that a child’s observations of real-life and symbolic models could influence subjective reward contingencies and decision-making processes. The processes initially proposed for acquiring a behavioral pattern through observational learning included attending to a model, cognitively retaining relevant aspects of the model’s behavior, enacting the observed behavior and then being reinforced for the reproduced behavior (Miller & Dollard, 1941). Early studies in this area found that children tended to imitate aggressive behavior when they observed a model being reinforced for aggression, and were less likely to imitate aggressive behavior when they observed a model being punished for aggression (Bandura, Ross, & Ross, 1963). Subsequent studies demonstrated that observational learning could be used to promote morality development (Bandura & McDonald, 1963) and delayed gratification (Bandura & Mischel, 1965). In addition, several factors were found to impact on the extent to which observational learning occurred in children, including characteristics of the model, the observer and the social context (Bandura, 1973). These early studies provided evidence that modeling could be used to influence children’s cognitions and promote positive behavioral change.

Cognitive Social Learning

Mischel (1973) proposed a cognitive social learning model of human behavior that combined developments in social learning theory (Bandura, 1969) with research on cognitive processing and symbolic mental representations (Neisser, 1967) in an attempt to explain the complex and dynamic interactions between children and their environment. He posited that the relation between environmental stimuli and behavior was mediated by individual difference characteristics such as construction competencies, encoding strategies, outcome expectancies and values, behavioral regulation systems and planning abilities. Environmental characteristics were believed to influence future behavior in so far as they changed an individual’s cognitive perceptions at these various stages or levels. In addition, Mischel (1973) theorized that children’s overt behavior could modify the amount and type of situations they experienced. As a result, children were viewed as active participants in their social environment, with the ability to influence social exchanges and reinforcement contingencies, as well as be influenced by them.
Cognitive Problem-Solving Models

In conjunction with the development of cognitive social learning models, researchers also began stressing the importance of deficient cognitive problem-solving in the development of emotional and behavioral problems in children. These early models suggested that ineffective interpersonal problem-solving in daily life could produce a wide variety of social and emotional adjustment difficulties (Jahoda, 1953, 1958). Along these lines, Shure, Spivack, and Jaeger (1971) noted that a well-adjusted person “is one who thinks through ways of solving real-life problems and has an appreciation of the potential consequences which could ensue from an act.” Early theoretical models of effective problem-solving often described five basic steps:

1. Recognizing there is a problem that requires a novel solution;
2. Defining the nature of the problem;
3. Generating possible solutions to the problem;
4. Evaluating the proposed solutions to determine which has the greatest chance of a favorable outcome; and
5. Evaluating the outcome that results from the chosen solution (D’Zurilla & Goldfried, 1971).

The last stage allows the individual to make self-corrections in future problem-solving scenarios in the event that the chosen solution was less than optimal. While outlined as distinct and sequential stages, researchers acknowledged that in real-life problem-solving situations these stages likely overlap and influence one another in a bidirectional manner (D’Zurilla & Goldfried, 1971). However, these stages have proven to be a useful heuristic for understanding the components of effective problem-solving and facilitating the teaching of these components to others.

Early research supported the notion that deficits in problem-solving may be driving conduct problems in youths. For example, elementary school children with disruptive behavior problems developed fewer logical strategies to solve problems and were less likely to foresee obstacles associated with implementing solutions in comparison with their non-externalizing peers (Shure & Spivack, 1972). In preschool children, poorer school adjustment was also associated with the generation of fewer solutions to problems and a narrower range of possible solutions (Shure & Spivack, 1970). Importantly, early research suggested that the link between poor problem-solving and disruptive behavior problems could not be accounted for by differences in intellectual functioning (Shure & Spivack, 1972; Shure, Spivack, & Jaeger, 1971). However, later studies have found mixed support for the notion that children with disruptive behavior generate fewer possible solutions to social problems (Quiggle, Garber, Panak, & Dodge, 1992; Youngstrom, Wolpaw, Kogos et al., 2000). Instead, finer-grained analysis suggests that disruptive behavior is more consistently associated with the generation of specific types of solutions (Lochman & Dodge, 1994; Lochman & Lampron, 1986). For example, children exhibiting disruptive behavior tend to generate a greater proportion of forceful solutions (Youngstrom, Wolpaw, Kogos et al., 2000), are more likely to choose an aggressive solution to solve the problem and indicate that an aggressive solution would be easy to implement (Quiggle, Garber, Panak et al., 1992) than children without these problems.

Research on problem-solving skills in children and adolescents exhibiting emotional problems also revealed relatively circumscribed deficits. Several studies indicate that children with emotional problems do not seem to have significant difficulties generating alternative solutions to hypothetical problems involving social interactions (Mullins, Siegal, & Hodgens, 1985; Quiggle, Garber, Panak et al., 1992; Youngstrom, Wolpaw, Kogos et al., 2000). However, depressed adolescents tend to be less confident in their ability to solve problems (Sacco & Graves, 1984), and are more likely to report making snap judgments in problem situations than non-depressed adolescents (Marcotte, Alain, & Gosselin, 1999). Depressed children were also more likely to evaluate withdrawal positively as a solution to conflict situations (Spence, Sheffield, & Donovan, 2003), and were more likely to expect that withdrawal would lead to positive outcomes than non-depressed youth (Quiggle, Garber, Panak et al., 1992). Taken together, this suggests that children with emotional problems tend to “cope by withdrawing from other children and from problems they cannot solve” (Shure, 1993, p. 50).

One of the earliest and best researched programs designed to teach children and adolescents problem-solving skills was Interpersonal Cognitive Problem Solving (ICPS) developed by Spivack and Shure (for a review of early studies see Urbain & Kendall, 1980). An early study on the preschool version of the training program was conducted with 219 African-American children (113 intervention, 106 no intervention) attending a federally funded daycare program (Spivack & Shure, 1974; Shure & Spivack, 1980). This version of the ICPS intervention consisted of 46 daily lessons implemented by the teacher, with each daily session lasting 20 minutes. The initial sessions focused on teaching children the basic word concepts necessary for consequential and causal thinking. The remaining sessions focused on developing three problem-solving abilities: alternative thinking, consequential thinking and causal thinking. Using both hypothetical and real-life interpersonal conflict situations, alternative thinking sessions focused on teaching children how to generate multiple possible solutions to a problem. Sessions on consequential thinking had children consider both the immediate and long-range consequences of the multitude of possible solutions to a problem. The final sessions of the intervention involved teaching children causal thinking, such as linking specific situations with their consequences to identify the solution that would best help them reach a desired outcome or goal. All sessions were taught using techniques such as role plays, games and puppet demonstrations.

Findings from this early study suggested that children who received the intervention showed improvements in alternative, consequential and causal thinking, as well as behavioral improvements, in comparison to a no-treatment control group at post-treatment (Shure & Spivack, 1980). Consistent with the theoretical underpinnings of the program, children who showed improvements in problem-solving skills were more likely to exhibit sustained behavioral improvements 1 year later. Over the years, Shure (1992a,b) has further developed the program.
CHAPTER 63

(for review see Akhutina, 1997). Their model of self-mastery and effect relationships in the real world, helping to facilitate behavioral planning and effortful self-control. In concert with Piaget, developmental theorists Vygotsky and Luria also proposed that children learned to master their behavior in a predictable pattern contingent upon early cognitive development (for review see Akhutina, 1997). Their model of self-mastery asserted that the behavior of preverbal children was initially directed and controlled by the verbalizations of adults, but as children developed the ability to speak, they began using overt self-verbalizations, and later internalized self-talk, to master their own behavior. Based on these early theories, impulsive children were believed to have difficulties using mental operations (e.g., internalized verbalizations) to guide and regulate their behavior (Meichenbaum & Goodman, 1969).

Inspired by the use of cognitive therapies to treat adult depression and guided by studies of child cognitive development, Meichenbaum developed the first cognitive self-guidance treatment program for impulsive children (Meichenbaum & Goodman, 1971). The program taught children to control their own behavior by modeling self-control verbalizations and instructing children on how to engage in private self-speech while performing sustained attention tasks. Findings suggested that impulsive children who underwent this treatment improved their ability to use private self-speech to orient attention and think carefully when making important decisions. Kendall and Braswell (1982) developed a more comprehensive cognitive therapy that taught impulsive children the general steps to problem-solving and how to use internalized coping statements to deal with frustration and failures when engaged in goal-directed behaviors. Children who received this intervention were shown to have better school compliance at a 10-week follow-up than children who received behavioral training alone. While relatively simplistic, these studies demonstrated that children could be taught cognitive strategies to help improve their behavioral functioning.

Uniqueness of Cognitive–Behavioral Therapy

A core feature underlying all cognitive–behavioral therapies is the idea that altering dysfunctional or deficient thoughts that accompany or precede problematic emotions or behaviors can be effective in treating various disorders (Graham, 2005). Whereas this concept may seem mundane given the widespread adoption of cognitive–behavioral approaches, it is important to recognize that cognitive therapies received substantial criticism from pure behaviorists as late as the 1970s. During this period, some behavioral journals were refusing to publish the word “cognition” in articles, and presentations on cognitive factors were banned from the American Association of Behavior Therapy (Meichenbaum, 2003). However, in contrast to purely cognitive therapies, interventions that are cognitive–behavioral in nature are more likely to incorporate techniques based on basic behavioral principles when appropriate (see chapter 62). For example, cognitive–behavioral interventions for very young children with conduct problems often teach parents how to use the behavioral principals of reinforcement, extinction and shaping to change their child’s behavior (Brestan & Eyberg, 1998). It is also important to note that contemporary cognitive–behavioral interventions often include elements of problem-solving therapy and parent-training interventions (Graham, 2005), which are described in greater detail within other chapters in this text. However, all cognitive–behavioral interventions seek to integrate these strategies into an overarching treatment model that emphasizes the influence of both cognitive factors and behavioral contingencies in the development of problematic emotions and behaviors.

Contemporary Cognitive Processing Models

Because various forms of social maladjustment are often the focus of cognitive–behavioral interventions with children and...
adolescents, social information processing models have been developed as a framework for understanding and treating both externalizing and internalizing problems in youth. Contemporary models have attempted to delineate the primary cognitive processing steps associated with encoding and interpreting social information, as well as generating and enacting solutions during social conflicts, as a mean of understanding the drivers of social maladjustment. In addition, research on the relative influence that cognitive schemas and emotional arousal have on social information processing guides contemporary cognitive–behavioral therapies for youth. The importance of distinguishing automatic from deliberate cognitive processing and distorted cognitions from cognitive deficits is also implicit in many cognitive–behavioral therapies.

Social Information Processing Model

Arguably the most influential and comprehensive social information processing model relevant for cognitive–behavioral interventions with children and adolescents was developed by Dodge (1993; Crick & Dodge, 1994). The model explicitly describes the “online” cognitive process steps that occur when children are engaged in social interactions and social problem-solving. In the most recent version of this model, a series of six sequential steps are outlined:

1. Encoding of external and internal cues;
2. Interpretation of these cues;
3. Determining goals or desired outcomes for the situation;
4. Generating possible responses;
5. Evaluating and selecting a response; and
6. Enacting and evaluating the chosen response.

Social adjustment problems in youth are believed to arise because of difficulties at one or more of these information processing steps. Whereas certain problem behaviors (e.g., aggression, depression) have been associated with specific social information processing problems, this framework is also useful for understanding heterogeneity among children exhibiting the same problem behavior. For example, the aggressive behavior of one child may be driven by a propensity to misinterpret others’ benign behaviors as hostile (stage 2), whereas a second aggressive child may be able to accurately interpret others’ intentions, but have particular difficulties generating non-aggressive solutions to social conflicts (stage 4). Understanding this heterogeneity in the context of CBT is important because the most efficient and effective treatment plans for these two children would focus on ameliorating fundamentally different social information processing problems.

Although it is important to recognize that there are individual differences within groups of children exhibiting the same problem behavior, there is considerable research indicating that children with disruptive behavior problems (e.g., aggression, conduct problems) tend to exhibit a general pattern of social information processing difficulties. At encoding, disruptive children recall fewer relevant cues about events (Lochman & Dodge, 1994) and overattend to hostile cues (Gouze, 1987; Milich & Dodge, 1984) than non-disruptive controls. In the interpretation stage, they are also more likely to infer that others are acting in an aggressive or hostile manner (Burgess, Wojslawowicz, Rubin, Rose-Krasnow, & Booth-LaForce, 2006; Dodge, Pettit, McClaskey, & Brown, 1986). When clarifying goals in conflict situations, disruptive and seriously antisocial youth tend to focus on dominance and self-centered rewards, and are less concerned with avoiding punishment and the suffering of others (Lochman, Wayland, & White, 1993; Pardini, Lochman, & Frick, 2003). In conflict situations, aggressive and disruptive children also tend to generate fewer verbal assertions (Asarnow & Callan, 1985; Lochman & Lampron, 1986) and compromise solutions (Lochman & Dodge, 1994), and generate more physically aggressive solutions (Pepler, Craig, & Roberts, 1998; Waas & French, 1989). When evaluating possible responses to social conflicts, children with disruptive behavior problems rate aggressive solutions more positively than children without these difficulties (Crick & Werner, 1998). Even when they choose prosocial responses, children with disruptive behavior problems tend to be less adept at enacting them (Dodge, Pettit, McClaskey et al., 1986).

There is also emerging evidence suggesting that children with emotional problems (e.g., depression, anxiety) tend to exhibit a unique pattern of social information processing problems. At the encoding stage, depressed children tend to recall more negative cues in the environment (Hammen & Zupan, 1984), whereas anxious children seem to have an attentional bias associated with processing environmental cues of potential threat (Ehrenreich & Gross, 2002). During the interpretation phase, both depressed and anxious children are more likely to attribute negative events to internal, stable and global characteristics (Jacobs & Joseph, 1997; Quiggle, Garber, Panak et al., 1992). There is also evidence suggesting that children with emotional problems may be less likely to generate assertive solutions to social conflicts (Quiggle, Garber, Panak et al., 1992) and tend to underestimate their own social competence (Rudolph & Clark, 2001). When choosing solutions to social problems, both depressed and shy or withdrawn children tend to adopt avoidant strategies and depressed children tend to view assertive social solutions as resulting in fewer positive and more negative outcomes (Burgess, Wojslawowicz, Rubin et al., 2006; Quiggle, Garber, Panak et al., 1992).

Role of Schemas

Recent revisions of social cognitive models have more explicitly introduced the role that children’s cognitive schemas have on information processing (Crick & Dodge, 1994; Lochman, Wayland, & White, 1993). Schemas are commonly regarded as patterns of thinking or beliefs that remain relatively consistent across social situations (Lochman & Lenhart, 1995). These latent cognitive structures are believed to promote the filtering of incoming information and can distort self and other perceptions (Fiske & Taylor, 1984). While schemas allow people to operate efficiently in their social worlds by providing prototypes for how to interpret social cues and manage social conflicts, dysfunctional schemas can perpetuate emotional and behavioral problems by negatively influencing several social information processing steps (Lochman & Dodge, 1998).
CHAPTER 63

When encoding social cues, schemas can narrow children’s attention to specific facets of the social environment at the expense of other social cues (Lochman, Nelson, & Sims, 1981). For example, a child with a general expectancy that others will try to dominate him, may be hypervigilant to verbal and non-verbal signals about a peer’s control efforts, while missing signs of the peer’s friendliness or attempts to negotiate. Children’s schemas can also influence the interpretation of encoded social cues, such as the tendency for a depressed or anxious child to attribute negative social events to internal, stable and global characteristics (Jacobs & Joseph, 1997; Quiggle, Garber, Panak et al., 1992). Schemas can also play a significant part at the end stages of information processing, as the child anticipates consequences for different problem solutions, and decides which strategy will be enacted. In this regard, social goals and outcome expectations that are consistently endorsed in social situations of a particular theme (e.g., social conflicts with peers) are often conceptualized as schemas (Mischel, 1990; Rotter, Chance, & Phares, 1972).

Emotional Arousal and Social Information Processing
It is important to recognize that social information processing might both influence, and be adversely impacted by, heightened levels of negative affect and emotional arousal. Emotions have been hypothesized to mediate the relationship between attributions and behavior (Weiner, 1990) and serve as an adaptive system that motivates individuals to solve their perceived problems (Smith & Lazarus, 1990). For example, when a child attributes blame for a social conflict to another person’s hostility, the child will tend to experience frustration or anger, but when the child attributes a social conflict to personal flaws or imperfections, the child will tend to experience sadness or depression (Weiner, 1990). These attribution-emotion linkages can then result in different decisions about social goals (e.g., revenge vs. conflict avoidance) and appropriate behavioral responses in interpersonal situations (e.g., aggression vs. withdrawal). In addition, emotional reactions in the early stages of interactions often persist across time, which can negatively influence social attributions and response styles throughout an extended social exchange (Dodge & Somberg, 1987; Lochman, 1987). Along these lines, a recent laboratory investigation found that young boys who experience increased heart rate as the result of provocation also experience increases in hostile attributional biases (Williams, Lochman, Phillips, & Barry, 2003). Whereas the temporal ordering of these relations (increased heart rate influences attributions or vice versa) could not be determined based on the design of the study, this study provides convincing evidence that changes in negative emotional arousal and dysfunctional cognitions are closely linked.

Distinguishing Automatic and Controlled Information Processing
When evaluating the social information processing of children and adolescents, it is often useful to differentiate between more automatic and more controlled processing problems (Lazarus, 1991). Automatic processing is commonly described as occurring outside of conscious awareness and is fast, effortless and unintentional. Effortful processing, on the other hand, occurs within conscious awareness and is depicted as slow, effortful and deliberate. At each stage of social information processing, the difficulties exhibited by children and adolescents with various emotional and behavioral problems can be conceptualized as being on a continuum from relatively automatic to more controlled (Daleiden & Vasey, 1997). Although a vast majority of research with children and adolescents has focused on effortful social information processing, studies have begun to examine the association between emotional problems and more automatic processing of social stimuli. For example, trait anxiety in adults has been associated with increased skin conductance responses to threatening pictures in comparison with neutral pictures, even when these stimuli are presented outside of conscious awareness (Najström & Jansson, 2006). Whereas this suggests that relatively automatic attentional biases to fear and threat cues may be associated with anxiety problems in adults, studies examining how automatic processes are related to children’s and adolescents’ anxiety, as well as other forms of psychopathology, are needed.

Differentiating Cognitive Distortions from Cognitive Skills Deficits
Cognitive–behavioral therapies with youth often make distinctions between cognitive distortions and cognitive skills deficits when treating social information processing problems. Cognitive distortions are self-defeating interpretations of people or events that do not accurately represent reality (Daleiden & Vasey, 1997). These thinking errors are believed to help maintain negative emotions and often result in dysfunctional social interactions and poor social problem-solving. A common cognitive distortion is an overgeneralization, in which an individual assumes that a specific negative event is part of a continual or pervasive pattern. For example, a depressed child may think “All people I care about will leave me” when a friend moves out of town, or an aggressive child my think “Everyone is out to get me” after being ridiculed by a single peer. Other common forms of cognitive distortion include jumping to conclusions about the intentions of others, catastrophizing relative minor setbacks, personalizing negative events and discounting positive events (Dodge, 1993). Within the context of cognitive–behavioral therapies, children and adolescents are often taught to recognize and refute these distortions, which is a process commonly referred to as cognitive restructuring. Replacing these distorted cognitions with more realistic and adaptive thinking patterns is designed to reduce negative emotional reactions to adverse social events and promote more competent social problem-solving.

Although negative appraisals of the self and social environment may be caused by cognitive distortions, it is also possible that these perceptions are actually accurate representations of reality that may arise from cognitive skills deficits. For example, a depressed child may accurately endorse having no friends at school because of an inability to start appropriate conversations with others. In this instance, the child is describing a deficiency
in the cognitive skills necessary to develop peer friendships, rather than engaging in cognitive distortions by exaggerating a complete absence of friends or lack of social skills. CBT with a child or adolescent exhibiting cognitive deficits focuses primarily on skill building, such as practicing how to start and maintain conversations. Often, it may be difficult to determine from the youth’s self-report alone whether social difficulties are the result of cognitive distortions, cognitive skills deficits or some other factor. As a result, it is often necessary to gather information from collateral informants (e.g., parents, teachers, peers) to garner an accurate depiction of the problem (Pardini, Barry, Barth, Lochman, & Wells, 2006). It is also important to keep in mind that cognitive distortions and deficits are not mutually exclusive categories. For example, Rudolph and Clark (2001) found that depressed children not only have greater difficulties engaging in skillful social interactions with peers than non-depressed children (cognitive deficit), but also tend to exaggerate the extent of their social problems (cognitive distortion). In addition, there are cases in which children’s emotional difficulties are brought about by life circumstances beyond their control (e.g., death in the family, victimization, physical deformity) rather than a cognitive deficit or distortion, in which case it may be more appropriate to focus on teaching children skills for coping with stressful life events.

Areas of Application

Conduct Problems

The largest application of CBT to child and adolescent psychopathology has focused on the treatment of conduct problems (e.g., aggression, defiance, oppositional behaviors, rule-breaking). Whereas cognitive-behavioral therapies for conduct problems differ based on the developmental level of the target population (e.g., preschool children vs. adolescents) and the severity of the behavior problems being targeted (e.g., treatment for conduct disorder vs. preventative-intervention for minor aggressive behavior), common elements pervade most empirically supported cognitive-behavioral approaches (for descriptions see Lochman, Phillips, McElroy, & Pardini, 2005; Pardini & Lochman, 2003). Nearly all of these treatments involve a child-parent intervention component, and there are several topic areas that are commonly addressed in these interventions. As a result, a prototypical cognitive-behavioral intervention for treating conduct problems in youth is described, followed by empirical evidence supporting the efficacy of these interventions with various populations.

Prototypical Youth Intervention for Conduct Problems

Most youth interventions for conduct problems are performed with small groups of 4–6 individuals over the course of several weeks to a year. There is typically an emphasis on anger management, social problem-solving and social skills development, and prosocial goal-setting. Anger management sessions involve assisting children in recognizing the level of arousal and anger they experience in difficult interpersonal situations and identifying the triggers that lead to these high arousal reactions. Perspective-taking sessions are commonly used to help participants understand how others can have a range of intentions in a given situation that are often unclear. This is done in an attempt to prevent children from assuming that other people are always trying to be cruel or mean in conflict situations, which often triggers increased anger. Coping techniques to manage anger arousal and to avoid impulsive rage-filled responses are often the focus of several sessions, including the use of distraction, relaxation and self-talk techniques. Children often practise using coping self-instructions and distraction techniques within the group, sometimes while being teased directly by other group members or by using puppets. Children are reinforced for creating a repertoire of coping self-statements that are relevant and useful for them, and are encouraged to use these strategies in real-life social situations. Parents and teachers are often taught to cue and assist the youth in using anger management strategies at home and school, and are instructed to reinforce the successful implementation of these skills.

Cognitive-behavioral interventions for conduct problems also focus on teaching youth appropriate social problem-solving strategies and social skills. Consistent with Dodge’s (1993; Crick & Dodge, 1994) social information processing model, participants are commonly taught to engage in a series of cognitive processing steps when solving social problems. In most interventions, youth learn to:

1. Identify the problem and their emotional reaction to it;
2. Analyze the possible intentions of the other party;
3. Come up with potential solutions to the conflict;
4. Analyze the short- and long-term consequences of each solution;
5. Choose and enact a final plan; and
6. Evaluate the effectiveness of the plan after it is implemented.

In addition, children are often taught basic social skills that are important for making friends: empathizing and co-operating with others, and successfully resolving interpersonal conflicts. These skills are often taught through a combination of verbal instructions, modeling and in-session role plays. The in-session role plays frequently focus on dealing with interpersonal conflicts experienced by youth (e.g., being teased by a peer), as well as other social situations that are difficult for youth with conduct problems, such as making new friends. As therapy progresses, children are often given homework assignments in which they are asked to apply their newly learned problem-solving and social skills to real-life interpersonal situations of increasing complexity. Parents and teachers are often taught to cue and assist the youth in using these problem-solving strategies and social skills, as well as to reinforce their successful implementation.

Another facet of cognitive-behavioral treatments for conduct problems involves having the youth identify and work on goals designed to improve their behavior. In order to help facilitate this process, teachers or parents are often asked to identify four or five behavioral goals designed to reduce problematic behaviors. Because initial successes are important in motivating children to work on challenging issues, children are
CHAPTER 63

often encouraged to select goals initially that are of low to moderate difficulty. Progress in meeting these goals is monitored regularly, and children receive rewards or privileges for reaching agreed-upon levels of goal completion.

Prototypical Parent Intervention for Conduct Problems

Most efficacious cognitive–behavioral programs for child and adolescent conduct problems involve a parent-training component. Cognitive–behavioral parenting interventions have received the most consistent empirical support for the successful treatment of conduct problems in youth, both in isolation and when combined with child interventions (Brestan & Eyberg, 1998). As a result, it is strongly recommended that cognitive–behavioral interventions for child and adolescent conduct problems involve a parenting component whenever possible. Typically, these sessions are conducted during several group sessions lasting approximately 2 h, with periodic individual contacts through home visits and telephone contacts to promote generalization of skills learned in group sessions. In order to lay a foundation for positive parent–child interactions, parents are initially encouraged to initiate non-threatening play sessions with their child in a manner that shows a genuine interest in and appreciation of their ideas. This typically includes using skills such as reflecting the child’s statements, describing and praising the child’s behavior, ignoring undesirable behaviors and avoiding the tendency to direct the play or criticize the child. Parents are coached on ways in which they can verbally and non-verbally express acceptance, warmth and caring toward their child. The purpose of this component is to strengthen a positive parent–child relationship and extinguish maladaptive behaviors that are reinforced by parental attention. Most interventions have parents practice these skills in session as the therapist provides feedback and suggestions for improvement.

Another common component of parenting interventions involves learning to analyze child behavior problems from a cognitive–behavioral mindset, and implement discipline strategies that target the drivers of conduct problems from a cognitive–behavioral perspective. Along these lines, parents are taught to use positive reinforcement to increase the frequency of their child’s prosocial behaviors, while using non-abusive, yet consistent, methods of discipline to deal with disruptive behaviors. The appropriate use of time out, verbal reprimands, negotiation and behavioral contracting is often discussed, as well as using a naturally occurring consequence for inappropriate behavior, such as giving children an earlier bedtime when they refuse to get up on time for school in the morning. Sessions also focus on teaching parents to use problem-solving strategies similar to those taught to their children to manage crises within the family.

After a home behavioral program is started, parents are encouraged to begin a school-based reinforcement program to help improve their child’s academic and behavioral compliance. The school program consists of negotiating certain school goals and monitoring the child’s progress in meeting these goals through the use of a home–school behavioral report card. Children are typically given reinforcement for achieving specific goals (e.g., special activities, privileges) and are frequently given feedback regarding their behavioral progress.

Outcome Research

Reviews of Efficacy of Cognitive–Behavioral Therapy for Conduct Problems

Several reviews have examined the efficacy of psychosocial treatments for conduct problems in children and adolescents in comparison to no treatment or waitlist control conditions. These reviews indicate that a vast majority of the empirically supported treatments for conduct problems in youth are based upon a CBT framework (Brestan & Eyberg, 1998; Farmer, Compton, Burns, & Robertson, 2002; Kazdin & Weisz, 1998; Nock, 2003). Meta-analytic studies suggest that the effect sizes for cognitive–behavioral interventions targeting conduct problems range from medium to large, i.e., 0.47–0.90 (for review see Nock, 2003). In addition, research suggests that cognitive–behavioral interventions that include a child component focusing on social problem-solving and social skills development together with a parent-training component produce broader positive effects and better maintenance of behavioral improvements over time than interventions with either component in isolation (Kazdin, Siegel & Bass, 1992; Nock, 2003; Webster-Stratton & Hammond, 1997). However, the parenting component of these interventions has been shown to produce particularly robust reductions in conduct problems and delinquent behaviors (Beauchaine, Webster-Stratton, & Reid, 2003; Lochman & Wells, 2004).

Two exemplars: The Incredible Years and Coping Power Programs

Two examples of intervention programs that have received empirical support for the treatment of conduct problems are the Incredible Years program and the Coping Power program. The Incredible Years program primarily consists of a parent and child intervention designed for children aged 4–7 who have conduct problems significant enough to warrant a diagnosis of either oppositional defiant disorder or conduct disorder (Webster-Stratton, Reid, & Hammond, 2004). Research findings regarding the effectiveness of the child and parent training interventions alone and in combination are impressive. The parent-training component has repeatedly been show to produce significant reductions in child conduct problems at home and school, decreases in negative parenting and increases in positive parenting in comparison with waitlist control conditions (Webster-Stratton, 1984; Webster-Stratton & Hammond, 1997; Webster-Stratton, Kolpacoff, & Hollinsworth, 1988; Webster-Stratton, Reid, & Hammond, 2004). In addition, evidence suggests that overall improvements in children’s behavior problems as the result of the parenting intervention can still be seen at 3-year follow-up (Webster-Stratton, 1990).

The Incredible Years child intervention has also been shown to produce significant reductions in the amount of conduct problems children exhibit at home and school, as well as produce increases in social problem-solving skills in comparison
with wait-list controls (Webster-Stratton & Hammond, 1997; Webster-Stratton, Reid, & Hammond, 2004). There is also evidence indicating that at 1-year follow-up approximately two-thirds of children who participated in the intervention have parent ratings of behavioral problems in the normal rather than clinically significant range (Webster-Stratton & Hammond, 1997).

In contrast to the Incredible Years program, the Coping Power program was developed as a preventative intervention to assist aggressive elementary schoolchildren in making a successful transition to middle school. The efficacy of the Coping Power program in comparison with no treatment has also been demonstrated in several studies. For example, aggressive boys randomly assigned to an early version of the program (i.e., anger coping) displayed less parent-reported aggressive behavior, fewer behavior problems in the classroom and higher levels of self-esteem at post-treatment than aggressive boys who did not receive treatment (Lochman, Burch, Curry, & Lampoon, 1984). At a 3-year follow-up, the intervention boys exhibited lower substance use involvement and increased self-esteem and social problem-solving skills than controls (Lochman, 1992). Aggressive children who have participated in the expanded Coping Power program have been shown to exhibit post-treatment reductions in self-reported substance use, proactive aggression, as well as improved social competence and teacher-rated behavioral improvements in comparison with non-treated controls (Lochman & Wells, 2004). The intervention has also been found to reduce several maladaptive cognitions related to aggressive behavior by post-treatment, such as hostile attributions, expectations that aggression will result in positive outcomes and an external locus of control regarding positive outcomes (Lochman & Wells, 2002a). At 1-year follow-up, findings indicate that aggressive boys who have participated in the Coping Power program exhibit lower levels of self-reported delinquency and parent-reported substance use, as well as higher levels of teacher-rated behavioral improvements than non-treated controls (Lochman & Wells, 2002a). The Coping Power effects on children’s self-reported delinquency and substance use, and teacher-reported aggressive behavior at the time of a 1-year follow-up, compared with a randomly assigned control condition, were replicated in a second sample (Lochman & Wells, 2003).

**Moderators and Mediators of Treatment Efficacy**

Whereas cognitive–behavioral treatments are generally effective for treating conduct problems in youth, it is also clear that some children’s behavior problems do not improve as the result of treatment. Along these lines, research has been increasingly focused on answering the question: “What child, parent, family, and contextual features influence (moderate) outcome?” (Kazdin, 2003). Although there has been some historical speculation that preschool children and youth with learning problems may not benefit from CBT for disruptive behavior, recent evidence suggests that this may not be the case. For example, children as young as 4 years old (Beauchaine, Webster-Stratton, & Reid, 2005; Webster-Stratton, Reid, & Hammond, 2004), and youth with mild cognitive impairments (e.g., learning problems, mild intellectual disability) have shown significant behavioral improvements as the result of developmentally appropriate cognitive–behavioral interventions (Kam, Greenberg, & Kusché, 2004; Kazdin & Crowley, 1997). More recently, researchers have suggested that conduct problem youth with a callous and unemotional (CU) interpersonal style may exhibit a particularly severe and recalcitrant form of antisocial behavior that is resistant to traditional treatments (see chapter 51; Frick, Cornell, Barry, Bodin, & Dane, 2003; Pardini, 2006). Along these lines, one study found that increased CU traits were associated with lower levels of behavioral improvements following a cognitive–behavioral parenting intervention for youth with conduct problems (Hawes & Dadds, 2005). However, this effect was relatively small in magnitude, suggesting that youth with CU traits may benefit from empirically supported CBT.

Many studies examining moderators of CBT for youth with disruptive behavior have produced contradictory or counterintuitive findings. Whereas early studies suggested that children with more global psychiatric impairment were less likely to benefit from CBT for disruptive behavior (Kazdin & Wassell, 1999), more recent evidence suggests that comorbidity and case complexity may not significantly influence therapeutic change (Kazdin & Whitely, 2006a). Similarly, lower socioeconomic status and increased parental psychopathology and stress have been found to predict poorer treatment outcomes in some studies (Dumas & Wahrer, 1983; Kazdin & Wassell, 1999; Reyno & McGrath, 2006; Webster-Stratton & Hammond, 1990), but not in others (Beauchaine, Webster-Stratton, & Reid, 2005; Hartman, Stage, & Webster-Stratton, 2003). Recently, a large and comprehensive examination of treatment moderators was conducted with 514 children who participated in six randomized trials of the empirically supported Incredible Years program (Beauchaine, Webster-Stratton, & Reid, 2005). Findings indicated that children whose parents had a history of substance abuse and those with co-occurring emotional disturbance showed greater improvements in disruptive behaviors by 1-year follow-up. Children of parents who exhibited lower levels of critical, harsh and ineffective discipline at baseline also exhibited greater behavioral improvements. In addition, the parent-training component of the program (in comparison with the other components) produced greater improvements in children’s disruptive behavior at 1-year follow-up for single mothers, mothers who reported low levels of marital satisfaction and children low on emotional disturbance. In contrast to theoretical conjecture (Lynam, 1996), the intervention was equally effective in reducing conduct problems among children with elevated levels of attention deficit/hyperactivity disorder (ADHD) symptoms as in those without these problems (Beauchaine, Webster-Stratton, & Reid, 2005; Hartman, Stage, & Webster-Stratton, 2003). However, evidence does suggest that CBT may not be effective for reducing core ADHD symptoms in youth (MTA Cooperative Group, 1999). Although these studies have begun providing insights into possible moderators of treatment efficacy, there remains a lack of understanding about why these factors lead to differential responses.
CHAPTER 63

to treatment (Nock, 2003). This issue seems particularly important given that research in this area has produced counterintuitive (e.g., parental substance use history positively influences treatment outcome) and contradictory findings.

An under-studied area involves examining the mechanisms through which CBT influences reductions in child and adolescent conduct problems (i.e., mediators). Evidence suggests that reductions in critical, harsh and ineffective parenting practices tend to co-occur with improvements in disruptive behavior problems at post-treatment and 1-year follow-up (Beauchaine, Webster-Stratton, & Reid, 2005). In addition, Lochman and Wells (2002b) found evidence indicating that intervention-related reductions in delinquency at 1-year follow-up were at least partially mediated by reductions in inconsistent parenting from pre- to post-treatment. However, evidence supporting the assertion that modifying maladaptive or deficient cognitions in children leads to subsequent changes in their problem behavior was limited.

Depression

Depressed youth have certain common social–cognitive characteristics. Depressed youth display both cognitive distortions and cognitive deficits, evident in their core symptoms of feelings of worthlessness, associated negative beliefs about themselves and their future, attributions of failures, and having an external locus of control (Gladstone & Kaslow, 1995). The onset of youth depression is often preceded by family conflict, physical illness, the break-up of romantic relationships or the loss of a friendship (Weersing & Brent, 2003). Depressed pre-adolescent children have similar causal attributions for the positive and negative events that they experience, which is quite different from non-depressed children, who perceive the causes of negative events to be external to themselves (Kaslow, Rehm, Pollack, & Siegel, 1988). These attribution distortions become even more apparent with adolescent in-patient samples, where the depressed adolescents attribute the cause of positive events to external, unstable and specific causes, consistent with findings that adolescents experience more anhedonia than younger depressed children (Curry & Craighead, 1990).

Depressed children’s distorted schemas and internal working models have been found to be linked to insecure attachment to parent figures (Cowan, Cohn, Cowan, & Peterson, 1996; Stark, Sander, Hauser et al., 2006b). In addition to these problems in their habits of thought, they often show problems in their low rates of social acceptance and high rates of isolation from their peers, caused by poor social skills and poor problem-solving skills. Garber, Brafflad, and Zeman (1991) found that depressed children had certain specific social information processing difficulties, evident in their patterns of generating avoidant and aggressive strategies to handle social difficulties, rather than using more adaptive strategies involving active problem-solving and distraction.

Contents of a Typical Cognitive–Behavioral Therapy Approach

Common treatment components across different CBT programs include:

1. Self-control skills, self-consequation (reinforcing themselves more, punishing themselves less), self-monitoring (paying attention to positive things they do), self-evaluation (setting less perfectionistic standards for their performance) and assertiveness training;
2. Social skills, including methods of initiating interactions, maintaining interactions, handling conflict, and using relaxation and imagery; and
3. Cognitive restructuring, involving confronting children about the lack of evidence for their distorted perceptions (Stark, Hargrave, Sander et al., 2006a).

An example of how the cognitive skills are separated from the behavioral skills is evident in the CBT program for adolescents developed by Weersing and Brent (2003). This program consisted of 15 sessions, 10 of which were manualized and structured, and 5 of which were highly individualized for the particular client’s strengths and abilities. In addition to the work in the session with the adolescent, there was take home work from a practice book, and there was some parent involvement. The skills were separated into two sets for the ACT behavioral skills (activities that solve problems, activities that the youth enjoys, being calm and confident, using one’s talents) and the THINK cognitive skills (think positive, get help from a friend, identify the silver lining, don’t replay bad thoughts, keep thinking and don’t give up). The youth develops a coping plan with sequential steps, and the skills are actively practiced in role plays and in vivo activities. CBT with depressed children can also be given in a group format, where the CBT sessions are typically carefully structured, going through a regular sequence of activities, each session including: rapport building, set agenda, goal attainment check-in, review of previous meeting and homework, coping skills activity, skill building, review, positive behavior review and assignment of therapeutic homework (Stark, Hargrave, Sander et al., 2006a).

Outcome Research

Reviews of Evidence-based Cognitive–Behavioral Therapy Approaches

Meta-analytic reviews indicate that children and adolescents benefit from CBT interventions regardless of severity of depressive symptoms, and that adolescents have larger effect-size improvements from CBT intervention than do younger children (Michael & Crowley, 2002; Stark, Hargrave, Sander et al., 2006a). Overall, CBT interventions have had similar effects for mildly to severely depressed adolescents in these reviews, but recent research has suggested that the beneficial effects of CBT may be most apparent with mild to moderate depression in youth (Melvin, Tonge, King et al., 2006). Treated youths’ reductions in depressive symptoms are maintained over time, and effect sizes at the end of treatment are in the moderate to large range across studies (Reinecke, Ryan, & DuBois, 1998).

Two Exemplars: CBT for Adolescents and the TADS Study

Typical of the positive results that have been reported from CBT programs for depressed youth, Weersing and Brent (2003)
described the results from the series of CBT studies conducted at the Western Psychiatric Institute Mood and Anxiety Disorders Clinic. In the 1997 clinical trial (Brent, Holder, Kolko et al., 1997), 107 youth were screened for major depressive disorder, were required to have at least borderline Beck Depression Inventory scores, and did not have psychosis, bipolar disorder, obsessive-compulsive disorder, eating disorders or substance abuse. The youth were randomly assigned to CBT, systemic behavioral family therapy (SBFT) or non-specific therapy (NST). SBFT was based on models of the effects of negative life events and family conflict on youth depression, and included a problem definition stage, in which adolescents’ problems were redefined as being problems for the entire family system and in which dysfunctional interactions and alliances were identified, and a problem-solving stage. NST controlled for the non-specific aspects of therapy by having adolescents express feelings with warm and non-directive therapists. At post-treatment, CBT had significantly higher rates of youth being diagnosis-free (CBT 83%, SBFT 38%, NST 39%), but these treatment group differences had become non-significant by the time of a 2-year follow-up (Birmaher, Brent, Kolko et al., 2000).

However, the utility of the CBT as a stand-alone treatment for depression has become less clear with the results of the large multi-site TADS study (March, Silva, Petrycki et al., 2004). A total of 351 adolescents who had received primary diagnoses of moderate to severe major depressive disorder were randomly assigned to fluoxetine, CBT, the combination of fluoxetine and CBT, or placebo. The CBT intervention included six structured skill-building sessions and six modular or optional sessions, to permit more careful tailoring of interventions to specific adolescents’ needs with regard to social engagement, communication, negotiation, compromise or assertion. The CBT intervention used in TADS did not have as many intensive cognitive elements as was evident in the Brent, Holder, Kolko et al. (1997) study (Stark, Sander, Hauser et al., 2006b). The greatest decreases in symptoms in the TADS study were evident in the condition that included both CBT and fluoxetine, followed by the fluoxetine-only condition. Both of these conditions were more effective than CBT only or placebo. Thus, CBT used in the TADS study was found to be useful in accompaniment to medication, and was found to produce greater reduction in the likelihood of suicidal ideation and behavior than the fluoxetine-only condition. However, CBT alone was less effective than fluoxetine in reducing depression symptoms among those adolescents with major depressive disorder. The findings of the lack of intervention effects for CBT alone may have been because of the inclusion of fewer cognitive treatment elements in the TADS CBT intervention, or to the use of less-experienced therapists.

**Mediation and Moderation**

Kolko, Brent, Baugher, Bridge, and Birmaher (2000) examined whether the CBT and SBFT conditions in the Brent, Holder, Kolko et al. (1997) study produced differential improvements in cognitive distortions. As anticipated, CBT was uniquely able to change adolescents’ cognitive distortions, unlike the SBFT condition, and was able to produce changes in general family functioning to a similar degree as the SBFT condition, suggesting that a mechanism of action in CBT is the ability to alter cognitive distortions.

In terms of predictors of outcomes, youth with more severe and chronic depression, evident in the presence of double depression and more severe cognitive distortions, have poorer outcomes after any form of treatment in the Brent, Holder, Kolko et al. (1997) study of CBT. Youth with serious suicidality were more responsive to CBT than to non-CBT treatment, with equal levels of CBT effectiveness for suicidal and non-suicidal youth (Barbe, Bridge, Birmaher, Kolke, & Brent, 2004). Youth with greater numbers of depressive episodes and younger age at first onset had the best outcomes in the Adolescents Coping With Depression program (Clarke, DeBar, & Lewinsohn, 2003). Thus, there is mixed evidence at this time about whether CBT would have its best effects with less severe or chronic depressive children.

**Anxiety**

CBT for anxiety disorders integrates cognitive and behavioral perspectives on the origin and maintenance of anxiety symptoms (Stark, Sander, Hauser et al., 2006b). There is a focus on the children’s internal and external environments, addressing behavioral, cognitive, affective and social factors. Children with anxiety disorders have been found to have certain information processing and emotional experiencing styles.

The children’s interpersonal contexts within their family and peer groups have also been linked to their experience of anxiety, and have implications for treatment. There is considerable correspondence between serious levels of child and maternal anxiety (Frick, Silverthorn, & Evans, 1994). Family factors that are linked to child anxiety include parental over-control, parental reinforcement of avoidant strategies, the presence of parental anxiety and the presence of anxiety in siblings. Interestingly, some parental anxiety has been found to decrease when mothers have been included as coaches to assist their children’s use of comforting self-talk, cue controlled relaxation and pleasant imagery in the management of their anxiety symptoms (Peterson & Shigetomi, 1981). Parents have benefitted by using the same skills themselves, and their anxiety may decline as children have reduced levels of symptoms.

**Contents of a Typical Cognitive–Behavioral Therapy Approach**

The Coping Model underlying Kendall’s Coping Cat program (Kendall & Suveg, 2006) emphasizes that the goal is not to alleviate anxiety entirely, but to assist the child to learn skills to better manage or cope with anxiety in the future. Three of the primary treatment targets are:

1. To identify physiological cues related to anxiety and to use relaxation skills to manage this arousal, because anxiety is associated with manifest physiological arousal;
2. To identify automatic thoughts and to learn countervailing coping thoughts, because children have cognitive distortions...
that lead them to overestimate the chance of negative events occurring and the impact of those events; and 3 To be exposed to the feared situations as the child learns and actively practices problem-solving skills.

The Coping Cat program consists of 16–18 sessions, with the first eight sessions focusing on teaching the components of the FEAR plan. In the FEAR plan, “F” refers to assisting children to becoming better aware of their feelings of being frightened, emphasizing greater awareness of physical symptoms as a cue to respond, and using deep breaths and muscle relaxation to teach the child that he or she has control over physical reactions. “E” refers to children’s identification of their incorrect expectations and self-statements that bad things will happen. Through modeling and role play, the child identifies his or her thoughts in anxiety-provoking situations, and learns to test out the negative expectations. “A” is a problem-solving step in which the child develops his or her confidence and ability to clearly define the problem situation and goals, and to generate alternative solutions to the anxiety-provoking situation. The idea of needing to deal with problems is normalized as part of everyday life, and the importance of not relying on initial reactions in problem situations is stressed. Finally, “R” reminds children to reward themselves and to take credit for the results they achieve. The critical aspect of self-evaluation for these children is to help them perceive that perfection is not the goal, because many of these children have unrealistically high achievement standards.

Exposure to the feared situation is an important part of the treatment process, and children move through exposure experiences in structured step-wise ways, starting with imaginal in-office exercises with low levels of anxiety, then moving to in vivo situations that have low levels of anxiety, and then moving to increasingly anxiety-provoking situations in imaginal and in vivo practice. In addition to the direct work with children, periodic meetings are held with parents to maintain their support and to collaborate on treatment plans.

The Coping Cat program has led to several other similar evidence-based programs such as Coping Koala and the FRIENDS program (Barrett & Shortt, 2003). Some of these more recent programs, such as FRIENDS, have a more substantial focus on working with parents. In group meetings, parents learn to deal with their own anxiety and to use behavioral reward skills with their children.

Outcome Research
Reviews of Evidence-based Cognitive–Behavioral Approaches

Reviews of empirically supported treatments for children with anxiety disorders conclude that behavioral and cognitive–behavioral procedures have more empirical support than do other approaches (Chorpita & Southam-Gerow, 2006; Kazdin & Weiss, 1998). Behavioral techniques (including imaginal and in vivo desensitization) are especially efficacious for phobias, and cognitive–behavioral procedures have been determined to be well-established and probably efficacious for other anxiety disorders (Kendall & Suveg, 2006).

Two Exemplars: Coping Cat and FRIENDS Programs

The Coping Cat program has been evaluated in a series of studies, beginning with Kendall’s (1994) study of 47 9- to 13-year-old youth diagnosed as having separation anxiety disorder, overanxious disorder or avoidant disorder. At post-treatment, 64% of those who had received Coping Cat no longer met diagnostic criteria for one of these disorders, in comparison to a 5% diagnosis-free rate for waitlist controls, and these gains were maintained at a 1-year follow-up. A longer-term follow-up of this sample, at a point over 3 years after the end of intervention, indicated that these intervention gains were long-lasting (Kendall & Southam-Gerow, 1996).

In a second sample, Kendall, Flannery-Schroeder, Panichelli-Mindel et al. (1997) followed 94 9- to 13-year-old children who were randomly assigned to Coping Cat or to waitlist control, and found that 50% of Coping Cat children were diagnosis-free at post-treatment, and for those who still had diagnoses there was a significant decrease in the severity of their conditions. These significant intervention effects were maintained at 1-year and 7.4-year follow-ups, and the intervention children had reduced risk for other related sequelae of the anxiety disorder, such as substance abuse.

In an effort to compare the different forms for delivering the intervention, Flannery-Schroeder and Kendall (2000) randomly assigned 37 8- to 14-year-old children to group CBT, individually delivered CBT or a waitlist control. At post-intervention, both intervention conditions demonstrated significant improvement, but the rate of improvement was stronger in children who had been seen individually (73% diagnosis-free in individual CBT, 50% in group CBT and 8% in the control condition).

The Coping Cat program was adapted in Australia as the Coping Koala program, and a first evaluation study randomly assigned 79 7- to 14-year-olds to child CBT, individually delivered CBT or a waitlist control. The combined intervention was somewhat more effective at post-intervention than the child-only intervention (88% diagnosis-free for child + family intervention, 61% diagnosis-free for child-only intervention), but both were more effective than the waitlist control condition (less than 30% diagnosis-free), and both had a similar rate of continued effectiveness at a follow-up that occurred 5–7 years after intervention ended (87% diagnosis-free for child CBT only and 86% for the combined intervention).

In a study of the FRIENDS program, Barrett (1998) randomly assigned 60 7- to 14-year-old children to either group CBT, group CBT plus family intervention or to waitlist control. The results favored the combined intervention at post-intervention (56% diagnosis-free for child group CBT, 71% for group CBT + family, 25% for control) and at a 1-year follow-up (65% diagnosis-free for group CBT, 85% for group CBT + family), indicating the added value of also working with parents in these CBT approaches for anxious children.
Mediation and Moderation

Variables that have been found to be predictive of poorer responses to the Coping Cat intervention are:

1. Higher levels of children’s internalizing problems, using teacher or maternal reports;
2. Higher rates of maternal self-reported depressive symptoms; and
3. Older ages (Southam-Gerow, Kendall, & Weersing, 2001). In contrast, variables that have not been found to moderate CBT intervention outcomes for children with anxiety problems are ethnicity, gender, family income, family composition, maternal-rated externalizing problems or child-reported internalizing problems. The family component of the Barrett, Dadds, & Rapee (1996) program is most effective with younger children, consistent with prior findings of moderators of child-oriented CBT programs, and with girls and with families that have parents with anxiety problems. Thus, child-focused CBT appears to be more appropriate for older and more seriously anxious children, and for children with depressed mothers. In contrast, parent-focused CBT is more effective with younger children.

Examining mediation effects, Treadwell and Kendall (1996) examined longitudinal changes in 8- to 13-year-olds who had received CBT intervention. Children’s reductions in negative cognitions and state-of-mind ratio were found to mediate the effects of intervention on children’s subsequent improvement in anxiety after treatment.

Factors that Influence Outcomes

Treatment Fidelity and Adaptation

Psychotherapy with children and adolescents has traditionally been a field in which many empirically unsupported approaches have been used (Roberts, Lazicki-Puddy, Puddy, & Johnson, 2003), and typical community-based care had consistently poor outcomes (Bickman, 2002). There was a scarcity of evidence-based research on child interventions until recent years (Rubenstein, 2003). However, in the past decade there has been a tremendous increase in efforts to identify and disseminate evidence-based treatments, many of them based on cognitive–behavioral models (Bickman, 2002; Hawley & Weisz, 2002). Efforts to study systematically the dissemination process of evidence-based interventions for children has only recently begun (Schoenwald & Hoagwood, 2001; Silverman & Kortines, 2004).

Although intervention developers may often insist on complete adherence to protocols, innovations inevitably change as development proceeds (Berwick, 2003), including adjustments made to program materials to address participants’ educational developmental and motivational levels. Arguments can be made for both sides of debates about whether adaptations to evidence-based prevention protocols promote effective use of the programs or not. On the one hand, careful use of the intervention protocol, with high intervention integrity, would be expected to produce outcomes similar to those obtained in rigorous efficacy trials with that intervention. On the other hand, innovative interventions often need to be adapted to the realities of intervening with children in applied settings (Stirman, Crits-Christoph, & DeRubeis, 2004). When exporting interventions from research laboratories to clinical practice settings, refinements can be made to fit clinic conditions (Weisz, Donenberg, Han, & Kauneckis, 1995a), and to make strategies appropriate for the target audiences. As long as rigid adherence to manuals is avoided (Henry, 1998) then clinicians may not regard a manual as a “required cookie cutter approach” (Kendall, 2002). The creative flexible use of CBT manual-based interventions can permit individualization of intervention and increases the likely transportability of the intervention to new settings (Kendall, Chu, Gifford, Hayes, & Nauta, 1998). Thus, manuals derived from intervention research may not be expected to be followed word-for-word in applied practice, but could instead provide a guide for core skills and concepts to be covered (Connor-Smith & Weisz, 2003).

Despite the likelihood of adaptation of programs over time, and the possibility that rigid inflexible use of manuals may lead to less effective outcomes when interventions are disseminated to applied settings, little research has examined the effects of program adaptations. Research on the overall usefulness of manuals in treatments with adults has had mixed results (Herschell, McNeil, & McNeil, 2004). Although some studies with adults have found the use of a manual to be related to better outcomes (DeRubeis & Feeley, 1990), other studies of the use of intervention manuals with adult clients have had negative outcomes (Castonguay, Goldfried, Wiser, Raue, & Hayes, 1996).

Only two studies have directly addressed this issue with child interventions (Harnett & Dadds, 2004; Kendall & Chu, 2000). Harnett and Dadds (2004) asked facilitators in a school-based dissemination of a universal prevention program depression to complete checklists on intervention integrity and on their degree of deviation from the manual’s instructions for specific activities. Prior analyses had found that facilitators’ ratings on this checklist were generally, although not completely, correlated with the ratings of independent observers ($r = 0.65$ for changes on activities; $r = 0.73$ for the percentage of core concepts presented). The program was not found to have an influence on outcomes in this dissemination study, and facilitators’ degree of deviation from session activities was not found to be significantly associated with program outcomes.

Kendall and Chu (2000) asked therapists who had used a structured evidence-based cognitive–behavioral intervention manual with 148 children (aged 9–13) who had primary anxiety disorders, what kinds of intervention adaptations they made. Therapists made retrospective ratings using the Flexibility Questionnaire. This measure had 7-point rating scales, and assessed the therapists’ degree of flexibility in using seven techniques and activities, and their flexibility in the scope of material discussed. The Flexibility Questionnaire had strong internal consistency (alpha = 0.83). Prior research with these samples had found very high treatment integrity, with 100% adherence to session goals. The study found that the therapists’
ratings of flexible adaptation of intervention activities were not related to intervention outcome. In addition, flexible adaptation was not found to be related to client characteristics such as their age, sex, race, family income, specific anxiety diagnosis or comorbid diagnoses. Thus, it appears that the combination of requiring strict adherence to session goals while permitting careful flexibility in adapting specific activities meant to address the session goals can lead to successful implementation of programs in “real-world” settings.

**Therapeutic Alliance**

Later studies have suggested that a rigid adherence to a manual could have a negative effect on the therapeutic alliance, because as therapists’ technical competence increased their attention to the relationship decreased (Herschell, McNeil, & McNeil, 2004). The therapeutic alliance has been found in a meta-analysis to be significantly, albeit modestly, associated with outcomes in child and adolescent therapy (Shirk & Karver, 2003). The therapeutic alliance was not found to be related to client characteristics such as their age, sex, race, family income, specific anxiety diagnosis or comorbid diagnoses. Thus, it appears that the combination of requiring strict adherence to session goals while permitting careful flexibility in adapting specific activities meant to address the session goals can lead to successful implementation of programs in “real-world” settings.

**Therapeutic Alliance**

Later studies have suggested that a rigid adherence to a manual could have a negative effect on the therapeutic alliance, because as therapists’ technical competence increased their attention to the relationship decreased (Herschell, McNeil, & McNeil, 2004). The therapeutic alliance has been found in a meta-analysis to be significantly, albeit modestly, associated with outcomes in child and adolescent therapy (Shirk & Karver, 2003).

Historically, the therapeutic relationship has been viewed as a key change mechanism in child psychotherapy (Shirk & Karver, 2003). Currently, the majority of child psychologists and psychiatrists report in surveys that the therapeutic alliance and other non-specific processes are critical for change in child treatment (Chu, Choudhury, Shortt et al., 2004; Kazdin, Siegel, & Bass, 1990). Therapeutic alliance can be conceptualized as (Chu, Choudhury, Shortt et al., 2004):

1. A means to an end, such as the working alliance in psychoanalytic therapy;
2. A necessary and sufficient mechanism for therapeutic change, as in play therapy and client-centered therapy; or
3. In CBT, the therapist serves as an active “coach,” with an emphasis on a collaborative process.

Thus, therapeutic alliance is assumed to be necessary but not sufficient in CBT. Therapeutic alliance may be especially important in child intervention, because children do not initiate treatment. The affiliative bond between client and therapist and the agreement and involvement in intervention tasks may be key in child interventions. These dimensions are expected to be inter-related (Shirk & Saiz, 1992), and are assessed in one of the few therapeutic alliance measures available for children (Shirk & Russell, 1996).

There is minimal research to date, but a meta-analysis (Shirk & Karver, 2003) and literature review (Green, 2006) indicated:

1. A small but significant effect for therapeutic alliance (0.21), with somewhat greater effect for disruptive behavior (0.30) than emotional (0.10) problems;
2. Measures of therapeutic alliance taken late in treatment are more strongly associated with outcome than measures taken early in treatment; and
3. There was little support for the predictive effect of therapeutic alliance.

However, recent research has found that a positive alliance between parents and therapists in parent management training for antisocial children has predicted improvements in parenting practices (Kazdin & Whitley, 2006b) and positive child–therapist alliance has predicted improvements in children’s behavior (Kazdin, Whitley, & Marciano, 2006). To address a lack of examination of therapeutic alliance in group forms of CBT, Lochman, Barth, and Czopp (2005, June) examined therapeutic alliance in a sample of 80 children screened as being in the top 30% of children according to 4th grade teachers. The children received the Coping Power group CBT program. Findings indicated that children’s baseline behavior problems predicted poor therapeutic alliances, and weak therapeutic alliances are related to higher levels of children’s problem behaviors at the end of intervention. However, the therapeutic alliance was not a very good predictor of change in children’s disruptive behavior during intervention, suggesting that therapeutic alliance was not the primary mechanism accounting for CBT effects in group interventions with children.

**Potential Iatrogenic Effects: The Example of Deviancy Training**

Before widespread dissemination of evidence-based CBT interventions occurs, it is critical to understand who the interventions successfully influence, and whether there are intervention characteristics that can produce iatrogenic effects or subgroups of youth who are vulnerable to iatrogenic effects of a given intervention program. Within the field of youth violence prevention, a critical such concern that has arisen is the potential iatrogenic effect resulting from working with antisocial children in group formats where they may escalate, rather than reduce, their behavior problems. Research results were sufficiently alarming to lead some researchers to recommend that practitioners must be cautious in how they provide group-based interventions (Dishion, McCord, & Poulin, 1999).

In one of the seminal articles on this form of iatrogenic effect, Dishion and Andrews (1995) randomly assigned high-risk young adolescents to one of four conditions varying in whether the youths received 12 youth-only sessions, their parents received 12 parent-only sessions, the youths and the parents both received combined intervention, or the youths and parents received no intervention. All three of the Adolescent Transition program (ATP) intervention cells had some positive effects at post-intervention, and the conditions providing youth intervention produced reductions in negative family interactions and good acquisition of the concepts presented in the intervention. However, by the time of a 1-year follow-up, the youths who had received youth sessions had higher rates of tobacco use and of teacher-rated delinquent behaviors than did the control children, and these iatrogenic effects were evident even if the parents had also received intervention in the combined condition. At a 3-year follow-up, the teen intervention conditions continued to have more tobacco use and delinquency (Poulin, Dishion, & Buraston, 2001).

Analyses of the iatrogenic group conditions revealed that subtle dynamics of deviancy training during unstructured transitions in the groups predicted growth in self-reported smoking and growth in teacher ratings of delinquency.

A recent meta-analysis by Weiss, Caron, Ball et al. (2005) concluded that the risk for iatrogenic effects may currently be

To understand the effects of group interventions, it is necessary to consider the context in which the intervention is implemented. This context includes the school environment and the characteristics of the school, such as its size, location, and the cultural and social norms of the community. The diffusion of innovations, such as Multisystemic Therapy (MST), can be influenced by these contextual factors. MST is a complex intervention that requires careful implementation to ensure its effectiveness. The implementation process involves training professionals and ensuring that they understand and can apply the intervention in a consistent manner. This includes providing ongoing support and supervision to ensure that the intervention is delivered effectively.

Implications for Training and Implementation in Clinic and School Settings

An issue that increases the difficulty of detecting the effects of interventions, especially cognitive–behavioral preventive interventions, is that they are typically implemented at a number of sites (Raudenbush & Willms, 1991). The degree to which the intervention is implemented fully, and the context in which the intervention is embedded, can vary markedly from site to site. With school interventions, contextual factors such as the characteristics of the schools and the school climate can be markedly different across schools. Raudenbush and Willms (1991) argue that this variation, rather than being a nuisance which must be controlled in analyses, can provide critical information and is more important than the overall average effectiveness of the intervention. Variations in the adoption, success and maintenance of interventions across sites can have major implications for the effective dissemination of preventive interventions. In studies of organizational structure and climate, the level of analysis of organization effects should be both at the group level (i.e., school level) and at the individual level (i.e., individual school staff implementing the intervention; Rowan, Raudenbush, & Kang, 1991).

Organizational Influences at the School Level

New interventions and programs need organizational support to be adequately implemented (Berwick, 2003; Henggeler, Lee, & Burns, 2002). One of the central influences within Rogers’ (1995) model of the diffusion of innovations involves characteristics of the social system in which the innovation will be embedded, including how decisions are made to adopt innovations and the organizational norms of the setting. The social environment of the organization, and the relationships between individuals in the work setting, are critical characteristics of the organization and are evident in the patterns of leadership, control, autonomy and communication among workers and supervisors (Mowdy & Sutton, 1993; O’Reilly, 1991; Pfeffer, 1983; Porras & Robertson, 1992; Turnipseed, 1994; Weich & Quinn, 1999; Wilport, 1995). The work environment can be conceptualized as having certain systematic characteristics (Moos, 1974, 2002; Trickett & Moos, 1973), consisting of a relationship dimension (involvement, peer cohesion, staff support), a personal growth and development dimension (autonomy, task orientation, work pressure) and a system maintenance and change dimension (clarity, control, innovation, physical comfort). School personnel who perceive that their school climate is negative have been found to think that innovations introduced into their schools are burdens, and they have more burn out (McClure, 1980). In contrast, positively perceived school climate has been found to lead to successful implementation of new reforms in schools (Bulach & Malone, 1994), and collegiality, shared authority among colleagues and positive leadership by principals have been linked to the ability to facilitate change in schools and to continue school improvements (Peterson, 1997). In addition, school-level factors that have been found to influence those perceived environment factors that operate at the school level, and which can affect the implementation of interventions and students’ behavior, are school size, school-wide achievement levels, the ethnic composition of schools, the socioeconomic level of the student body and school-wide aggression levels among students (Barth, Dunlap, Dane, Lochman, & Wells, 2004; Kellam, Ling, Merisca, Brown, & Ialongo, 1998; Rowan, Raudenbush, & Kang, 1991).

Effects of Training

The characteristics of the training process and the integrity of the intervention implementation can influence the outcomes of intervention and can contribute to weaker effects of an intervention when it is transported to new settings (Henggeler, Melton, Brondino, Scherer, & Hanley, 1997; Henggeler, Schoenwald, Borduin, Rowland, & Cunningham, 1998). Meta-analyses of the child treatment literature have found that a higher degree of provision of structure (through intervention manuals) and monitoring (through review of intervention session tapes) in treatments offered in a variety of university and community settings were directly linked to superior intervention effectiveness (Weisz, Donenberg, Han et al., 1995a; Weisz, Donenberg, Han et al., 1995b).

Although rarely examined in the intervention literature, the degree of intensity of training can be anticipated to affect intervention outcomes. Henggeler, Schoenwald, Borduin et al. (1998) have advocated that Multisystemic Therapy (MST) can
only have maximal impact when training is both intense (5-day initial training), ongoing (weekly supervision by MST trained supervisors) and carefully specified. With sufficient intensity, training can achieve its primary purpose of enabling high levels of adherence to the intervention protocol, and producing high levels of intervention integrity (Henggeler, Schoenwald, Borduin et al., 1998). For example, adherence to MST intervention principles has been found to be an important predictor of key outcomes of criminal activity, incarceration and psychiatric symptoms for adolescents receiving MST (Henggeler, Schoenwald, Borduin et al., 1998).

Future Development and Refinement of Cognitive–Behavioral Interventions

Comorbidity
Structured manualized CBT may ignore the complexities of individual cases and neglect the individual idiographic nature of each client (Henry, 1998; Herschell, McNeil, & McNeil, 2004). Thus, the manual may be targeted at the average client with the particular disorder being addressed, but it may not permit a focus on comorbid problems or on individuals with extremely serious versions of the disorder (Weisz, Donenberg, Han et al., 1995b).

Range of Acceptable Adaptation
The clinician may perceive that a CBT manual’s predetermined intervention components have to be presented in a linear, invariant order, limiting the efficiency of the program (Weisz, Donenberg, Han et al., 1995b). If so, a manual may limit the clinician’s flexibility in addressing issues that go beyond the scope of the portion of the manual currently being used in a given session, but that are still relevant to the treatment plan and the specific issues being raised in the session (Kendall & Chu, 2000; Weissman, Rounsaville, & Chevron, 1982).

Booster Interventions
The current intervention literature indicates that one of the greatest difficulties with interventions for children with disruptive behavior problems is that the children’s improved changes in behavior tend to erode over time (McMahon & Wells, 1998), because following intervention the children remain in the same peer, family and neighborhood settings that may have contributed to the child’s baseline level of problems. Thus, gains are not positively reinforced, and others, such as teachers, still expect that the formerly aggressive child will continue to behave in antisocial ways. One solution to this problem has been to consider the use of booster interventions, which have been found to assist in maintaining intervention effects (Bry, Catalano, Kumpfer, Lochman, & Szapocznik, 1998). In research on the Anger Coping program, Lochman (1992) found that earlier intervention-produced reductions in children’s disruptive off-task behavior in school settings was maintained at a 3-year follow-up only for aggressive children who had received a booster intervention.

Technology and Internet Use
Empirical evidence indicates that individuals pay more attention to and learn more deeply from multimedia presentations than from verbal-only messages, resulting in greater problem-solving transfer (Eveland, Seo, & Marton, 2002; Lieberman, 2001; Mayer, 2003; van der Molen & van der Voort, 2000). Given this and the popularity of computers and video games among children and adolescents (Vorderer & Ritterfeld, 2003), it is not surprising that electronic media have become a popular modality for youth preventive interventions. Indeed, children and adolescents indicate that their preferred method of learning involves interactive multimedia (Lieberman, 2001). Multimedia programs have been developed to prevent youth violence. One such program, SMART Talk (Students Managing Anger and Resolution Together) aims to teach middle school students anger management and conflict resolution skills through a similar set of computer-based activities. While no significant changes in the frequency of aggressive behavior were found in a randomized controlled study of SMART Talk, significant effects were observed on several mediating factors associated with violence. In particular, students in the intervention condition were less likely to value violence as a solution to conflict, were more likely to report intentions to use non-violent strategies and reported more self-awareness about their response to anger in conflict situations than students in the control group (Bosworth, Espelage, & DuBay, 2000). Thus, multimedia programs display promising effects on risk and protective factors for negative youth outcomes, and may have effects on their actual behavior, especially for children already motivated to change. Research will need to explore whether multimedia programs can produce effective behavior change in children without a therapist, and without a therapeutic alliance, or whether multimedia programs can best be considered to be adjuncts to therapist-provided CBT.

CHAPTER 63

Parenting Programs

Stephen Scott

Advice on how to rear children has been around for a long time. Socrates (435 BC) reports on how a girl should be brought up “so she might see, hear, and speak as little as possible”; both sexes should be brought up to be schooled in modesty and self-control, a girl’s physique is designed for indoor work (childcare, breadmaking and woolworking), whereas a boy’s was designed for outdoor activity (ploughing, planting and herding) so their rearing should be focused towards these skills. Thus, from early on we have a notion of raising children to function well in their future worlds, taking into account their characteristics. This is usually believed to be reasonably successful – in the Bible it is written “Train up a child in the way he should go: and when he is old, he will not depart from it” (Proverbs 22:6). However, the question is how best to do this: should one use plenty of physical chastisement “Spare the rod and spoil the child” (Samuel Butler, 1660); or should one believe in the virtue of rewards, “And he who gives a child a treat/makes joy-bells ring in Heaven’s street” (John Masefield, 1908). Beliefs about how children should be raised vary enormously, within the same culture over time, and across differing cultures at any one time, including the present. Designing materials for parenting programs for disruptive children is not new; Jonathan Swift (1708) stated: “I conceived some scattered notions about a superior power to be of singular use for the common people, as furnishing excellent materials to keep children quiet when they grow peevish.”

Because of the wide range of theoretical ideas about how children should be brought up, this chapter first reviews evidence concerning parenting styles in relation to child outcomes. Then programs based on attachment theory and social learning theory have been especially influential in recent times and have led to rather different types of parenting programs. Attachment theory has led to interventions mainly for babies and infants, and social learning theory has led to interventions mainly for children from around 3 years upwards.

Attachment Theory

Attachment theorists (Ainsworth, Blehar, Waters, & Wall, 1978; Bowlby, 1969/1982; Cassidy & Shaver, 1999) developed a model of parent–child relationships from a broad theoretical base, including ethology, cognitive psychology and control systems (see chapter 55). Bowlby was particularly interested in identifying the nature, significance and function of a child’s (or animal offspring’s) tie to his or her parent. Although the theory had its roots in clinical observations of children who experienced severely compromised, disrupted or deprived caregiving arrangements, it has been applied as a model for normal and abnormal development. “Parent–child attachment” is not synonymous with “parent–child relationship” insofar as the former was conceptualized as being far more limited in scope. Attachment theory is concerned with fundamental issues of safety and protection; in psychological terms, attachment theory focuses on the extent to which the relationship provides the child with protection against harm and with a sense of emotional security or, to use the term made famous by Bowlby, a “secure base” for exploration. Many components of the parent–child relationship are not central to an attachment assessment, such as cognitive stimulation or discipline.

The theory proposes that the quality of care provided to the child, particularly sensitivity and responsiveness, leads to a secure or insecure attachment. Attachment theorists use the term “pathway” to make explicit that early attachment experiences do not shape subsequent development in a fixed deterministic manner (Bowlby, 1988). Insecure attachment is not synonymous with disturbance, and neither is a secure attachment a guarantee against disturbance. Indeed, long-term follow-up studies suggest that it is family relationships that are more important for child functioning than attachment insecurity per se (Grossman, Grossman, & Waters, 2005). However, we now know that a particular form of non-secure attachment in infants and young children termed “disorganized” is strongly related to risk for psychopathology and is a marker of particular risk in the caregiving environment (Greenberg, 1999; Lyons-Ruth, 1996), although it is important to note that it occurs in 15% or more of normal populations. Attachment

Theoretical Basis

Theories Linking Parenting to Child Outcomes

Whereas many theories link parenting to child outcomes, two perspectives – attachment theory and social learning theory – have
relationships are, it is suggested, internalized and carried forward to influence expectations for other important relationships, a process mediated by what Bowlby referred to as an “internal working model.” A history of consistent and sensitive care with the parent is therefore expected to lead to the child developing a model of self and others as lovable and loving and helpful. Effective attachment-based interventions have been developed and validated for a range of clinical problems (Bakermans-Kranenburg, van Ijzendoorn, & Juffer, 2003; Cicchetti, Rogosch, & Toth, 2000).

Social Learning Theory
Social learning theory evolved from different roots in general learning theory and behaviorism (Bandura, 1977). Broadly put, the notion behind social learning theory is that children’s real-life experiences and exposures directly or indirectly shape behavior; processes by which this learning occurs can be diverse. For many, there is a focus on traditional behavioral principles of reinforcement and conditioning, and so there is a near-exclusive focus on observed behavior (Patterson, 1969, 1996). The fundamental tenet is that moment-to-moment exchanges are crucial; if a child receives an immediate reward for their behavior, such as getting parental attention or approval, then they are likely to do the behavior again, whereas if they are ignored (or punished) then they are less likely to do it again. Other advocates of social learning models have expanded this focus to consider the cognitive or “mindful” processes such as attributions and expectations that underlie the parent’s behavior (Bugental, Blue, & Cruzcosa, 1989; Dix, 1992) and its effects on children (Dodge, Pettit, Bates, & Valente, 1995). Thus, social learning theory can be applied to behavior, cognitions, or both. Whether the assessment and conceptual focus is on behavior or cognitions, the model suggests that children learn strategies about managing emotions, resolving disputes and engaging with others, not only from their experiences, but also from the way their own reactions were responded to. For younger children especially, the primary source of these experiences is in the context of the parent-child relationship and the family environment. Furthermore, children take these strategies and apply them to other settings, for example to relationships with peers and teachers. This means that there will be a carrying forward of the effects of parent-child relationships across setting and time.

Given its historical emphasis on altering negative, aggressive behavior in the child, social learning theory-based models of parenting traditionally emphasized the harmful effects of parent-child conflict, coercion and inconsistent discipline. The focus was on the extent to which children’s aggressive behaviors were learned from and reinforced by parallel negative behaviors by the parents. More recently, social learning theory has explicitly incorporated positive dimensions of parenting as a way of promoting child positive behavior and affect, improving the pleasurable nature of parents’ and children’s interactions with one another, and providing a more positive and effective relationship context for parental disciplinary interventions (Gardner, 1987).

Research on social learning theory-based approaches to parenting interventions, especially as applied to antisocial children, is most closely associated with the work of Patterson (1969), founder of the Oregon Social Learning Center. Also influential was Hanf (1969), who developed play therapy based on rewarding child behavior through attention. Many leading current interventions directly incorporate social learning principles, notably the programs of McMahon and Forehand (2003), Brinkmeyer and Eyberg (2003), Forgatch and DeGarmo (1999) and Webster-Stratton (1981). Several interventionists expanded the social learning model to incorporate consideration of the parents’ social setting that may contribute to poor parenting, including Wahler, Winkel, Peterson, and Morrison (1965), whose program recognized the particular needs of isolated “insular” mothers. They were instrumental in showing, with hard evidence, that “insular” mothers were harsher to their children on those days when the few other adults with whom they had contact – such as local government officials or their own mothers – had been rejecting of them.

Parenting Styles
There are other many theories of parenting, some with a considerable evidence base. One is mentioned here, as it has been influential, even though to date it has not led to specific interventions. This is what can broadly be described as the parenting styles approach, and is associated with the work of Baumrind (e.g., 1991) and elaborated by others (Hetherington, Henderson, & Reiss, 1999; Maccoby & Martin, 1983; Steinberg, Lamborn, Darling, Mounts, & Dournbusch, 1994).

Baumrind observed interactions between parents and young children. Several important dimensions of parenting were measured and repeatedly found in subsequent studies carried out by successive generations of researchers. Core dimensions were warmth (versus conflict or neglect) and control strategies. Parenting typologies were thus constructed from a cross of warmth/conflict and control: authoritative (high warmth, positive/assertive control, and in adolescence high expectations), authoritarian (low warmth, high conflict, and coercive, punitive control attempts), permissive (high warmth coupled with low control attempts) and neglectful/disengaged (low warmth and low control). These four typologies have proved to be surprisingly robust and have been repeatedly associated with child outcomes. Children and adolescents of authoritative parents are consistently found to be more prosocial, academically and socially competent, and less symptomatic. Children whose parents are described as authoritarian, permissive or disengaged show significantly worse outcomes, with children of authoritarian parents showing typically the most disturbed adjustment of the four parenting types. As discussed below, these associations may be in part brought about by child characteristics shaping parental responses, but nonetheless there are likely to be substantial parent to child effects. Although some parenting programs may make parents more authoritative, they have not been conceptualized in these terms – it would be interesting to see the effectiveness of a new program developed on these principles.
CHAPTER 64

Evidence Linking Parenting to Child Psychopathology
Aggression, Conduct Disorder and Delinquency

The finding that parent-child relationship quality is associated with aggressive behavior, conduct disorder and delinquency is one of the most widely reported findings in the literature, repeatedly found in:

1. Large-scale epidemiological investigations, such as the Cambridge and Isle of Wight studies in the UK, and the Dunedin and Christchurch studies in New Zealand;
2. Intensive clinical investigations, such as the work of Patterson and colleagues; and
3. Numerous naturalistic studies of diverse samples using a mixture of methods (Denham, Workman, Cole et al., 2000; Dodge, Pettit, Bates et al., 1995; Dunn, Deater-Deckard, Pickering et al., 1998; Gardner, Sonuga-Barke, & Sayal, 1999; Hetherington, Henderson, & Reiss, 1999; Kilgore, Snyder, & Lentz, 2000; Lyons-Ruth, 1996; Steinberg, Lamborn, Darling et al., 1994).

The sort of parenting behaviors associated with these outcomes are high criticism and hostility, harsh punishment, inconsistent discipline, low warmth, low involvement, low encouragement and poor supervision.

More recent research has begun to disentangle different aspects of parenting that may be associated with antisocial behavior; for example, after controlling for the effects of conflict in the relationship, the amount of warmth or type of control predict additional variance in externalizing problems (Fletcher, Steinberg, & Williams-Wheeler, 2004; Kerr & Stattin, 2000). The main take-home message is that several aspects of the parent-child relationship are important. An implication for parenting programs is that they should not be simplistic and focus only on one dimension of parenting. The connection between parent-child relationships and disruptive behavior holds for variation within the normal range as well as for clinical disturbance. That is so both for parenting (e.g., harsh parenting versus documented maltreatment) and child outcome (e.g., moderate aggression to conviction for minor and serious offenses; Lansford, Dodge, Pettit et al., 2002; Patterson & Bank, 1989). An implication for parenting programs is that the same principles (albeit differently applied) are important for preventive work and less severe populations, and for “hard-end” cases.

Depression, Anxiety and Other Emotional Problems

Evidence supporting a link between quality of parent-child relationships and depression, anxiety and other emotional problems (e.g., somatic complaints, social withdrawal) is clear although weaker than that found for disruptive outcomes. Here again, the association is obtained from large-scale epidemiological investigations as well as clinical and normative developmental studies, and is evident in a range of samples and according to diverse methods (Dadds, Barrett, Rapee, & Ryan, 1996; Garber, Little, Hilsman, & Weaver, 1998; Wood, McLeod, Sigman, Hwang, & Chu, 2003). Just as it is the case for disruptive behavior, there is mounting evidence that individual variation in emotional symptoms is not speci-
Again, parenting programs may be more likely to be successful if they attend to all these dimensions.

**Impact of Abusive Parenting on Physiological Functioning**

Rutter (1981) in his book *Maternal deprivation reassessed* concluded that it was not separation *per se* that necessarily was very harmful; rather, more important for child well-being was the quality of parenting that had preceded the separation, and in particular the quality of parenting and other experiences that then followed it. Research on animal models has illuminated some of the physiological concomitants of the stress that can arise from particular types of separation and poor parenting. For example, the work of Meaney and colleagues (Kaffman & Meaney, 2007) showed that after infant rats were separated from their mothers for short periods (less than 15 min) in the first 2 weeks of their lives, they showed much more marked rises in stress hormones (on the hypothalamic–pituitary–adrenal axis [HPA]), leading to sharp rises in cortisol in response to aversive stimuli, but that this overreactivity went back to normal after a few days. However, longer separations (3 h per day) during this period led to large and lasting overreactivity to stress, physiologically with six-fold increases in adrenocorticotropic hormone (ACTH) and cortisol production a year later in response to a mildly aversive stress (a puff of air in the eye), and behaviorally with far greater fearfulness, emotional arousal and poorer sociability with other rats. The core component is likely not to be the separation, but the treatment of the infant rat on reunion by the mother, who largely ignores it, seldom licking or grooming it, and sometimes trampling over it.

Moreover, differences in physiological and behavioral responses to stress are not confined to cases of relatively extreme abuse. Amongst mother rats who have undisturbed access to their infants, there are marked differences in the prevalence of licking and grooming (L/G). Infants exposed to higher L/G grow up to have lower physiological reactivity, less fearful behavior and more prosocial behavior (Francis, Caldji, Champagne, Plotsky, & Meaney, 1999). This also affects brain growth, with offspring of high L/G mothers showing increased neural growth factors, specific receptors and cholinergic innervation of the hippocampus, which correlates with improved spatial learning and memory (Liu, Diorio, Day, Francis, & Meaney, 2000; Zhang, Chretien, Meaney, & Gratton, 2005); in contrast, pups of low L/G mothers show increased hippocampal cell death (apoptosis). The mechanism is environmental because cross-fostering studies show that infants of low L/G mothers develop normally when reared by high L/G mothers (Caldji, Diorio, & Meaney, 2000). Various interventions can mitigate the effects of poor early rearing, including gentle handling by humans, provision of a more stimulating environment and even antidepressants. Each of these interventions was reasonably successful in both physiological and behavioral terms (Bredy, Humphartzoomin, Cain, & Meaney, 2003). Broadly similar findings apply to primates, who have more similar developmental trajectories to humans; they provide good models for examining how much is a result of genetic susceptibility and how much is due to rearing, and for examining gene–environment interactions in the development of psychopathology (Barr, Newman, Becker *et al.*, 2003).

These findings are likely to obtain for humans too. Thus, Nemeroff and colleagues found that, compared with controls, women who had a history of child maltreatment showed a six-fold increase in HPA axis reactivity to laboratory-induced stress (Heim, Newport, Bonsall, Miller, & Nemeroff, 2001). The child and adolescent literature is emerging (see chapter 28), but as yet there have been few studies.

These studies have implications for parenting programs. First, children who have experienced repeated deprivation and abuse are likely to be biologically affected. The emotional overreactivity seen in some is not likely to be caused solely by learned habits in a background of typical physiology. Rather, some abused children may have been “set” to have far stronger reactions to stressors. This has implications for how they are seen, whether they are blamed for their reactions and may account for possible slowness to change behavior and “treatment resistance” compared with more appropriately raised children. Treatment implications are, compared with most children who had adequate parenting:

1. They need to be managed with understanding—reacting explosively in response to difficulties or frustrating situations may be far harder for them to control;
2. They should be managed in as calm and non-stressful a way as possible, to avoid setting off over-arious with its concomitant outbursts of destructive aggression; and
3. They may take more learning trials to achieve goals, and may achieve less.

Second, the biological data suggest that prevention and early intervention may be even more important than previously appreciated, in that children are not, as it were “only” psychologically affected by poor early experiences that can then be “corrected” by psychological therapy, but rather they experience may have lasting physiological and brain effects (Heim, Newport, Bonsall *et al.*, 2001). Further research is now needed to determine the type, severity and duration of harmful experiences, how these interact with individual susceptibility and, crucially, how far early and later benign experiences and therapeutic interventions can modify not only behavioral responses, but also physiological responses. Helpful interventions worth investigating include biological and pharmaceutical ones in addition to psychosocial interventions.

**Limitations of Parenting Effects on Child Outcomes and Psychopathology**

Although there is increasing interest in the public and in government in promoting parent-based initiatives to improve the well-being of children, this is based on the assumption that improving parenting will lead to improvements in children’s well-being. However, the link is not a straightforward unidirectional one of simple cause and effect. If this is not understood, then parenting programs will be expected to deliver more than is possible, and disappointment will follow. Concerns
CHAPTER 64

about these limitations have been expressed in no uncertain terms in some quarters. Thus, Scarr (1992) asserted that for most children, parenting had little influence on their outcomes. By this she meant that apart from abusive parenting, the new behavioral genetic research alluded to below was showing that most of the variability in children's outcomes was brought about by genetic factors, implying that so long as parenting was reasonable and "good enough," differences in children's developmental trajectories would be brought about by inherent factors. That parenting is not irrelevant is shown by the evidence of solid links provided in preceding sections, but it is nonetheless important to consider the limits of parenting effects.

Genetic Influences on Parenting

Genetically informed designs such as adoption studies can help tease out direction of effect. Parenting itself is not a purely socially determined activity. Results from several samples and methods show genetic mediation (Kendler & Baker, 2007; Neiderhiser, Reiss, Pedersen et al., 2004). Parents who are monozygotic (MZ) twins report engaging in more similar patterns of child-rearing with their children than do parents who are dizygotic (DZ) twins; this is also true for directly observed, dynamic, moment to moment, close interchanges in the parent–child relationship (Plomin, Reiss, Hetherington, & Howe, 1994). This has implications for those interventionists who believe parenting behavior is entirely socially determined.

One consistent exception to the pattern of moderate to large genetic mediation of parent–child relationship quality is attachment. Studies of attachment in twins find similar rates of attachment security in MZ and DZ twins, suggesting only a small part is played by genetic factors in child attachment security (Bokhorst, Bakermans-Kranenburg, Fearon et al., 2003; O'Connor & Croft, 2001). Why genetic factors in attachment security exert considerably less effect than for other aspects of parent–child relationship quality is not readily apparent, but it is a replicated finding.

Genetic designs can also help show environmental effects. In an unique “cross-fostering” study, in which adoptive parents of high and low socioeconomic status (SES) adopted children who were born into high and low SES families, Dumaret, and Tomkiewicz (1999) found that low SES children adopted into high SES families exhibited a higher IQ than children who were adopted into low SES families, a difference of approximately 8 IQ points. By using a behavioral genetic “tool,” these researchers have provided some of the strongest evidence that an improved home environment can indeed have a causal link with children's intellectual ability.

Broader Social Influences

There is a substantial covariation of risk factors in the child's environment, such as marital discord, lack of money and poor schools; the same may be so for protective factors. Studies that fail to account for these environmental risks may overestimate the importance of the link between parenting and child outcomes. Further, the same parenting practice may have different effects in different contexts. For example, Pettit, Bates, Dodge, and Meece (1999) reported that parental monitoring of a child (e.g., knowing who he or she is with and what he or she is doing) played a particularly important part in preventing delinquency in adolescents living in violent and high-risk neighborhoods. The effect of similar levels of monitoring in low-risk environments was less. Thus, the larger social context moderates the patterns of associations and likely causal processes that operate more proximally to the parent–child relationship.

A second example of research on contextualizing parenting focused on the child's temperament. Kochanska (1997) reported that, for temperamentally fearful children, gentle parental control was associated with optimal behavioral/emotional regulation whereas temperamentally more aggressive (“fearless”) children required more firm control to achieve the same positive results. Other studies have similarly shown that children with difficult/irritable temperament may be less likely to develop behavioral problems under conditions of firm compared with lax or less restrictive control (Bates, Pettit, Dodge, & Ridge, 1998). Belsky (1997) has taken this view further in suggesting that children differ from one another in how susceptible they are to rearing influence. In his model, those children who are more irritable may be more susceptible to rearing influence. The implication for parenting programs is that they should not follow a “one size fits all children” rigid manualized approach, but rather should vary their recommendations according to child characteristics and the wider social context.

Influence of Child Characteristics on Parenting

The notion that there are “child effects” on parenting behavior is hardly new. Indeed, Bell and Harper's (1977) book summarized numerous studies of several types showing the myriad ways in which child characteristics shape the parenting they receive. Key child characteristics included gender, age, temperament and presence of physical or intellectual or behavioral disability. In one classic study, Anderson, Lytton, and Romney (1986) crossed parent–child dyads in which the child was antisocial with parent–child dyads in which the child was not antisocial. Observations of parent–child interactions across the mixed pairings demonstrated that parents of non-antisocial children exhibited increased negativity toward the antisocial child, but parents of the antisocial children did not exhibit elevated conflict toward the non-antisocial child. In other words, it appeared to be the child’s behavior that was driving the interaction and not the parent's.

Another study used a longitudinal follow-up of a sample of adopted children (Croft, O'Connor, Keaveney et al., 2001). When the parent–child interactions were observed at age 4, the researchers found that child developmental status, indexed by lower cognitive ability, was associated with lower levels of parental positive interactions and higher levels of parental negative behavior. Two years later, many of the children had shown a significant improvement in cognitive ability. However, this developmental catch-up was not predicted by earlier parenting;
instead, gains in the children’s cognitive ability predicted positive changes in the parents’ behavior between assessments.

Intervention strategies with children with disorders can illuminate child effects on parenting. Compared with other mothers, mothers of children with attention deficit/hyperactivity disorder (ADHD) exhibit more negative control and less warmth. However, giving children medication for ADHD leads to positive changes in their parents’ behavior (Barkley, 1988). Thus, improvements in parenting behavior can be made without targeting the parent but merely improving children’s behavior. As well as making the theoretical point that child characteristics affect parenting behavior, this process has practical implications. In families where a child is overwhelming their parents’ parenting capacity, in addition to targeting parenting skills, changing child characteristics directly may also enable parenting to be better.

In summary, recent research suggests that parenting styles are to some extent genetically influenced; parenting effects will vary in their impact on the child according to the context in which they live; and children with different temperaments will elicit different parenting styles and will have different parenting needs. All these considerations have implications for parenting programs, including the need for a careful assessment prior to commencing treatment, which should then be tailored accordingly.

Programs for Infants Based on Attachment Theory

In the last decade or so, many new parenting programs have sprung up that directly use attachment theory. Some use it in a very focused way, whereas others use it more loosely and incorporate other concepts. The core notion is that parents should increase sensitive responding to provide a secure base. For a review of the effects of disrupted early attachments, see Dozier and Rutter (in press).

Content of Typical Programs

Focused interventions typically last 5–20 sessions and videotape mother–infant interactions and then replay them. During replay the idea of recognizing the infant’s signals is brought out—in early stages, even if a mother is usually ignoring her infant, the therapist will try to find one bit of videotape where nonetheless she does respond. Perhaps the infant will smile and she will smile back, leading the infant to gurgle with pleasure. The therapist might say “Look, when he smiled you smiled back so warmly that he showed he loved it by gurgling!” In later sessions, when the mother’s confidence has been gained (over 95% of participants are mothers, but the principle is the same for fathers or other carers), a less satisfactory piece of interaction may be examined. When a mother is not responding, the therapist can point this out, and ask “What was going through your mind at that moment?” This may elicit many interesting responses, from preoccupation with the mother’s own needs or hassles (“I was wondering how to pay off my debt”) to misperception of cues (“I thought he was trying to wind me up” said of a messy eater), to strong negative emotions arising from her past experience (“When he does that I think he’s just like his father, who ruined my life”). The great strength of this approach is that:

1. It gives parents an accurate picture of what is actually happening (rather than just talking about their perception of their relationship with their infant, as in traditional parent–infant psychotherapies);
2. It enables them to see for themselves that when they change their behavior, this impacts on their infant;
3. It allows simultaneous exploration of the mother’s mental state, so that mental blocks to more sensitive responding can be explored and often overcome.

Examples of focused programs include that by the Leiden group (Velderman, Bakermans-Kranenburg, Juffer et al., 2006).

Broader attachment-based therapies have been developed for infants and children who have been abused and who may have been transferred to foster families. This provides an interesting context in which to apply attachment theory because by definition these children have experienced disruption of attachment figures, and almost always suffered abuse or neglect at their hands. These include the program devised by Dozier, Lindheim, and Aciernan (2005), which is used with both birth and foster-parents. It lasts 10 sessions and is based on the following (empirically based) notions:

1. Like parents in intact families, foster-carers may have their own insecure (unresolved or dismissing) attachment representations which will predispose them to be insensitive to their foster-children, who will have elevated need in terms of disorganized attachment patterns. Dozier concludes that because of their states of mind, some carers may find that providing nurturance does not come naturally. Thus, the first goal of the intervention is to help foster-carers provide care even if it does not come naturally to them.
2. Infants in foster care often fail to elicit nurturance. Dozier’s group showed that fostered children fail to elicit nurturance from carers who would normally provide it. For example, after falling from a chair, such an infant may turn away; even an autonomous mother might say “Oh, I’m glad you’re OK” and tidy up the toys without picking the infant up and comforting him, as she would have had be shown distress. The intervention therefore aims to train foster-mothers to act in nurturing ways even in the absence of cues from the infant.
3. Abused infants are often poorly regulated at physiological, emotional and behavioral levels. This means they sleep poorly, often eat sporadically, show disruptive behavior and abnormal arousal patterns. The response by Dozier’s group is to teach parents to follow the child’s lead. Others might counsel that parents should stay especially calm so as not to over-arouse the child, be more patient and turn away from conflicts, but be quick to soothe the child and look assiduously for ways to do this.
4. Abused infants often have experienced threatening situations. This may lead them to cut off or dissociate or have other maladaptive interactions. Foster-parents are therefore trained to avoid being threatening, either emotionally through being...
CHAPTER 64

angry, or by threatening the security of the relationship (e.g., saying they will return the child to social services). Other attachment-based programs include the Circle of Security program developed by Cooper, Hoffman, Powell, and Marvin (2005) for at-risk children in birth families.

All three programs mentioned so far use video-feedback. Other interventions that do not use video-feedback include that developed by Zeanah and Smyke (2005) for children who were severely deprived in institutions such as Romanian orphanages, and more lengthy and intensive psychodynamic ones such as that of Slade, Sadler, and Mayes (2005). Olds (2006), in contrast, developed a home visiting program delivered by nurses (Nurse-Family Partnership) that is not based on attachment theory but on systematic evaluation of and evidence-based interventions for risk factors from pregnancy onwards. Thus, parents are encouraged to reduce cigarette and alcohol consumption in pregnancy through understanding the effects on their babies; once the baby is born, parent–child interaction is coached, including how to stimulate the baby appropriately, and wider issues such as partner violence and further general education for the mother are addressed.

Effectiveness

There have been several trials for attachment-based approaches. The meta-analysis by Bakermans-Kranenburg, van IJzendoorn, & Juffer (2003) found 81 studies with a total of over 7000 parent-infant pairs assessed. Overall, they improved parental sensitivity by 0.33 standard deviations (SD) and attachment security by 0.20 SD. However, there were large variations between approaches used. Perhaps surprisingly, the most effective interventions were relatively short (under 26 sessions) and started later (after the infant was 6 months). Both of these findings go against cherished notions that early intervention must be better, and that more effort should lead to more change (in fact, the mean effect size for long interventions was –0.03). However, were the findings true for disorganized attachment patterns, which carry a worse prognosis? A separate meta-analysis of this group again found the more focused interventions still worked better (Bakermans-Kranenburg, van IJzendoorn, & Juffer, 2005). Was it the case that short interventions were not effective for multi-problem families? Again, this was not the case, the short interventions still worked better than long ones (effect size 0.48).

Possible reasons for these findings are that the short interventions focus more specifically on sensitive responding and mostly use video-feedback in a pragmatic behavioral way, rather than taking a more counseling or traditionally psychotherapeutic approach. Is it then the case that the longer interventions have a broader impact on a wider range of outcomes? There is rather limited information on this issue, but again the data do not appear to support this (van IJzendoorn, Bakermans-Kranenburg, & Juffer, 2005).

What about parenting programs that do not rely heavily on attachment theory? Some use a general notion that if the parents are supported, then they in turn will relate better to their infants. For example, in a trial of the home visiting program Homestart, which involved a mean of 97 h of face-to-face contact with mothers, none of the many mother or child variables measured changed (McAuley, Knapp, Beecham, McCurry, & Sleed, 2004); a similar lack of effectiveness was found for the Oxfordshire Home Visiting project (Barlow, Parsons, & Stewart-Brown, 2005). In contrast, interventions that focus precisely on specified risk factors, even when these are many, seem to fare much better. Thus, the Nurse-Family Partnership (NFP) approach has been evaluated in three randomized controlled trials involving over 1000 mother-infant pairs. This has shown benefits for the children in terms of improved cognitive and emotional development and fewer accidents and injuries, and for the mothers in terms of fewer harmful health behaviors (e.g., smoking) and higher take-up of further education, less use of public handouts and a longer interval until subsequent pregnancy (Olds, 2006). Interestingly, in the third NFP trial (in Denver), mothers were randomized to receive the program from volunteer paraprofessionals or nurses. Both were given the same amount of training in the program, but overall the paraprofessionals failed to change the child or parent outcomes, whereas the nurses did. The problems of making early parenting interventions work under field conditions rather than in university trials was underlined by Spieker, Nelson, Deklyen, and Staerkel (2005), who embedded a trial of video-feedback with high-risk mothers in a Head Start preventive program in the USA, but there were no changes in parenting or child attachment status.

Current Status of Attachment-based Interventions

A number of conclusions seem warranted. First, interventions that only offer “support” for parents do not appear to improve quality of parenting or child attachment status, even though they are appreciated by parents. Second, the more specifically focused interventions that target particular parental behaviors such as sensitive responding lead to greater effect sizes on parenting and child attachment status. Third, the same is true of interventions that target broader risk factors such as maternal alcohol intake and further education; those with specific goals that make use of previously tested methods are more effective than less focused interventions. Fourth, it seems likely that using more skilled staff leads to larger effects.

There are a number of unanswered questions that future studies could address. How important is increasing child attachment security, in itself? If the interventions only improve attachment security but not other outcomes, that will be of limited interest. Generally, long-term follow-up studies suggest that infants brought up in favorable circumstances who have insecure attachment patterns nonetheless do well in terms of later relationship quality and attainment, whereas those brought up with harsh parenting and disadvantaged circumstances do relatively poorly irrespective of attachment status (see summaries of the major longitudinal studies in Grossman, Grossman, & Waters, 2005). This is not to say that attachment patterns are not important, but rather to say that the research needs to broaden out to embrace other aspects of parent and child functioning.
Programs for Children Based on Social Learning Theory

Programs based on social learning theory have evolved over 40 years and there is a large evidence base. The vast majority are aimed at antisocial behavior as their proximal target outcome. The content and delivery of a typical program are shown in Table 64.1.

Most basic programs take 8–12 sessions lasting 1.5–2 h each. Full accounts of programs are given by the developers (e.g., Triple P, Markie-Dadds & Sanders, 2006; Helping the Non-compliant Child, McMahon & Forehand, 2003; Parent–Child Interaction Therapy, Brinkmeyer & Eyberg, 2003; Defiant Children, Mash & Barkley, 2006; and The Incredible Years, Webster-Stratton & Reid, 2003).

Format of a Typical Social Learning Program

A typical individual program might run as follows.

Part 1. Techniques for Promoting a Child-Centered Approach

The first session covers play. This is seen as a fundamental aspect of improving the relationship with the child. Parents are asked to follow the child’s lead rather than impose their own ideas. Instead of giving directions, teaching and asking questions during play, parents are instructed simply to describe what the child is doing, to give a running commentary on their child’s actions. The target is to give at least four of these “descriptive comments” per minute. If the parent has difficulty in getting going, the practitioner suggests precisely what they should do, for example by saying “I’d like you to say to Johnny ‘You’ve put the car in the garage’.” As soon as the parent complies, the practitioner gives feedback, “That was a good descriptive comment.”

After 10–15 min, this directly supervised play ends and the parent is “debriefed” for half an hour or more alone with the clinician. How the parent felt during the session is explored, and reservations and difficulties that arose are addressed. Usually, the effect of their behavior on the child during the training session is soon observed by the parent. Experiencing this close non-judgmental attention is surprisingly powerful for children, who at best feel they are “the apple of their parent’s eye.” For cases where virtually all communication with the child has become nagging and complaining, play is an important first step in mending the relationship. It often helps the parent to have fun with the child and begin to have some positive feelings towards them. Parents are asked to practice these techniques for 10 min every day.

The second session involves elaboration of play skills. For the first 20 min, the previous week’s “homework” of playing at home is gone over with the parent in considerable detail. Often there are practical reasons for not doing it (“I have to look after the other children” or “I’ve got no help”) and parents are then encouraged to solve the problem and find ways around the difficulty. Solutions arrived at might include doing the play after the younger sibling has gone to bed or getting the oldest child to look after the baby while the parent plays with the toddler. For some parents there may be emotional blocks (“It feels wrong – no one ever played with me as a child”) which need to be overcome before they feel able to practice the homework.

After this discussion, live practice with the child is carried out. This time the parent is encouraged to go beyond describing

1053
part of the child’s behavior and to make comments describing the child’s likely mood state (e.g., “You’re really trying hard making that tower” or “That puzzle is making you really fed up”). This process has benefits for both the parent and the child. The parent gets better at observing the fine details of the child’s behavior, which makes them more sensitive to the child’s mood. The child gradually gets better at understanding and labeling their own emotional states, a crucial step in gaining self-control in frustrating situations.

Subsequent sessions follow the same pattern:
1. Reviewing the previous week’s homework;
2. Direct training of interaction with the child; and
3. Discussion afterwards of how it went.

The speed at which the content is covered depends on progress. Later sessions cover the following ground:

Part 2. Increasing Acceptable Child Behavior
Praise and rewards are covered here. The parent is required to praise their child for lots of simple everyday behaviors such as playing quietly on their own, eating nicely, getting dressed the first time they are asked, and so on. In this way the frequency of desired behavior increases. However, many parents find this difficult. They may say “But he should be doing these things anyway, without being praised for it – there’s really no need.” When their child has misbehaved earlier in the day they are still cross, and this prevents them praising good behavior when it occurs. Some parents find that even when they want to praise their child, the whole process feels alien to them. Often, they never experienced praise themselves as a child. Usually, with directly coached practice, it becomes easier. Later sessions go through the use of reward charts.

Part 3. Setting Clear Expectations
Clear commands are covered next. A hallmark of ineffective parenting is a continuing stream of ineffectual nagging demands for the child to do something. In the program, parents are taught to reduce the number but make them much more authoritative. This is achieved through altering both the manner in which they are given, and what is said. The manner should be forceful (not sitting down, timidly requesting from the other end of the room; instead, standing over the child, fixing him in the eye and in a clear firm voice giving the instruction). The emotional tone should be calm, without shouting and criticism. The content should be stated as a fact (“I want you to . . .”) and not indirectly or as a question (“Wouldn’t you like to . . .”). It should be specific, labeling the desired behavior which the child can understand, so it is clear to him when he has complied (“Keep the sand in the box”) rather than vague (“Do be tidy”). It should be simple (one action at a time, not a chain of orders), and performable immediately. Commands should be phrased as what the parent does want the child to do, not as what he should stop doing (“Please speak quietly” rather than “Stop shouting”). If a child is in the middle of an activity, rather than abruptly ordering a stop, a warning should be given (“In two minutes you’ll have to go to bed”).

Rather than threatening the child with vague, dire consequences (“You’re going to be sorry you did that”), when–then commands should be given (“When you’ve laid the table, then you can watch TV”).

Part 4. Reducing Unacceptable Child Behavior
Consequences for disobedience are covered next. They should be applied as soon as possible. They must always be followed through – children quickly learn to calculate the probability they will be applied, and if a sanction is only given on every third occasion, a child is being taught he can misbehave the rest of the time. Simple logical consequences should be devised and enforced for everyday situations. If water is splashed out of the bath, the bath will end; if a child refuses to eat dinner, there will be no pudding. The consequences should fit the crime, should not be punitive and should not be long-term (e.g., no bike riding for a month), as this will lead to a sense of hopelessness in the child, who may see no point in behaving well if it seems there is nothing to gain. Consistency of enforcement is central.

Ignoring is an important additional technique. This sounds easy but is a hard skill to teach parents. Whining, arguing, swearing and tantrums are not dangerous to children and other people and can usually safely be ignored. The technique is very effective. Children soon realize they are getting no pay-off for the behaviors and soon stop. Vice versa, if acting this way gets attention and shows them they can annoy and wind-up their parents, they will continue to hone their skills in so doing. Ignoring means avoiding discussion, avoiding eye-contact, turning away, but staying in the room to monitor. As soon as the child begins to behave appropriately, it is essential to attend and give praise. This is central to shaping up desirable behavior. Many parents find this difficult as they are often still angry with the child.

Time out from positive reinforcement remains the final “big one” as a sanction for unacceptable behavior. The point here is to put the child in some boring place away from a reasonably pleasant context. This will not be the case if the home is generally negative, when being sent to a room alone will be a relief and not a punishment. Equally, if the room has lots of interesting toys it will also not be a punishment. Time out should be for a previously agreed reason (hitting, breaking things – not minor infringements) for a short time (say 1 min for each year of age). However, the child must be quiet for the last minute – if he is still screaming, he stays in for as long as it takes until he’s been quiet for a minute. Parents must resist responding to taunts and cries from the child during time out, as this will reinforce the child by giving attention. Time out provides a break for the adult to calm down too.

Part 5. Strategies for Avoiding Trouble
These include planning ahead to avoid troublesome times of day and situations, negotiating with the child how to accommodate their wishes while fitting in with the family goals, and developing a problem-solving approach with the child to promote independence, along the lines of problem-solving approaches taught directly by professionals to children (Kazdin, 2005).
**Effectiveness of Social Learning Programs**

**Outcomes**

Research has predominantly looked at children with antisocial behavior. This is a reasonable target because it indexes a wide range of poor outcomes, and because parenting is implicated as a major contributory factor (see review above, and chapter 33). A decade or so ago there was still a question as to whether parenting programs improved child antisocial behavior. Since then systematic reviews and meta-analyses of scores of studies usually with no-treatment controls have confirmed that they do indeed generally work well for children aged 3–10 (Lundahl, Nimer, & Parsons, 2006; Maughan, Denita, Christiansen et al., 2005; McCart, Priester, Davies, & Azen, 2006; for a narrative review including comparison of individual versus group based studies see Scott, 2002). Mean effect sizes across studies vary from around 0.4 to 1.0 according to outcome, showing reasonably good effectiveness. The field has moved on to consider further questions, including comparison with active controls such as non-behavioral programs, investigation of predictors of treatment response and mechanisms of change.

**Comparison with Non-behavioral Programs**

There have been a number of head-to-head comparisons of non-behavioral humanistic approaches with behavioral programs, although most trials have been on relatively well-functioning volunteer samples. Humanistic approaches are usually based on the notion that supporting the parent in a non-judgmental accepting way will make them feel better and parent more effectively. Pinzer and Geoffrey (1981) compared a behavioral group with a humanistic approach, Parent Effectiveness Training (PET). On parent report, the behavioral group showed a significant reduction in child problem behavior whereas PET and controls did not; on direct observation, both treatment groups did better than controls. Bernal, Kinnert, and Schultz (1980) compared a client-centered group with behavioral management and waitlist controls, and found on parent report the behavioral group did better than the other two, but on direct observation no group changed. With a clinical sample, Nichol, Smith, Kay et al. (1988) studied families referred by local social services for active physical abuse and allocated them to individual play therapy for the child plus support from social worker for the mother, or home-based work that offered parent training plus parent support through casework. Parent training led to a greater reduction in parental coerciveness and aversive behavior towards their children, measured using direct observation. In summary, behaviorally based programs appear to improve child outcomes more reliably.

**What Makes Parenting Programs Work?**

**Predictors and Moderators of Outcome**

In a controlled trial, if a characteristic of the participants such as child age or severity of symptoms predicts outcome in both the intervention and control groups, then it is a predictor. However, if after allowing for this there is additionally an inter-action with treatment, so that one subgroup (say, younger children) do better than another (older children) in the intervention group only, then the characteristic is operating as a moderator. Until recently, analyses have mainly been at the level of predictors only, with one or two exceptions. A number of predictors have been identified.

**Child Age and Gender**

Clinicians often gain the impression that boys and older children, especially adolescents, do worse. Indeed, adolescents are generally found to do less well in parenting programs for antisocial behavior. Bank, Marlowe, Reid, Patterson, and Weinrott (1991) found a far smaller effect size when using parent training with adolescents than with younger children at the same institution. More generally, the meta-analyses of interventions for antisocial behavior and juvenile delinquency (see chapter 68) find that their effectiveness was considerably smaller than parent-training studies on younger children. However, studies on adolescents generally have the most severe, persistent cases. When cases of similar severity are compared directly, there is no age effect; Ruma, Burke, and Thompson (1996) compared response to treatment using the parent Child Behavior Checklist (CBCL) score for groups in early childhood (2–5 years), middle childhood (6–11 years) and adolescence (12–16 years). The adolescent group did slightly less well, but the difference disappeared on multiple regression analysis, which showed that greater initial severity was the only significant predictor of poorer response. Within the prepubertal age group, Dishion and Patterson (1992) had expected to find parent training more effective for younger (2.5–6.3 years) than older children (6.5–12.3 years) assessed by direct observation. However, they found it was of similar effectiveness for both age groups, a finding replicated by Beauchaine, Webster-Stratton, and Reid (2005). The meta-analysis by Serekitch and Dumas (1996) found that across 36 studies (not within them), effectiveness was greater in older children, within the range 3–10 years.

In summary, it appears that age is not a clear determinant of outcome. Naturally, in adolescence different approaches are needed, with more emphasis on negotiation, and close supervision when the young person is out of the house, but the belief that adolescents are inevitably very difficult to change is not supported by the evidence. Likewise, boys are as likely to improve as girls (Beauchaine, Webster-Stratton, & Reid, 2005; Scott, 2005). There is therefore room for some optimism when treating adolescents, so long as evidence-based approaches are skillfully applied.

**Child Psychopathology**

The meta-analysis by Reyno and McGrath (2006) found that more severe initial antisocial behavior predicted less change, but this was a bivariate association with no controlling for related factors such as family adversity. In contrast, taking such factors into account, Scott (2005) found the opposite: those with higher initial levels improved more. Further studies that address this issue using multivariate statistics are needed. Child ADHD generally predicts a less good response (MTA
Mediators of Change

In recent years, researchers have begun to investigate what mediates outcome, as recommended by Rutter (2005). To mediate treatment outcome:

1. The treatment has to change outcome;
2. Treatment has to change the mediator;
3. The mediator has to correlate with outcome; and
4. The effect of treatment on outcome has to reduce or disappear after controlling for the mediator (Baron & Kenny, 1986; Kraemer, Wilson, Fairburn, & Agras, 2002).

In other words, the treatment does not work unless it changes the mediator. It would seem likely that for parenting programs to change child behavior, some aspect of parenting would first have to change. This is worth testing as it might not be the case – for example, the parenting program could make a couple realize that they should, say, stop arguing in front of their child, but still spend the same amount of time in play and joint activities and use the same disciplinary strategies; or the parenting might stay the same but as a result of the program, the parents may have changed the child’s school. These wider aspects of a child’s world are typically not measured in parenting intervention studies.

Beauchaine, Webster-Stratton, & Reid (2005) found that changes in critical, harsh and ineffective parenting both predicted and mediated child change in antisocial behavior. Similarly, Tein, Irwin, MacKinnon, and Wolchik (2004) found that parental discipline and mother–child relationship quality mediated reduction in antisocial behavior in post-divorce children, whereas Gardner, Burton, and Klimes (2006) found that positive parenting also mediated change. In adolescents, there have been two high-quality studies. Eddy and Chamberlain (2000) investigated mediators of change in seriously antisocial adolescents (average 13 police contacts at age 15) looked after by specially trained foster-parents. They found that all three measured parenting constructs mediated change, namely effectiveness of discipline (fairness, punitiveness, use of positive reinforcement); quality of supervision (youth reports of supervision and of doing things the foster-parent did not know about, difference between fosterer’s and youth’s accounts of problem behavior, percentage of time spent by youth in the presence of an adult); and an overall positive adult–youth relationship (how much they liked each other). Additionally, the amount of time spent with deviant peers including the degree of their influence also mediated outcome. Taken together, these four factors accounted for 32% of variance in subsequent antisocial behavior – a substantial amount. Similarly, Huey, Henggeler, Brondino, and Pickrel (2000) in a trial of multi-systemic therapy for delinquency showed that a positive relationship and firm discipline mediated outcome, and good supervision mediated deviant peer association, which in turn mediated subsequent antisocial behavior. Recent studies are beginning to investigate the extent to which parental beliefs, rather than just behavior, need to change – Doolan (2006) found that improvement in the positive view of the child mediated reduction in antisocial behavior.

These studies have moved the field on, because they indicate not just which dimensions are associated with antisocial behavior in longitudinal studies, nor baldly whether treatment works, but rather show which variables need to change for a good outcome, thus helping to understand how treatment works (Rutter, 2005). This is turn has led to changes in programs. Thus, there is now a much stronger emphasis on preventing deviant peer association – for example, the Oregon Social Learning Center (OSLC) foster program penalizes youth for every minute they cannot verifiably account for their where-abouts. Future program modifications may include specifically cognitive elements to address negative cognitions that appear to stop change occurring (Sanders, Pidgeon, Gravestock et al., 2004).

Future studies will need to take measures of mediators at several time points, to determine the sequence of changes – to answer, for example, whether parenting must change before child behavior can change; whether all aspects of the parenting relationship need to change to get most child improvement, or just those that are poorly practiced; how much parenting change is necessary for child change to occur; and what systematic interactions are there between parenting styles and child psychopathology that could inform how best to improve outcomes.

Dissemination: The Role of Therapist Skill

Many of the cited trials have taken place in university clinics...
run by highly motivated originators of programs, who supervise carefully chosen therapists intensively in demonstration projects. In the meta-analysis of child psychotherapy trials by Weisz, Donenberg, and Han (1995) those conducted in university clinics had a large mean effect size of 0.7 SD. In stark contrast, all the clinic-based studies reviewed since 1950 did not have any significant effects. This has enormous implications for service delivery, as it is of little use if interventions do not work under “real-life” conditions. Reasons postulated include:

1. Children with comorbid conditions are typically excluded from trials;
2. Therapists in trials deliver evidence-based programs for the condition under study only, whereas in real life therapists see many diverse conditions and do not deliver evidence-based programs – they have to be “jacks of all trades” (and so perhaps “masters of none”);
3. Even where therapists in everyday clinics do deliver evidence-based approaches, they do not receive good quality ongoing supervision.

Therefore, for a therapeutic approach to be considered useful, findings need to be replicated in ordinary clinical settings by therapists who are part of the routine service and independent of the program originator. Weisz noted that fewer than 1% of published child psychotherapy trials met all three of the following criteria:

1. Carried out by teams independent of the program developer;
2. Delivered by clinicians employed in regular clinical practice; and
3. Used clinically referred children as participants.

To address these concerns Scott, Spender, Doolan, Jacobs, and Aspland (2001) carried out a trial of Webster-Stratton’s Incredible Years program on regular clinical referrals for severe conduct problems (98th percentile), most of whom had co-morbid ADHD (mean hyperactivity percentile 90th). Therapists were local clinicians given additional training. Despite these constraints, the effect size was large (over 1 SD) and maintained 1 year after the end of treatment (Scott, 2005). The authors suggested that the effectiveness was related to having skilled staff who, despite having regular clinical jobs, made time to come to supervision each week, when videotapes of practice were examined and alternative therapeutic approaches rehearsed. This approach to supervision is in contrast to traditional supervision, where therapists recount what they think went on, and are given advice.

Therapist Variables

Therapist performance can be divided into the following:

1. The *alliance*, which could be defined as how well, both personally and collaboratively, client and therapist get on together;
2. Fidelity or adherence to specific components of a model, which concerns the extent to which the therapist follows the actions prescribed in the manual;
3. The skill or competence with which the therapist carries out the tasks (i.e., how well the therapist performs the actions).

A meta-analysis of youth studies of the alliance found it contributed on average an effect size of 0.21 SD to outcome; this held across treatment types, and across youth, parent and family approaches (Shirk & Carver, 2003). Kazdin, Whitley, and Marciano (2006) found about 7% of the variance in outcome of treatment for antisocial children was related to the alliance, although findings varied by informant.

Given the importance of these qualities that are therapy type independent, does it matter what the warm and genuine therapist who makes a strong alliance does during the sessions? One might expect fidelity would be central, because if the “wrong” therapy is given, it should be less effective. However, studies are somewhat equivocal, thus Henggeler, Melton, Brondino, Scherer, and Hanley (1997) compared a total of 15 parent, therapist and youth-rated fidelity scales with seven youth outcomes in a trial of multisystemic therapy, and found statistically significant effects for only 11 out of 105 associations. The same group (Huey, Henggeler, Brondino et al., 2000) found that when they used a latent variable approach, therapist-rated fidelity improved family functioning and parent monitoring, both of which in turn reduced youth delinquency, but that parent- and youth-rated fidelity had no effect. This last finding could be because it requires a therapist to appreciate the complexity of fidelity, and also because therapists working across cases will be more consistent in their ratings than parents and youths, who may differ widely in their rating of the same phenomena.

These somewhat modest findings for the role of adherence or fidelity raise the question whether applying the treatment according to the manual is necessary or sufficient to bring about change. Often adherence and fidelity ratings concern the extent to which certain actions specific to the therapy were carried out, such as following sequences as laid down in the manual during sessions, using certain questioning techniques, issuing homework, and so on.

It is possible that a more important and relevant influence on effectiveness is the skill or competence with which these tasks are carried out. Thus, for example, two therapists running a parenting group might to the same extent discuss punishment, explore parents’ beliefs, teach time out as an alternative to spanking, rehearse it and issue homework. However, the more skilled one might do this in a more sensitive way with greater complexity, and so characterize the client’s mental state more accurately and be more proficient in overcoming barriers to rehearsal and homework, thus leading to more change. Supporting this notion, Forgatch, Patterson, and DeGarmo (2005) developed an observer-based instrument to assess therapist variables which included skill in a parenting program for recently divorced parents. They measured knowledge, structure, teaching skill, clinical skill and overall effectiveness. The outcome assessed was the proximal one of observed parenting practices, rather than child behavior; greater therapist skill led to more change in parenting. Likewise, in their trial under regular clinical conditions described above, Scott, Carby, & Rendu (2006a) found that therapist skill had a large effect on child outcomes; the worst therapist made outcomes slightly worse. If replicated, these findings have major
implications for service delivery, because they suggest that at least for multiproblem clinical cases, a high level of therapist skill is required; staff training will need to reflect this.

Conclusions

Parenting programs have developed considerably in recent years. The best now incorporate modern empirical findings from developmental studies and use these to alter dimensions of parenting shown to improve specified child outcomes. Future developments may include better assessments of parenting so that programs can be tailored to specific needs rather than “one size fits all.” Studies are needed of the mechanisms that mediate changes in parenting behavior; for example, whether it is necessary for parental beliefs about the child to change, or whether it is sufficient for parents to learn better habits. Then how changes in parenting mediate child change and interact with different types of child temperament and behavior problems needs clarifying. Finally, how therapy works and the degree of therapist skill needed to bring about change are beginning to be worked out. Future studies will be able to help service delivery by elucidating which families can improve sufficiently using computer-based self-instruction, allowing scarce resources to be targeted on those who most need them.

PARENTING PROGRAMS
Family therapy, like other psychotherapies, has evolved over several decades and today includes a broad range of ideas that are often described as representing discrete theoretical models or schools (e.g., structural, strategic, Milan systemic, narrative; Carr, 2006). Different approaches to family therapy tend to focus on one particular aspect of change (e.g., the structural model on the need for change in relationships, or the Milan approach on the need to change beliefs) and are usually associated with particular groups or centers. In practice, the conceptual ideas as well as the techniques associated with each of them tend to be adopted quite widely and most family therapists integrate ideas from different approaches in their work, as single theoretical models often do not provide sufficient conceptual breadth or choice of treatment techniques to address the wide range of difficulties presented to clinicians.

The boundary lines between family therapy and other therapeutic approaches are also indistinct and there are many overlaps. The distinctions are often more about historical developments and professional and philosophical allegiances than clearly defined conceptual differences. This is reinforced by research on common factors in psychotherapy, which suggests that they may account for as much as 90% of outcome variance (Asay & Lambert, 2000; Wampold, 2001), although the actual role of common factors is subject to much debate ( Sexton & Ridley, 2004; Sexton, Ridley, & Kleiner, 2004; Simon, 2006; Sprenkle & Blow, 2004, 2007). Alongside this, the growing body of research on evidence-based practice identifies a number of clearly defined family treatments as effective (Lundahl, Risser, & Lovejoy, 2006; Shaddish & Baldwin, 2003; Stanton & Shaddish, 1997; Woolfenden, Williams, & Peat, 2007). Taken together they suggest that while there may be common factors across all psychotherapeutic approaches, particular problems may respond well to very specific treatment components which may be incorporated in a number of different treatment models, albeit sometimes conceptualized in different ways. At the same time, the research also indicates that successful treatments are united at another level by factors such as empathy or warmth of the therapist or the level of motivation of the client (Beutler, Malik, Alamohamed et al., 2004; Clarkin & Levy, 2004; but see chapter 18 for a somewhat different conclusion). Part of the effectiveness of family therapy will be the skill of the therapist to use the most appropriate approach and interventions and to maintain the engagement and motivation of family members.

Theoretical and Empirical Developments

The Family as a System

Family Systems Theory, the conceptual framework for much of the thinking about working with families, has evolved considerably over the years. The original notion of the family as a system (Ackerman, 1938; Burgess, 1926), strongly influenced by cybernetic concepts (von Bertalanffy, 1968), described a number of features such as the recursive nature of relationships, the multilevel nature of communication (Bateson, 1972; Bateson & Ruesch, 1951), the development of recognizable patterns of interaction, the role of relationships and beliefs, and the allocation of family roles (Bateson, Jackson, Haley, & Weakland, 1956; Palazzoli, Boscolo, Cecchin, & Prata, 1978). More recent theoretical developments in family therapy theory have come from social constructionism (Berger & Luckman, 1966) and in particular narrative therapy (White & Epston, 1989). This emphasizes that what we consider as objective everyday reality is derived from and maintained by social experiences and that through social interactions we develop narratives to make sense of our own lived experience. Later in the chapter we discuss the impact that the incorporation of social constructionist ideas has had on the field.

The second main strand in family therapy theory is the Family Life Cycle model (Carter & McGoldrick, 1999), which provides a “developmental lens” for understanding the way the family as a system evolves over time. Families need to provide stability and predictability but they also have to be able to change in order to adapt to new circumstances and the developmental demands of individual family members (Byng-Hall, 1991; Eisler, 1993). For instance, the child’s need for dependence and attachment requires a degree of stability and constancy in the family but, as the child develops, the family must find ways of meeting his or her needs for independence and separation too. As the family evolves through the predictable stages of the family life cycle, it needs to be able to adapt and change its habitual style of functioning. These expected stages of the family life cycle can be complicated by unexpected events such as illness, death, family separation or migration and the com-
bined stress can contribute to the development of problems. There is evidence that at these transitional times there is an increased vulnerability and increased psychological morbidity (Gorell Barnes, Thompson, Daniel, & Burchardt, 1998; Hetherington, 1989; Kendler & Prescott, 1999; Ritsner & Ponizovsky, 1999; Sartorius, 1996; Varnik, Kolvs, & Wasserman, 2005). The way the family responds to an emerging problem is a crucial factor in determining the extent of individual vulnerability to such pressures (Walsh, 1997).

**Role of the Family in the Development and Maintenance of Psychological Difficulties**

Early theorizing assumed that particular types of family organization or patterns of family interaction would be connected with specific presenting problems. Explanatory models such as the “double-bind” theory of schizophrenia (Bateson, Jackson, Haley et al., 1956) or the “psychosomatic family” model of anorexia nervosa (Minuchin, Rosman, & Baker, 1978) were highly influential and led to important clinical innovations. Paradoxically, while many of the treatments developed in this way seem to be efficacious, the theoretical models themselves have generally proved to be flawed (Eisler, 1995; Kog, Vandereycken, & Vertommen, 1985; Olson, 1972). This has resulted in a somewhat unfortunate legacy. On the one hand, there are those who still see family therapy in its original guise (i.e., a treatment that aims to correct family dysfunction which was thought to lie at the heart of individual problems). Although few family therapists would today subscribe to this notion, outside of the field the view is still held quite widely. On the other hand, many within the field of family therapy, partly as a reaction to concerns about families being blamed by the early theoretical models, argue that the impact of family factors on child development is part of such a complex matrix of influences that any explanation that focuses on them is bound to be misleading. While we have some sympathy with the latter view, it clearly does not take into account the large body of research that now exists on the role of family factors in the development of the child. These include a range of adversities from prenatal factors such as being an unwanted child (David, Dytrych, & Matejcik, 2003; Kubicka, Roth, Dytrych, & Matejcik, 2002) or maternal stress (Huizink, Robles De Medina, Mulder, Visser, & Buitelaar, 2002), the consequences of growing up in an environment characterized by negative emotion, harsh parenting, high levels of discord or hostility (Fergusson & Lynskey, 1996; Fergusson, Horwood, & Lynskey, 1992; Moffitt, Caspi, Harrington, & Milne, 2002; Riggins-Casper, Cadoret, Knutson, & Langbehn, 2003) or the impact of neglect (Rutter & O’Connor, 2004). Equally, there are factors in the family that may have a protective role or promote resilience (Rutter, 1999, 2006).

There are three reasons why one has to be cautious about how these findings are interpreted in relation to clinical practice. First is the often-made point that there is a complex interaction over time between the effect of the family environment, personality and temperamental characteristics of the child, the impact of the developing disorder on the family, and resilience factors as well as mediating genetic factors (Fergusson & Lynskey, 1996; Rutter, 1999). This is highlighted by behavior genetic research showing the differential impact of the family environment on children within the same family (Dunn & Plomin, 1990; Reiss, Hetherington, & Plomin, 1995; Rutter, Silberg, O’Connor, & Simonoff, 1999). The second is the reciprocity of influences between parents and children, which is well documented empirically (Crockenberg & Leerkes, 2003; Crockenberg, Leerkes, & Lekka, 2007; Deater-Deckard, Atzaba-Poria, & Pike, 2004; Scaramella & Leve, 2004). The third and probably most important is the variability of the findings showing that the impact of even the most powerful factors is anything but uniform (O’Connor, Rutter, Beckett et al., 2000). There are many examples but perhaps the best way of illustrating our point is to use a specific example of how research findings of this kind do not easily translate into practice.

There are a number of clinical and research accounts of the possible adverse effects of maternal eating disorder on the infant or young child (Lacey & Smith, 1987; Park, Senior, & Stein, 2003a; Russell, Treasure, & Eisler, 1998) showing obstetric complications, low birth weight, poorer physical development and in some cases the development of an eating disorder in the offspring when they reach adolescence. A series of observational studies by Stein and colleagues (Park, Lee, Woolley, Murray, & Stein, 2003b; Stein, Woolley, Cooper et al., 1994; Stein, Woolley, Cooper et al., 2006) has shown that mothers with a history of an eating disorder tended to be more intrusive and express more negative emotion with their infants during mealtimes and the children themselves had a more negative emotional tone and their mealtimes were more conflictual compared with controls. The children tended to be lighter than controls and their weight was related to the amount of conflict during mealtimes and the extent of the mother’s concern about her own body shape. The problematic interaction around mealtimes persisted at 5 years and when followed-up at 10 years the index children showed increased levels of shape and weight concerns and greater dietary restraint compared with controls (although at a considerably lower level than would be found in children with early-onset anorexia nervosa). A further study in the form of a randomized controlled trial (Stein, Woolley, Cooper et al., 2006) showed that a video-feedback intervention was effective in improving mother-infant interaction at mealtimes. Thus, we have research that identifies not only risk factors, but also some likely mechanisms through which these might operate and a possible effective preventive intervention derived from this.

In spite of this, the clinical implications are much less straightforward than may seem at first sight. First, although the group effects in comparison with controls are strong, the findings apply only to a minority of the children in the index group. For instance, 27% of the index group was below the 25th centile for weight. This is much higher than the 4% in the control group but is still only a quarter of the sample. At age 10 there were no differences in the children’s weights. Similarly, there is considerable variability in the findings of
mother–child interaction within the index group, both in the initial study and at follow-up, and at 10 years there was no difference in levels of criticism or intrusive behaviors on the part of the mothers compared with controls. Second, while there is an association between the degree of a mother’s psychopathology and the disturbed interactional pattern, it is not clear what mechanism underpins this. Thus, it is unclear to what extent it is a direct consequence of the mother’s eating disorder (e.g., fearing that her infant might put on too much weight) or if the problems arise out of her lack of confidence in her parenting, resulting in being unnecessarily controlling with the child. The point we want to emphasize, however, is the complexity of the process through which adversity operates over time in individual cases. While it is clear that although as a group the children were at increased risk of developing disturbed eating attitudes, most in fact did not.

Consider now the opposite scenario when as a clinician we see an adolescent with an eating disorder whose mother also had an eating disorder. Stein’s work would indicate that the two might be linked but actually tells us very little about how this potential link may have operated for these individuals and even less about what the target of our intervention would need to be. Knowing what factors may have a negative impact on a child’s development is of course useful, but without knowing if these are still operating and if so how they operate, our clinical interventions remain blunt instruments. The current emphasis by most family therapy approaches on family strengths and resilience (Walsh, 1997), and on trying to optimize the family’s own resources, may be no better in terms of the science that informs it but it has the merit of engaging families in positive ways instead of adding to their sense of failure and self-blame.

Impact of Individual Problems on Family Life

When one member of a family begins to develop a problem it affects other members and also the relationships within that system (Rolland, 1999). Some of the effects may be readily apparent such as bullying or aggression from a young person with attention deficit/hyperactivity disorder (ADHD), at other times the impact may be less obvious and not immediately apparent (e.g., “well” siblings receiving less attention from parents). The stress of dealing with difficulties may put a strain on the parents’ relationship or the relationships with wider family. For the clinician, the crucial issue is to understand the gradual process of reorganization of the family in response to the problem to the point where it becomes the “central organizing principle” in the family’s life (Eisler, 2003; Steinglass, 1998). The process will often start through the activation of protective and supportive processes in the family but can in time become part of what reinforces or maintains the problem. For example, what may start as supportive reassurance of an anxious and perhaps somewhat perfectionist child may with hindsight turn out to be the start of a process of parents being drawn into the emerging rituals of a developing obsessive-compulsive disorder (OCD; Amir, Freshman, & Foa, 2000; Calvocoressi, Mazure, & Kasl, 1999). Useful models for understanding the process through which the family accommodates to the child’s problem can be found in the studies of the impact on the family of serious and enduring physical illness and disability (Rolland, 1987, 1994; Steinglass, 1998) and anorexia nervosa (Eisler, 2003; Neilsen & Barca-Carril, 2003). Understanding how families respond to emerging problems is an area demanding further research.

The way families respond to this invasion into their lives will vary, but there is a tendency for the problem to magnify certain aspects of the family’s dynamics and narrow the range of their adaptive behaviors (Whitney & Eisler, 2005). As the symptomatic behavior increasingly takes a central role in family life what may be normal variations in family functioning may become more pronounced and take on new meanings. Concern may begin to feel like overprotection and intrusiveness, while attempts to promote independence may feel like lack of care. For the clinician, the important thing to be aware of is that much of what is observed in families is, at least in part, an outcome of the process of family accommodation to the problem and should not be too readily labeled as dysfunctional.

Family Interviewing and Family Therapy

Interviewing Families as Part of the Assessment Process

The family interview is an important component in a comprehensive assessment. It provides the clinician with an opportunity to observe the family in direct interaction, to assess patterns of relationships, the emotional climate of the family and a chance to see how the family is organized around the symptoms presented by the child. Interviewing the family for purposes of assessment is a good starting point for making an effective treatment alliance with the family. Hearing the concerns of family members and their hopes for the future is as important as gathering information and making an assessment of the problem and can determine the most effective ways of helping the family to promote change.

Observing Patterns of Interaction

From the first contact with the family the clinician has opportunities to observe patterns of interaction, both immediately and over time (Byng Hall, 1995; Minuchin, 1974), which provide information about family structure and the nature of relationships in the family. Who presents the problem, how others respond, who finds it easy or difficult to have their say and how disagreements are handled will all provide initial impressions about the family’s preferred style. Careful observation of the interaction process will provide information that may confirm or contradict the content of what is being said. For instance, a mother may describe her relationship with her teenage daughter as difficult or conflictual. This may be supported by observing regular clashes or irritable responses between the two but at the same time one may notice that there are also many warm and supportive interactions taking place.
When making observations it is important not to draw conclusions too readily as to what the observed patterns might “mean” or how they might be related to the presenting problem. While certain interactions may be clearly unhelpful (e.g., a parent, perhaps unwittingly, reinforcing the challenging behavior of a 6-year-old or frequent changes of topic preventing the discussion of difficult emotional issues), there may be a range of different (often overlapping) explanations for the observed behaviors. It is important to explore the family members’ own perceptions of such patterns and how they are connected to the beliefs and expectations of the family and how much flexibility or rigidity there is around them. Some patterns may reflect family beliefs, often strongly influenced by cultural or specific family traditions about the nature of family life, gender roles and parenting tasks, and may include patterns of which the family members themselves may not be aware.

Family Beliefs and Meanings Attached to Behaviors
These can be useful in making sense of behavior and relationships but also aid the process of engagement so that a family feels more understood. Beliefs relating to the presenting problem are particularly important. Future therapy may focus on exploring those beliefs and questioning them so that new meanings can develop. It may be possible to identify strong individual and family narratives that cloud the possibility of other options for change (Parry & Doan, 1994). One of the central aims of interviewing families is to explore alternative perceptions and meanings. This will include giving space to family members whose voices are not readily heard but also looking for different ways of framing the family narrative in a way that may provide a more constructive way forward. For instance, when a family is invited to a clinical meeting only one parent (e.g., mother) might attend the session. A variety of explanations may be given (dad is too busy; mum normally deals with doctors’ appointments; he doesn’t really understand). Implicit in such explanations is often a suggestion that the father is somewhat detached or does not really care. Often the most effective way of getting the father to attend the next session would be to ask him what he would want to be here? (“Is he not here because he doesn’t care or is it because he does not believe he can help?” “If he believed that coming here would make a difference to you, would he come?” “If he thought that coming here would help him understand better, would he want to be here?”). The value of such questioning is that it creates a new frame of reference for familiar behaviors and may allow new conversations to develop.

Social and Cultural Contexts
One of the criticisms of some of the earlier models of family therapy is that they were based on a normative western model of the family and did not take sufficient account of the diversity of family life across cultures and the considerable change that families have undergone in most societies. The notion of what family life means in terms of the nature of relationships within the family, the expectations of the way in which families change over the life cycle or the roles of different family members varies hugely. Children may grow up in foster and adoptive families or a succession of different families or may be part of more than one family constellation following marriage break-up. Single-parent families, same-sex parent partnerships and friendship networks provide different forms of family life. While much of this may seem self-evident, it is crucial to be open to the different experiences and expectations that families bring with them. We also have to be aware that as professionals our own personal and cultural contexts will inevitably color our observations and assessments.

Exploring the family’s social and cultural contexts will help to give meaning to specific behaviors, beliefs and relationships, but it may also provide information on stresses (e.g., specific social expectations in the community) and resources such as sources of networking and support (Falicov, 1995). An evaluation of the role of professionals in the referral process and the history and relationship of the family with other helping systems is important, particularly where there has been multi-agency involvement, which may itself have become disabling for the family (Asen, 2002).

Exploration of the Presenting Problem in the Context of Individual and Family Development
An understanding of current life cycle and developmental demands and how the family is meeting these can be very helpful (Carter & McGoldrick, 1999). Sometimes, outside pressures such as illness or bereavement or internal changes such as separation and divorce add extra demands for change in addition to and sometimes contradictory to developmental demands. For instance, when an adolescent develops psychosis the normal developmental need for greater autonomy may be countered by the need for greater care and supervision. Accommodating to the needs of the illness is an understandable (and generally positive) response, although over time it may itself become unhelpful and limit the possibilities for change. Enquiring about the impact of the problem on family life is a good way of understanding the way the family is functioning and can often also reveal areas of strength and resilience that are not at first evident.

Assessing the Family’s Style of Dealing with Problems and Identifying Strengths and Weaknesses
This should help to address the important question about how best to work with a family, identify transferable skills and also aid the engagement process. The therapist will draw from the evidence relating to positive parenting and resilience factors to identify areas of strength which can be developed. For example, the capacity for reflection and empathy can be developed through sensitive and skillful questioning. The ability to make sense of past experiences can also be developed through the therapeutic process. Completing a family genogram (Bloch, Hafner, Harari, & Szmukler, 1994; McGoldrick & Gerson, 1985) is a useful way of learning about the way in which the family has dealt with other problems, family traditions and beliefs about family coping with adversity.
CHAPTER 65

Family Interview Techniques

It is beyond the scope of this chapter to cover in depth the variety of techniques that have been developed for interviewing families (Dallos & Draper, 2005; Palazzoli, Boscolo, Cecchin, & Prata, 1980; Tomm, 1988). Much of this literature is concerned with the way in which different types of question can shape the therapeutic relationship and the importance of questioning (as opposed to information giving) in general, in maintaining a position of curiosity which aims to keep the therapist and the family open to new information and new meanings. The following is a brief outline of some of the different styles of questioning that have proved useful in family interviews. Tomm (1988) suggests the following classification.

Lineal Questions

All interviews will include some questions of this type (e.g., “What is the problem that you have come with?” “How long has it been going on for?”). The disadvantage of lineal questions is that they tend to elicit a rather well-rehearsed way of presenting the problem which may be quite fixed, and not only expresses the family’s belief about the nature of the problem but also often connects with feelings of helplessness, guilt, blame and resentment.

Circular Questions

These differ from lineal questions not only in form but also in their underlying assumption. They draw on the assumption that individual problems are connected or embedded in patterns of relationships, and the aim of these questions is to illuminate or make visible what these patterns are. So, instead of simply asking “What is the problem?” one might ask “How would different people in the family describe your problem?” “Who worries about it?” “When people get worried about how unhappy you are, does it make you more or less depressed?” Other questions might require family members to describe what they make of behaviors that they observe, or speculate about thoughts and feelings of other family members. For instance, instead of asking just about the duration of the problem, the therapist might ask “When did your family first notice that you had a problem?” or “What effect did it have on you when your parents started talking about the problem?” Additional questions might be asked about the way different people in the family responded to the problem and what interactions this might lead to “When your mother shows her worry, what does your father do?”

Asking circular questions starts to provide a basis for describing the problem in a more contextual way and also allows for alternative descriptions to be heard. For instance, the family might explain that “Mum worries a lot whereas father does not show his feelings much,” implying that mother is too anxious and father too detached. Useful questions to develop alternative aspects of this might be “How do you know when your husband is getting worried?” and “When your dad tries to reassure your mum, what effect does it have on her worry?” This may lead to a discussion of the differences between experiencing and showing feelings, and the interplay within the family between behaviors and emotion of different family members. It may also be an opportunity to talk about individual and gender differences and perhaps the different expectations that each parent brings with them from their own family of origin.

One way of organizing the use of circular questions is to connect them to a systemic hypothesis. The therapist links information about the family to form a hypothesis about the family and their relationship to the presenting problem. This hypothesis is then tested through circular questions and continually revised in the light of feedback until an idea is arrived at that fits well enough with the family to provide some useful new information for them. For example, a systemic hypothesis might suggest that when a child feels sad his mother becomes anxious that she is not a good mother and hands over the care to her husband, who worries about his wife and criticizes his son, who finds that self-harming is a way of bringing his parents back into a caring contact with him. This hypothesis could be tested with reflexive questions such as “What would happen if your father was not at home?” or to the mother “If you felt more confident in yourself as a mother what might you do differently?”

Strategic Questions

These are questions that are used with the primary aim of influencing the family in a particular way rather than obtaining information and are analogous to giving instructions but because they are formulated as questions this may not always be immediately apparent. “Why do you let your mother speak for you?” is as much a statement that implies that it would be better for the adolescent to speak for him or herself as a question asking for an explanation. Challenging interventions of this kind can be useful at times but should be used sparingly, as they can induce feelings of guilt and they may also undermine the therapeutic relationship with the family (Tomm, 1988).

Reflexive Questions

These are questions that are also intended to influence the family but are less directive, instead requiring family members to reflect on how things might be different under changed circumstances, or if they took a different course of action: “What would happen if you were able to hide your worry when your daughter got depressed?” “If your mother didn’t try to help next time you have a row with your father, which one of you would be more likely to find a way of ending the argument; who would be the one to suggest a compromise solution?” Reflexive questions will typically introduce an alternative way of framing a particular behavior, opening up new possibilities and challenging the assumptions that may underlie a particular pattern of behavior. They may address an emotion or an aspect of behavior that is not being expressed overtly and may only be guessed at. They may include an implicit assumption: “What will you argue about with your mother when you are no longer bulimic?” – implying both that there will be change and that arguments between adolescents and parents are normal. Reflexive questions, like circular questions, assume that behaviors and the meanings that we attach to them are
part of the relational context of the family and that there may be more than one meaning that might be attached to a particular behavior. The aim is for the family to reflect on this context and to explore the way in which thoughts, feelings and behaviors of different family members connect and how they might change.

Relative Influence Questions
These are specifically linked with the technique of externalizing the problem and explore the influence the problem has had on the person(s) and, more importantly, the influence the person has had on the problem. Through the process (e.g., of exploring how the family has helped a young child with fears or anxiety) it may be possible to establish exceptions or unique outcomes when there has been some control over the problem and how these can be developed further.

It is important for the clinician to be able to use a range of interview styles with families and to have a repertoire of different types of question. Circular questions can be extremely useful in illuminating patterns of relationships in the family and this in itself may be an important and powerful part of the therapeutic process. However, such questions are most usefully applied when the interviewer has developed a clear hypothesis about the nature of the family relationships and the part played by the symptomatic behavior in the family organization (Burnham, 1986). When the interviewer has a clear focus, one question will naturally lead to the next one, helping to confirm or disconfirm the particular hypothesis. However, if such questions are used without a clear focus they are more likely to create confusion and a sense of alienation (Reimers, 1999; Strickland-Clark, Campbell, & Dallos, 2000).

Intervening in the Family Interaction Process
Careful and sensitive observation of the processes within the family allows the therapist to assess the nature of the relationships, provides opportunities for joining the family but is also the basis for introducing change in more active ways. There are numerous techniques (Minuchin & Fishman, 1981) for this, including blocking repetitive patterns (e.g., when one person in the family regularly acts as a peacemaker), reinforcing behaviors such as positive parenting, setting rules to prevent repetitive escalation of arguments or encouraging a family member whose voice tends to get lost to make sure they are heard. Interventions may range from fairly unobtrusive non-verbal ones (fixing the gaze of the person who is speaking, making it more difficult for others to interrupt) to much more overt, even dramatic gestures (“Why don’t you go and sit next to your dad and try to work out a compromise with him without getting mum to help you?”) and may include specific suggestions or homework tasks. Alternatively, the therapist may ask a question or make a comment in a way that draws attention to what is happening. When commenting on family process it is always important to recognize that the same phenomenon can be described in a number of ways ranging from neutral, through ascribing agency to one or other participant in the interaction, to overtly critical. Even quite neutral comments from the therapist may appear critical to family members. The clinician therefore has to be careful in choosing an appropriate style of comment or question. Andersen (1987) recommends that reflections of this kind are best carried out in a tentative way rather than being pronouncements or authoritative interpretations which are likely to come across as being judgmental.

Involving Children and Adolescents in Family Interviews
Even very young children can be effectively included in family interviews, provided they are engaged in an age-appropriate way. All too often, however, such interviews end up simply as an adult conversation in the presence of the child. It is helpful to provide appropriate toys and drawing materials, and use creative and play techniques in a similar way that they would be used in individual interviews with a child. Engaging a child effectively is often reassuring for parents, who may be concerned whether bringing the child to a psychiatric setting is the right thing to do. The choice of language in talking to parents about their child’s problems is also important with young children present as it may be difficult for the child to understand what is being said. Often it is better to ask the parents to explain things to the child, rather than the clinician doing this directly as this may be less threatening for the child, and reinforces the sense that the parents are the experts for their own child.

With very lively active children the first task is to create a working environment in which what family members have to say can be attended to. This is best achieved by actively collaborating with the parents. Asking the parents for advice on how best to occupy young children will reinforce the parents’ sense that they are being respected and also may make it easier for the child to listen and join in spontaneously at some point during the interview. Children may not be too keen to take part in discussions at first. Making it clear at the start of the session that everyone in the room will have an opportunity to have their say, while stressing that it is also OK to sit and listen, is important for some children, to avoid making them feel that they are being put on the spot. When the pressure on them to join in is removed, children will often join in spontaneously. Joining with a child in creative play or talking about a drawing he or she has made can also provide an opportunity for the child to have a voice in the session (see also Dare & Lindsey, 1979; Larner, 1996; Wilson, 1998).

A similar situation can sometimes arise with adolescents who may be reluctant to talk, while the parents may have an expectation that the “experts” will succeed where they have failed. Sometimes, such an adolescent may be more willing to talk when seen individually, but this is by no means always the case. The advantage of a family interview is that even a reluctant or unwilling participant can be included in an interview through indirect means. Making it clear that the therapist respects the adolescent’s right not to speak can help avoid an unhelpful battle. This can be done in a way that respects the adolescent’s autonomy while at the same time making sure that he or she is not simply being ignored. One might encourage
the adolescent to listen but also to correct other family members if he or she thinks they have misunderstood or got things wrong. The therapist can check this out from time to time.

**Who to See and When**

Although it is always useful to see the whole family interacting together, conjoint interviews also have their limitations in both the assessment and treatment phases. During assessment there may be indications that some individuals do not have an effective voice in the family group. For example, an adolescent may not want his or her parents to know about drug use or there may be concern that a child has been abused and may not want to talk about this in front of their parents. Similarly, there may be issues that parents may not wish to discuss with the child present (e.g., to do with marital issues or perhaps when parents of a child with disability may not be able to share negative feelings in front of the child). For these reasons it is generally useful to make at least some separate sessions a routine part of practice even when family therapy is indicated as the main mode of treatment. There are several other considerations that should be taken into account when deciding on individual or conjoint sessions. For instance, we might decide that it is age-appropriate to see an adolescent on their own, particularly if they express a wish for this. We should consider (and enquire about) to what extent this is determined by a wish to avoid talking about a painful or upsetting issue, which may not necessarily be a helpful thing to do. Some topics may seem difficult to address in a conjoint meeting although the discomfort may be largely to do with the clinician’s own uncertainty about how or whether to raise the issue. Asking questions about what is acceptable or usual in the particular family will tell the clinician what can or cannot be easily talked about and may open up the topic for discussion. Questions such as “If your parents thought you were smoking dope, what would they do?” or “Some teenagers are very up-front about what they get up to, others keep things closer to their chest – what is your son like?” may quickly lead to frank and open conversations. More importantly, this kind of discussion will clarify what the actual boundaries in the family are rather than being assumed by the therapist.

In families where there is much hostility, criticism or open conflict, conjoint meetings may not always be helpful particularly if the hostility or conflict simply escalates in sessions. There is evidence that families with high parental scores on criticism are more likely to drop out of treatment (Szmukler, Eisler, Russell, & Dare, 1985). In a study comparing conjoint therapy with separated therapy (i.e., separate meetings with parents and the adolescent) for adolescent anorexia nervosa, critical families did better in separated therapy (Eisler, Dare, Hodes et al., 2000). It is sometimes assumed that family dysfunction should be the main indication for family therapy. In fact, the opposite is the case. Several studies have shown (Barrett, Healey-Farrell, & March, 2004; Eisler, Dare, Hodes et al., 2000; Hampson & Beavers, 1996a) that the quality of family functioning moderates the effect of family therapy, with poorly functioning families gaining less benefit. This should not be interpreted as simply showing that more dysfunction leads to poor outcome, as there is evidence that these effects might be specific to particular types of family intervention. For instance, collaborative approaches to treatment (which are often favored by therapists) are less effective with disorganized families (Hampson & Beavers, 1996b), who tend to respond better to a more directive and less open style whereas the opposite is true of more balanced type families. Our own study of separated and conjoint therapy was interesting in this context in showing a three-way interaction between level of criticism at the beginning of treatment, type of treatment and long-term outcome, but somewhat surprisingly this effect disappeared when end of treatment level of criticism was considered (Eisler, Simic, Russell, & Dare, 2007). This suggests that it may be an effect that is operating at the level of treatment engagement rather than a persistent effect of criticism itself.

In general, it is often useful to try to separate the question of how and when to involve the family in treatment to help deal with the child's problem from the question of how to address possible problems in the family. This is partly to avoid reinforcing disabling feelings of guilt and blame and partly that, as we discussed earlier, much of what may appear dysfunctional is part of the way the family has accommodated to the problem. Most importantly, it is seldom going to be the case that resolving a family difficulty is itself going to resolve the child’s problem.

**The Family Therapist in the Multidisciplinary Team**

Most clinicians working with children and adolescents will to a greater or lesser degree include families in their work. This is sometimes referred to as “family work” to distinguish it from “family therapy” although the divide between the two is somewhat artificial. Family therapists by virtue of their training will have developed specialist skills in working with families and may therefore take on more complex work but where there is an indication for family interventions the same principles should apply whether the work is carried out by the specialist family therapist or the non-specialist. The role of the family therapist within the multidisciplinary team is of course much wider than just seeing families. They will have to be able to identify when a family approach is likely to be helpful and the different styles of work that might be best suited for the specific problem or a particular family. The family therapist can provide support and supervision for other team members working with families which may involve using a one-way screen or video link. This can have a number of purposes. It allows for “live supervision” for less experienced therapists and provides a training environment in which other team members can learn new skills. It can provide a rich team experience in which professionals pool their ideas and thinking in order to understand the family and move forward with the therapy. As in all clinical work, there is a need to attend carefully to ethical issues. These can be more complicated when a number of people are being worked with at the same time and members of the team are observing through one-way screens.
Frameworks for Intervention
This section sets out a framework for grouping treatment approaches for working therapeutically with families under several conceptual headings and describes some basic interventions that arise from them. We believe that this is more useful than to focus on models of family therapy which provide a somewhat artificial categorization and do not reflect day-to-day practice particularly well. This also provides a way of grouping the empirical evidence for effectiveness of family interventions for different types of disorder.

Maintenance Frameworks
Much of the early theoretical work informing family therapy was concerned with the idea of the family as a self-regulating social system (Jackson, 1957) and the way in which family interactions and family structures maintain problems. Two influential strands of family therapy (structural and behavioral) have drawn heavily on these notions. As a number of authors have argued (Kraemer, Stice, Kazdin, Offord, & Kupfer, 2001; Schmidt & Treasure, 2006; Stice, 2002), a focus on maintenance mechanisms provides one of the strongest ways of gaining an understanding of what makes treatments work and, perhaps not surprisingly, the strongest body of empirical evidence for the effectiveness of family therapy is found in this area.

Structural Family Therapy
Structural family therapy, developed by Minuchin and colleagues (Minuchin, 1974), originated derived from work with deprived families of delinquent boys (Minuchin, Montalvo, Gueney, Rosman, & Schumer, 1967) and was later applied to work with psychosomatic problems, particularly anorexia nervosa (Minuchin, Rosman, & Baker, 1978). The model assumes that well-functioning families have a number of specific features such as clear and flexible boundaries between individuals and subsystems and well-defined roles within the family, and that they provide an appropriate balance between closeness and independence. Individual problems were seen to be embedded in self-perpetuating dysfunctional family structures. The model, because of its emphasis on family relationship and interaction, relies to a great extent on interventions into transactional patterns in the “here and now” – that is, within the therapeutic session. Interventions include strengthening the “parental subsystem”, where the therapist encourages the parents to work together to find a way of jointly managing the difficulty. This includes actively intervening in the process of discussion with encouraging language, highlighting success and framing the role of the parents as responsible and “in charge” of the children. During enactments, families are encouraged to demonstrate their usual family processes and interactions within the therapeutic session to provide an opportunity for the therapist to help the family to “do it differently” and to assess the impact of following a different pattern. In boundary making the therapist enquires about rules (or boundaries) defining the roles of different family members and the degree of flexibility with which they are maintained. The family are helped to redefine boundaries, increase flexibility by encouragement to “talk more” or “make clearer rules” within the safe environment of the session. Sometimes, the intervention is to “de-triangulate” a particular family member (e.g., when an adolescent becomes involved in helping parents to stop arguing).

Behavioral Family Therapy
Behavioral family therapy approaches draw on similar ideas as structural family therapy. They focus on the behavioral sequences that occur in family life (Patterson, 1971, 1982) and interventions are aimed at interrupting unhelpful patterns and strengthening positive ones. As in structural therapy, the therapist tends to work with observed processes within the therapy session, often focusing on specific areas such as communication skills, problem-solving or interrupting escalating patterns of symmetrical communication. Behavioral approaches include interventions aimed primarily at parents in the form of Parent Management Training (PMT), by far the best researched of all family interventions (for a full account see chapter 64).

Evidence for Effectiveness
Structural and behavioral approaches have been the most widely researched of all family interventions. The largest body of evidence is for behavioral family therapy and in particular parenting interventions for child and adolescent behavior problems (Brosnan & Carr, 2000; Kazdin, 2004) with PMT alone being evaluated in over 60 high-quality randomized controlled trials (Lundahl, Risser, & Lovejoy et al., 2006). There is also persuasive evidence for structural and behavioral approaches in the treatment of anorexia nervosa (but see chapter 41 for some reservations). A series of randomized controlled trials at the Maudsley Hospital, London, compared family therapy with individual supportive therapy following hospitalization for anorexia nervosa (Russell, Szumukler, Dare, & Eisler, 1987) and also compared two forms of out-patient family therapy (Eisler, Dare, Hodes et al., 2000; Le Grange, Eisler, Dare, & Hodes, 1992), demonstrating the efficacy of family therapy with continued improvement post-treatment for up to 5 years (Eisler, Dare, Russell et al., 1997; Eisler, Simic, Russell et al., 2007).

The research has led to a gradual refinement of the treatment approach (Dare, Eisler, Colahan et al., 1995; Eisler, 2005; Rhodes, Gosbee, Madden, & Brown, 2005) from the original structural model described by Minuchin, Rosman, & Baker, (1978) but has retained as a central feature the empowerment of parents in helping their child tackle his or her eating problems. Similar results were obtained in the USA by Robin, Siegal, Koepke, Moye, and Trice (1994) using behavioral systems therapy and Lock, Agras, Bryson et al., (2005), Lock, Couturier, & Agras (2006), who adapted the Maudsley approach (Lock, Le Grange, Agras, & Dare, 2001). Several studies (Barrett, 1998; Barrett, Dadds, & Rapee, 1996; Barrett, Healey-Farrell, & March, 2004; King, Tonge, Heyne et al., 1998; Mendelowitz, Manassiss, Bradley et al., 1999; Silverman, Kurtines, Ginsburg et al., 1998) have shown that behaviorally based family therapy was effective in treating children with OCD and anxiety disorders. An interesting addition to these findings comes
CHAPTER 65

from Cobham, Dadds, and Spence’s (1998) study comparing cognitive–behavioral therapy (CBT) and CBT combined with PMT for children with anxiety problems. For children of non-anxious parents, both CBT and CBT + PMT resulted in good outcome in about 80% of cases. However, for children with anxious parents, individual CBT resulted in good outcome in approximately 40% of cases compared with 80% good outcome for CBT + PMT.

Influencing Frameworks

All psychotherapies are concerned with bringing about change but what characterizes the family therapy approaches that we discuss under this heading is that they have focused primarily on how change is brought about while being agnostic to the question of how the problems might have arisen. The two groups of therapies that are most clearly defined by an influencing framework are Strategic therapies (Haley, 1963, 1976) and Brief therapies (Watzlawick, Weakland, & Fisch et al., 1974) developed by the group at the Mental Research Institute (MRI) in Palo Alto, the latter eventually developing into what is now known as Solution-focused therapy (de Shazer, 1985). Similarly to the originators of the approaches described in the previous section, the Palo Alto group were interested in the way in which symptoms became part of the family regulatory system but also introduced the idea that repeated ineffective attempts at solutions could themselves maintain the problem. Their focus was on the interactive process that interfered with change, rather than the processes that maintained problems. They assumed that the process that blocked change would be specific to each individual or each family and, unlike structural therapy for example, did not assume that the family organization or family structure needed to be changed in a specific predetermined way.

While there is obvious overlap with the structural and behavioral approaches described earlier, the main interest in the strategic approaches has been in how change happens rather than the kind of change that should be achieved. Brief solution-focused therapy (de Shazer, 1985) has some overlaps with Motivational interviewing approaches (Miller & Rollnick, 2002) in developing differential strategies depending on the level of motivation of family members, who are classified as “clients” (ready for change), “visitors” (do not see themselves as having a problem) or “complainants” (have a problem but not sure they want to do anything to change).

The following example may serve as an illustration of a strategic intervention. In an early family session with an adolescent with anorexia nervosa the therapist asks the following question: “Have you reached the stage when you feel that people trying to encourage you to eat are on your side and helping you fight anorexia or do you still always feel that they are against you?” The girl thought for a bit before responding: “Sometimes, but not very often at the moment.” The therapist nodded and added: “It is important that you go on noticing these instances. As they become more frequent it will make it easier for you to deal with the times when you feel that everyone is against you.”

One can see several ideas underlying this intervention. The therapist had noted that the young woman and her parents were regularly locked in repetitive battles at mealtimes which resulted in the daughter partly giving in and the parents backing off. The daughter acknowledged that she had a problem and wanted to get better but after every meal felt resentful and angry with her parents. Asking the above question had a number of goals: 1 To establish an exception to the disabling family belief that every mealtime is inevitably a battle of wills; 2 To imply that when an exception happens, it is an indication of the start of a process of recovery; and 3 To imply that the exceptions will increase in frequency. The therapist was also using his position as an expert who had been through a similar process with many other families. While the discussion was with the daughter, it was important that it was witnessed by the parents, who were perhaps as much paralyzed by seeing their daughter’s despair as they were by their own sense of helplessness.

Strategic ideas were also the basis of the early work of the Milan group. The Milan associates developed a stylized form of interviewing the family in which a co-therapist pair was supported by a team behind a one-way screen. The central assumption that guided the therapy was that the symptomatic behavior was part of a paradoxical bind that prevented the family system from changing and the aim of the therapeutic team was to devise an intervention that would counter the paradox of the symptom (Palazzoli, Boscolo, Cecchin et al., 1978). The therapeutic team developed hypotheses that were explored with the family through the use a “circular interview” (Bertrando, 2006). The observation of the family’s response to these questions was used during a mid-session discussion of the team to gain other perspectives and the therapist (especially in the earlier versions of the approach) would deliver a message aimed at “perturbing” what were thought to be stuck patterns of interaction and fixed beliefs (Palazzoli, Boscolo, Cecchin et al., 1980).

Evidence for Effectiveness

The therapies that we have grouped under this heading are relatively poorly researched. The strongest evidence has come from the work of Szapocznik and Kurtines (1989), who have systematically and over many years evaluated Brief strategic therapy for substance misusing adolescents. In addition to demonstrating the effectiveness of their treatment approach in a number of randomized controlled trials (Szapocznik & Williams, 2000), they have also shown the specific value of strategic techniques in engaging difficult-to-reach families (Coatsworth, Santisteban, McBride, & Szapocznik, 2001; Santisteban, Suarez-Morales, Robbins, & Szapocznik, 2004). Many of the treatment components developed by Szapocznik and colleagues have been incorporated into the well-researched multidimensional treatments described later.

Meaning Creating Frameworks

An important idea that underpins all family therapy approaches is that all problems are embedded and shaped by
their social context and to a lesser extent help to shape the context. If we try to understand the interpersonal nature of problems it is almost inevitable that we become concerned with language, beliefs, cognitions and narratives because these are central to understanding the process of social interaction. In the early developments of the family therapy field, these ideas were focused primarily on the exploration of interpersonal communication and in particular the way in which the overt content of communication was given different meanings by communication at another (meta) level (e.g., tone of voice, non-verbal cues).

The ideas about the importance of beliefs in shaping behavior have been developed by a number of authors in the field. Following their split from the original Milan team in the early 1980s, Boscolo and Cecchin started developing a style of work that abandoned much of the early strategic components and focused on the process of the interview and the way it could bring forward new perceptions, unexplored stories and hidden meanings (Bertrando, 2006; Boscolo, Cecchin, Hoffman, & Penn, 1987). This was accompanied by a change in the understanding of the therapist’s role in bringing about change and a shift in emphasis away from behaviors to beliefs and narratives.

The Therapist as Participant Observer

Up until the early 1980s the therapist was invariably seen as an outside observer of the family process who could use his or her “metaposition” to gain an understanding of the family dynamic and intervene in a purposeful way to bring about change. This was challenged first by von Foerster (1979), who argued that the act of observation (and the describing of the observation) make the observer part of the system. The implication for the clinician was the need to recognize not only that any observations being made are influenced by the subjectivity of the observer’s perceptions, but also that they become part of a recursive pattern of mutual influences between clinician and family. This shift has had a major impact on the practice of family therapy. The first was a change in the conceptualization of family therapy from a treatment of families (with the implication that the family was problematic or dysfunctional) to a treatment with families, where the meetings with families provide the context for change rather than the target of change. Secondly, thinking about the therapist as being part of the system also led to the re-examination of issues of power and control (Hoffman, 1985) and to a more collaborative and less “expert” role for the therapist. Where a team was used, its role also changed and became a more open and transparent vehicle for bringing alternative perspectives on the work, for instance by making sure that families meet the team rather than always keeping the team invisible behind a one-way screen. Other developments leading to greater respectfulness and collaboration with families was the practice of inviting families to observe the team reflecting on the session in front of them (Andersen, 1987) or therapists developing their hypotheses jointly with families (Bertrando & Arcelloni, 2006).

Language and Narratives

The interest in meaning systems and their influences on shaping family interactions have always had their place in the family therapy field (Ferreira, 1963; Palazzoli, Boscolo, Cecchin et al., 1978; Watzlawick, Beavin, & Jackson, 1967). However, the more recent developments have placed language and narratives center stage for several influential therapy approaches, in particular narrative therapies (Parry & Doane, 1994; White & Epston, 1989) and the collaborative language approaches (Anderson & Goolishan, 1988; Goolishan & Anderson, 1987). These approaches have been the most overtly embedded in a social constructionist understanding which emphasizes the relativity of observed reality and which sees language and narratives as the vehicle through which people acquire their definitions of self. Individual problems are understood to be, at least in part, the result of the filtering of experiences through narratives that people have about themselves. These individual narratives are seen as being embedded in wider systems narratives such as cultural, political or educational narratives (Paré, 1995; White, 2005).

Although the narrative and language approaches are theoretically distinct, there is a clear overlap with cognitive therapies both at a conceptual level (i.e., in seeing beliefs and meanings attached to problems as central targets of treatment) and borrowing each others’ intervention techniques (e.g., the use of behavioral scaling techniques by narrative therapists or the use of externalization of the problem in some CBT approaches).

Evidence for Effectiveness

The evidence for the value of approaches that have been described in this section is limited. There are a small number of studies that have directly evaluated treatments such as narrative therapy. Seymour and Epston (1989) followed up 45 cases of childhood stealing where the family intervention used a narrative approach and found that over 80% of cases were treated successfully. Carr (1991) reviewed 10 studies using a Milan systemic approach and concluded that they provided evidence for the effectiveness of the treatments. However, only four of the studies were randomized controlled trials and the samples were mostly small with a mixture of problems. More recently, there have been several studies evaluating family therapy for depression (Campbell, Bianco, Dowling et al., 2003; Diamond, Reis, Diamond, Siqueland, & Isaacs, 2002; Trowell, Joffe, Campbell et al., 2007), in which the family approach had as a main focus addressing cognitions, beliefs and narratives that showed evidence for the efficacy of these approaches. The most recent of these studies (Trowell, Joffe, Campbell et al., 2007), which compared family therapy with brief psychodynamic psychotherapy, was notable in two respects. Both treatments achieved around 75% remission by the end of treatment (with an average of 11 sessions of family therapy or 25 sessions of individual psychotherapy) and both treatments showed a continuing improvement at 6-month follow-up.

Multidimensional and Integrative Frameworks

In recent years there has been a growing move towards integrating different approaches, both from within the family therapy field and outside it (Norcross & Goldfeld, 2005). In
CHAPTER 65

clinical practice it is not uncommon to find clinicians drawing on a number of conceptual models and using intervention techniques developed within a different approach than the one they see as their primary treatment approach. As Fraenkel and Pinsof (2001) point out, this happens in one of two ways. Clinicians include techniques or ideas from other approaches and incorporate them into their own conceptual framework, which Fraenkel and Pinsof describe as “technical eclecticism” (or “assimilative integration” following Messer, 1992). This can be contrasted with integration at a theoretical level or “theoretical eclecticism” (Fraenkel & Pinsof, 2001), in which different conceptualizations of the therapy process are drawn on and applied depending on the nature of the problem, stage of treatment or difficulties encountered in treatment.

In this section we briefly describe four treatment models (Functional Family Therapy, Multisystemic Therapy, Multidimensional Family Therapy and Multidimensional Treatment Foster Care) that have integrated several family therapy approaches and have been well researched, and a model that has integrated systemic, cognitive–behavioral and psychodynamic approaches (Integrative Problem-Centered Therapy). Finally, we describe recent developments in using multi-family approaches with child and adolescent problems which also draw on a number of different conceptual frameworks.

Functional Family Therapy
This is an approach developed by Alexander and Parsons (1982) and Alexander and Sexton (2002) combining aspects of behavioral and structural approaches with strategic family therapy. Functional family therapy starts from the assumption that problem behaviors and symptoms (whatever their origin) take on a functional role in the way that relationships and family hierarchies are maintained and aim to replace problem behaviors with more appropriate behaviors that can serve the same function but in a positive way in the family organization. For example, in a family with a child with OCD the child may have a very close and intense relationship with mother centered on assurance seeking/receiving behaviors, and a more distant relationship with father, who tends to respond dismissively to requests for reassurance. The family might be encouraged to find alternative activities that would meet the need for closeness and assurance but not of symptom-related behaviors and would also seek to involve the father in spending time with the child in such activities.

Multisystemic Therapy and Multidimensional Family Therapy
Multisystemic Therapy (MST; Henggeler, 1999; Henggeler & Borduin, 1990) and Multidimensional Family Therapy (MDFT; Liddle, 1992; Liddle & Hogue, 2001) are two well-researched treatments that have been designed to include interventions at several different levels, drawing on conceptualizations from strategic, structural and behavioral family therapy. Both have been designed with a fairly specific target population in mind (delinquent and substance misusing adolescents). The integration of conceptual ideas from other approaches is based on an analysis of the target problem which both MST and MDFT see as needing to be addressed at individual and family as well as social levels. Interventions are targeted at several levels which aim to address individual and contextual issues around the problem behavior but also motivational and engagement issues, recognizing that the adolescent with the problem may be the least motivated person in the system. For both MST and MDFT, the analysis of the nature of the problems (delinquency and substance misuse) is central and provides the framework within which the integration of conceptual ideas from different treatment approaches takes place (which differentiates them, for instance, from Functional Family Therapy). A further treatment program could be added to this group, Multidimensional Treatment Foster Care (MTFC; Chamberlain, 2003). Although distinct in some ways (not least in the fact that the youth offenders enrolled in the program are placed in foster families) there are many overlaps with MST and MDFT in the structure and intensity of the treatment interventions as well as in many of the conceptual ideas that inform it.

Multiple Family Approaches
Multiple family approaches have also developed with a focus on particular problems and draw on multiple theoretical frameworks. They have a history in adult psychiatry, particularly in the treatment of schizophrenia (Lacquer, La Burt, & Morong, 1964; McFarlane, 2005; Strelnick, 1977), but in more recent years have increasingly been utilized with child and adolescent mental health problems (Asen, 2002; Asen & Schuff, 2006; Eisler, 2005; Saayman, Saayman, & Weins, 2006). The initial impetus for working with several families at the same time was partly pragmatic (i.e., to maximize the use of limited resources and to address the social isolation that patients and their families were experiencing). Theoretically, they drew on a mixture of systemic, group and psychodynamic ideas, and most multi-family groups also include a significant psychoeducational component. The practical experience of bringing together several families very quickly brought forward new ideas about the nature of the therapeutic relationship, the importance of maximizing family resources in dealing with individual problems and ways in which clinicians can facilitate change through providing a structured setting in which families can interact and learn from each other. Seeing several families together is not simply a matter of pragmatic or economic convenience. The multi-family group format affords many opportunities for helping families to learn from each others’ strengths, to reduce the sense of isolation and stigma and to use the group as a resource for problem-solving (Asen, 2002; Eisler, 2005).

The most common form of multi-family work has 5–7 families meeting weekly or fortnightly for 1.5–2 h. Groups of this kind have now been developed for a growing range of problems including mood disorders (Fristad, Goldberg-Arnold, & Gavazzi, 2002; Goldberg-Arnold, Fristad, & Gavazzi, 1999), eating disorders (Geist, Heinmaa, Stephens, Davis, & Gavazzi, 2000), behavior problems (McKay, Harrison, Gonzales, Kim, & Quintana, 2002), schizophrenia (Asen & Shuff, 2006; Schepp, O’Connor, Kennedy, & Tsai, 2003), learning diffi-
cultures (Russell, John, Lakshmanan, Russell, & Lakshmidevi, 2004) and school problems (Kratochwill, McDonald, Levin, Bear-Tibbetts, & Demaray, 2004). In the UK a more intensive format of multi-family treatment has been developed by Asen, Dawson, and McHugh (2001) in which families take part in a brief multi-family day program. Originally developed for work with multi-problem “multi-agency” families (Cooklin, Miller, & McHugh, 1983), it has been modified for treatment of anorexia nervosa (Eisler, 2005; Scholz, Rix, Scholz, Gantchev, & Thomke, 2005) and for school problems (Dawson & McHugh, 1994, 2006).

**Integrative Family Therapy Approaches**

A different approach to integration of treatment approaches is found in the work of authors who start from an analysis of the conceptual overlaps between different psychotherapeutic models (Breunlin, Schwartz, & MacKune-Karrer, 1997; Fraenkel & Pinsof, 2001; Lebow, 1987; Pinsof, 1994, 2005). Pinsof’s (2005) Integrative Problem-Centered Therapy (IPCT) provides a good example. IPCT integrates six different therapeutic orientations (behavioral, biobehavioral, experiential, family of origin, psychodynamic, self-psychology) and three treatment contexts or modalities (family/community, couple, individual). The underlying assumption of IPCT is that individual problems are maintained by a set of constraints (social/organizational, biological, meaning, transgenerational, object relations, self) which roughly correspond to the therapeutic orientations. IPCT starts from a premise that individuals and families can usually resolve problems with minimal interventions aimed at reinforcing and building upon existing individual and family strengths. A brief problem-focused behavioral family intervention is recommended as an appropriate starting point for most child and adolescent problems and only when these have failed would the therapist need to start exploring potential deficits and constraints at other levels.

The strength of IPCT (like that of other integrative approaches) is that it attempts to find common conceptual ground between different therapies and to maximize their potential by targeting different levels of difficulties by appropriate interventions. The disadvantage is that it assumes that the framework can be fitted to any kind of problem and that the way that treatments are tailored to individual needs comes purely from an analysis of the different levels of constraints that particular individuals and their families are faced with. This is theoretically attractive but difficult to evaluate empirically. It is notable that approaches such as MST, MDFT and MTFC have generated considerable outcome research whereas integrative approaches such as IPCT have not.

**Evidence for Effectiveness**

The strongest evidence for treatment approaches described in this section come from studies of multidimensional approaches used for treatment of youth offenders (Curtis, Ronan, & Borduin, 2004; Littell, Popo, & Forsythe, 2007; Wooffenden, Williams, & Peat, 2007) and substance misuse (Stanton & Shaddish, 1997). The meta-analyses in the above studies included mainly treatments using a multidimensional approach and these were also the studies producing the clearest results (although none of the meta-analyses compared multidimensional with other family therapy approaches). The evidence for the efficacy of multifamily therapy compared with other treatments is sparse so far. There have been few randomized studies and while they provide positive support (Barrett, Healey-Farrell, & March, 2004; Kratochwill, McDonald, Levin et al., 2004), the current overall conclusion has to be “promising but unproven” (McDonell & Dyck, 2004).

**Overview and Conclusions**

Family therapy, in our account, covers a broad range of approaches. Many of the things that apparently differentiate treatments are a matter of what is emphasized and inevitably there will be large overlaps with other approaches. We have suggested a way of conceptualizing different frameworks of treatments as a way of understanding some of the differences and similarities both within the family therapy field and outside of it. The empirical evidence in support of family therapy in the broadest sense is considerable. There have been more than 20 meta-analyses of family interventions, approximately half of which either included or were solely concerned with child and adolescent problems (for a review see Shadish & Baldwin, 2003). The findings are consistent in showing family therapy to be effective when compared to no treatment or waitlist controls (with an average effect size of 0.65) and to do at least as well as, or better than, alternative treatments, although the differences here are generally small. However, the quality of the evidence is variable depending on the type of problem being considered. In some areas (such as the treatment of substance misuse, anorexia nervosa, delinquency and behavior problems) the evidence for the effectiveness of family therapy of one kind or another makes it currently the treatment of choice. In other areas (depression, anxiety disorders, OCD) there is more limited evidence but nevertheless it points to family-based treatments being effective. When one takes a look across the field as a whole, perhaps the most striking thing is that taking a broad definition of family therapy (as any family-based or family-oriented treatment) then for most if not all child and adolescent problems it is shown to be effective. However, what is also clear is that for different kinds of problem often quite different types of family intervention have been shown to be useful. To what extent this is really a result of the specificity of treatment needs generated by particular problems or simply a reflection of the particular interests of researchers who have investigated these problems is unclear, as very little research exists at present comparing different family therapy approaches and what comparisons do exist are quite general and do not focus on specific components that might be needed when dealing with specific types of problem.

In the treatment of conduct disorder, juvenile delinquency and substance misuse there is considerable conceptual as well as technical overlap between the best-researched treatments...
(MST, MDFT, MTFC and, to a lesser degree, Functional Family Therapy) although the proponents of these approaches do not always acknowledge the similarities. One of the negative consequences of the current emphasis on developing evidence-based practice is that it encourages treatments to be viewed as complete and competing packages, which tends to obscure the common ground between treatment models. The family therapy field has been particularly prone to this malaise and is awash with differently labeled (similar) treatments with little attempt to compare them at either a theoretical or an empirical level.

The other downside of the focus on evaluating treatment models has been the dearth of research on factors that might act as mediators and moderators of treatment. At present, the evidence is thin on the ground but nevertheless indicates that these are clinically crucial areas to investigate. We discussed earlier the moderating effect of disorganization in the family (Hampson & Beavers, 1996b) and high levels of criticism (Eisler, Simic, Russell et al., 2007) which has implications for the style of family therapy best suited for these types of family. Such findings are rare at present yet they have important implications for clinical practice. Even less is known about family factors that might act as mediators of treatment (i.e., those that might be amenable to treatment and might need to change in order for treatment to be effective). This may well include variables that have been well researched from a developmental or etiological perspective such as attachment but that need to be looked at from a different angle. For instance, our clinical experience suggests that parent(s) with insecure attachment patterns can sometimes be difficult to engage in treatment and may feel they are being covertly blamed when asked to take quite an active role in their child's treatment. Of course, this may be because of the particular way in which we work with families and it is possible that for such families an attachment-oriented therapy (Byng-Hall, 1991; Diamond, Reis, Diamond et al., 2002) may be able to engage them more effectively in treatment regardless of whether attachment is shown to have a role in the development of the particular problem their child has.

In order for these issues to be addressed by empirical study two major shifts are needed in the conceptual ideas informing family therapy research and indeed psychotherapy research in general. The first is the recognition that much more work is needed to find the common ground between treatments in order to highlight the specific aspects that differentiate them. This will allow outcome research to target much more focused variables that have been well researched from a developmental or etiological perspective such as attachment but that need to be looked at from a different angle. For instance, our clinical experience suggests that parent(s) with insecure attachment patterns can sometimes be difficult to engage in treatment and may feel they are being covertly blamed when asked to take quite an active role in their child's treatment. Of course, this may be because of the particular way in which we work with families and it is possible that for such families an attachment-oriented therapy (Byng-Hall, 1991; Diamond, Reis, Diamond et al., 2002) may be able to engage them more effectively in treatment regardless of whether attachment is shown to have a role in the development of the particular problem their child has.

In order for these issues to be addressed by empirical study two major shifts are needed in the conceptual ideas informing family therapy research and indeed psychotherapy research in general. The first is the recognition that much more work is needed to find the common ground between treatments in order to highlight the specific aspects that differentiate them. This will allow outcome research to target much more focused questions about core ingredients of treatments and how these might interact with other factors. The second requires a re-examination of the theoretical models of change underpinning different family therapy approaches and testing these empirically. While our knowledge of what works has increased considerably in recent years, our understanding of how treatments work is still extremely limited. We should not assume that the process of change will necessarily follow the same path for everyone or that the role that the family will play in this process will be the same.

CHAPTER 65

What is Psychodynamic Psychotherapy?

The term “dynamic” first began to be used in the late 19th century by Leibniz, Herbart, Fechner and Hughlings-Jackson to highlight the distinction between a psychological and a fixed organic neurological impairment model of mental disorder. Dynamic approaches offer an alternative perspective to descriptive phenomenological psychiatry with the latter’s focus on accurate categorization of mental disorders; in contrast, dynamic approaches emphasize the way mental processes interact to generate problems of subjective experience and behavior. Such interactions can occur consciously as well as unconsciously, but the psychodynamic model has historically been understood as a model of the mind that emphasizes wishes and ideas that have been defensively excluded from conscious experience. In our view this is a narrow and somewhat misleading definition of psychodynamic concepts. The psychodynamic approach is better understood as a comprehensive account of human subjectivity that aims to understand all aspects of an individual’s relationship with their environment, external and internal.

Freud’s great discovery was the power of the conscious mind to alter its position radically with respect to aspects of its own functions. In our view, psychodynamic should refer to this potential for dynamic self-alteration. All psychodynamic therapies aim to strengthen patients’ capacity to understand the motivations and meanings of their own and others’ subjective experiences, behavior and relationships. In this sense there is overlap with cognitive therapy, which of course also has psychodynamic origins, but at least classically focuses more narrowly on particular aspects of subjectivity (e.g., particular types of cognitive distortion) and is more targeted at specific behaviors or problems. By contrast, psychodynamic therapists strive to understand the organization of the child’s mind in its full complexity, the social influences on the child’s emotional experience and the ways in which the child’s subjectivity has adapted to internal and external pressures. The therapist aims to expand the child’s and parents’ conscious awareness of these mechanisms and influences, so that they are better able to use their increased emotional awareness to manage continuing pressures. It assumes that once the mechanisms are made conscious, the individual will be able to change their inner world or their behavior to improve matters.

Psychodynamic psychotherapy can take a variety of forms; correspondingly, this chapter covers a number of therapeutic modalities. These include child psychoanalysis, individual and group psychotherapy, together with (using the above definition) certain family-based approaches, interpersonal approaches and psychodrama. Techniques differ in the extent to which they make use of play, supportive versus expressive techniques, or structured directive (group) work. Many current cognitive-behavioral therapies share with traditional psychodynamic approaches concerns such as the developmental and relational origin of particular ways of thinking, and use the relationship with the therapist as an example of broader patterns of relating (Beck, Davis, & Freeman, 2004). The following eight assumptions may be considered core to modern psychodynamic therapy. While some are shared by other approaches, as a set other orientations would be unlikely to embrace them wholeheartedly:

Common Assumptions

Notion of Psychological Causation

The child’s problems are understood in terms of their thoughts and feelings. The emphasis is more on the child’s interpretation of events and the world than on its external reality. It is assumed that mental disorders can be adequately comprehended as specific organizations of a child’s conscious or unconscious beliefs, thoughts and feelings, whatever the root cause of such maladaptive organizations might be. The individual’s motivations (wishes and anxieties, including expectations of others) are assumed to underlie experience, mental functioning and behavior. Alternative explanations such as genetic predispositions or chance are not prominent.

Limitations of Consciousness and the Influence of Non-conscious Mental States

Psychodynamic clinicians generally assume that to understand conscious experiences we need to refer to other mental states of which the individual is unaware. Psychodynamic models assume that non-conscious narrative-like experiences, analogous to conscious fantasies, profoundly influence children’s behavior, capacity to manage their emotions and their social interactions. For example, attachment theory assumes that a mental representation of distress soothed by the parent is internalized as an unconscious expectation of future caregiving,
CHAPTER 66

and becomes the foundation for a sense of the self as having understandable feelings that are deserving of care. This unconscious expectation guides the infant to seek soothing. Through the repetition of such experiences the capacity to self-soothe emerges without undue recourse to denial or amplification of distress.

There is substantial empirical support for Freud’s suggestion that human consciousness cannot account for its maladaptive actions (Westen & Gabbard, 2002), but this should not be taken to imply a diminution of the emphasis placed on consciousness. Helping the child and caregivers to become aware of the unconscious expectations underlying the child’s behavior can help them to gain control of previously unmanageable emotions and behavior. For example, when working with young people who apparently deliberately mismanage their diabetes, helping them elaborate their subjective experiences of peers and parents turns out to help them bring their diabetes under control (Moran, Fonagy, Kurtz et al., 1991). It was helpful, for example, when the therapist could help a girl to understand that throwing away her insulin could be seen as an attempt to escape the intrusiveness of her overconcerned father, who used to listen outside her bedroom door in case she had a hypoglycemic attack. Once this was understood, more space could be created within the relationship without the need for her self-destructive protest.

Assumption of Internal Representations of Interpersonal Relationships

Psychodynamic clinicians consider interpersonal relationships, particularly attachment relationships, to be central to the organization of personality, and that representations of these intense relationship experiences are aggregated across time to form schematic mental structures, perhaps metaphorically represented as neural networks. These structures are seen as shaping interpersonal expectations and self-representations. Within many models self–other relationship representations are also viewed as organizers of emotion: certain feelings come to characterize particular patterns of interpersonal relating (e.g., sadness and disappointment at the anticipated loss of a person).

Ubiquity of Psychological Conflict

Psychodynamic approaches assume that wishes, affects and ideas will sometimes be in conflict. These conflicts are seen as key causes of distress, undermining a sense of safety and leading to maladaptive attempts to overcome this. Experientially insurmountable conflicts are commonly associated with adverse environmental conditions. For example, neglect or abuse is likely to aggravate an arguably natural ambivalence of the child towards the (in this case maltreating or neglectful) caregiver, who is nevertheless perceived as vital to the child’s continuing existence. Psychodynamic techniques often aim to identify and elaborate perceived inconsistencies, conscious or unconscious, in feelings, beliefs and wishes in order to reduce the individual’s distress when conflicts have become entrenched. Not only are conflicts thought to cause distress, they are also considered potentially to undermine the normal development of key psychological capacities that in turn reduce the child’s ability to resolve incompatible ideas. At times psychodynamic models attempt to contrast conflict and development-focused approaches, but the reality of developmental trajectories means that the two are most often seen together in the same individual.

Assumption of Psychic Defenses

Historically, the psychodynamic approach has been particularly concerned with defenses: mental operations that distort conscious mental states to reduce their potential to generate anxiety. The term may risk reification and anthropomorphism (who is defending whom against what?) yet it is generally accepted that self-serving distortions of mental states relative to an external or internal reality take place. Classifications of defenses have been frequently attempted, often in order to categorize individuals or mental disorders (Kaye & Shea, 2000), but few of these approaches have achieved general acceptance. Nevertheless, most might agree that mental operations such as projection (attribution of a self-state to the other), denial (refusal to acknowledge self-states) or splitting (simultaneously holding self-states with opposite valence but experiencing them only sequentially) are characteristic of an early phase of development and are more commonly found in individuals with more severe mental disorder diagnoses. By contrast, intellectualization (elaborating a self-serving but inaccurate rationale for one’s actions) or sublimation (diverting mental energy from drive-oriented to more constructive activity) are relatively mature and, when not used to excess, non-pathological forms. Aside from such broad categorizations, the cognitive and socio-cognitive strategies associated with reducing anxiety or displeasure and enhancing safety are perhaps better thought of not as independent classes of mental activity or psychological entities, but as a pervasive dynamic aspect of complex cognition interfacing with emotional experience.

Assumption of Complex Meanings

Psychodynamic approaches assume that behavior can be understood in terms of mental states that are not explicit in action or within the awareness of the person concerned. Symptoms of mental disorder are classically considered as condensations of wishes in conflict with one another, alongside the defense against recognition of that wish. It is striking that different psychodynamic orientations find different types of meanings “concealed” behind the same symptomatic behaviors. Some clinicians focus on unexpressed aggression or sexual impulses, others on a fear of not being validated, yet others on anxieties about abandonment and isolation. Within a contemporary context it is the effort of seeking further personal meaning that would be considered most significant therapeutically. Elaborating and clarifying implicit meaning structures rather than giving the patient insight in the terms of any particular meaning structure may turn out to be the essence of psychodynamic psychotherapy (Allen & Fonagy, 2006).

Emphasis on the Therapeutic Relationship

There is consensus that it is helpful to establish an attachment
A Developmental Perspective

In common with many child therapists, psychodynamic psychotherapists are invariably oriented to the developmental aspects of their patients’ problems (when and how they started, when and how they changed, and how they relate to an idealized “normal” developmental sequence), and work at least in part to optimize developmental processes. Varying assumptions are made concerning normal and abnormal child and adolescent development. Importantly, the outcome of interventions is often evaluated in developmental terms, less in terms of reduction of problem behaviors associated with a disorder and more in terms of what emotional, social and behavioral characteristics may be expected of a particular child at a particular age. There are developmentally sensitive measures of social adjustment that have operationalized Anna Freud’s ideas concerning lines of emotional and social development (Fonagy & Target, 1994); how these map onto to mainstream measures of social and emotional functioning needs to be researched.

Outdated Assumptions

Some features of the original psychodynamic model are no longer shared by all contemporary psychodynamic approaches. A good example concerns insight. Classically, psychotherapists regarded the patient’s insight into their repressed unconscious as central to the process of change. It is now clear that improvements commonly occur in the absence of insight into non-conscious processes (Gabbard & Westen, 2003). Insight does not guarantee improvement even if the two sometimes occur together. Modern psychodynamic psychotherapy focuses on (mixed) feelings, confusing interpersonal expectations, the complexity of relationship experiences and much less on identifying derivatives of unconscious drives. Whereas some therapists remain committed to the insight-oriented interpretive approach, most feel that uncovering repressed unconscious content is less important than engaging with children and helping them to think about their experience in a psychological way.

Similarly, not all psychodynamic psychotherapists see a focus on transference as a key component of therapeutic work. However, it is commonly accepted that the relationship that the child creates in the therapeutic setting, either with the therapist or with other children in a group, can serve as a window on the child’s inner world. Modern, especially relational, psychodynamic psychotherapists often rely on their subjective reactions to help them understand the parts the child implicitly asks them to play. By this indirect route they hope to gain an understanding of the child’s internal struggles and the child’s representations of themselves and others. This is very different from the use of such understanding as part of an interpretive process.

It may also be misleading to think of psychodynamic therapies as being invariably about “the unconscious.” Uncovering neurotic motivations that have been dynamically defended against is no longer the defining feature of the psychodynamic approach. Psychodynamic therapies are often about increasing mental coherence, and randomized controlled trials of the treatment of borderline personality-disordered adults show that improvement in psychodynamic psychotherapy is specifically associated with increased coherence of attachment narratives (Levy, Meehan, Kelly et al., 2006). It is postulated that having one’s attention drawn to an aspect of one’s experience that one is unaware of may increase this coherence. For example, if a child is continually failing at school to his parents’ distress, drawing his attention to his ambivalent feelings may help him recognize a secret wish to upset his parents. This may enable him to find ways to stand up to his parents without damaging his own prospects. However, under certain circumstances, such insight may undermine coherence, increasing the child’s confusion with iatrogenic consequences. For example, interpreting the masochistic wishes of a child who has been abused within the family may only add self-loathing and self-blame to his distress, making it harder for him to recover.

Risks of Psychodynamic Psychotherapy

Whereas pharmacological studies routinely test for the possibility of adverse reaction, psychological therapists mostly assume that their treatment is at worst inert. There are few systematic studies of adverse reactions. There may be particular disorders where psychotherapy represents significant risk to a patient. Irrespective of the assumed mechanism of change, most psychotherapists assume that the client is capable of considering their experience of their own mental states alongside the psychotherapist’s representation of these. We have recently drawn attention to the fact that this may be an unrealistic expectation in cases where the client’s capacity to represent their own mental states with any degree of coherence is very limited (Fonagy & Bateman, 2006). Such individuals may react to a therapist’s attempts to teach them about the “true” contents
of their mind by either breaking off the therapy or playing
along without real understanding. It is possible that the diffi-
culties psychodynamic therapists have in the past reported in
relation to conduct problems may be associated with limitations
in the ability of young people with severe behavioral problems
to represent their own mental states (mentalize). Adolescents’
resistance to psychodynamic therapy could also be explained
by age-specific limitations in social cognition (Blakemore &
Choudhury, 2006). In general, it seems to us that modifications
to classic psychodynamic technique along the lines described
above may be necessary for these techniques to be appro-
priately used with young people whose mental disorder is asso-
ciated with limitations in their mentalizing capacity. Also,
psychodynamic therapists who continue to give their therapy
alone when it is ineffective while failing to recognize and refer
on conditions for which there is a solid evidence base (e.g.,
attention deficit/hyperactivity disorder [ADHD] or obsessive-
compulsive disorder [OCD]) are allowing unnecessary harm
to befall their patients.

Theoretical Frameworks in
Psychodynamic Therapy

Developmental Considerations in
Psychodynamic Thinking

The theoretical bases for psychodynamic psychotherapy are
rooted in Freud’s establishment of his developmental approach
to the understanding of psychopathology. In Freud’s view, per-
sonality types and neurotic symptoms could be best understood
in terms of fixations at and regressions to specific points of
development; this has not been supported by any empirical
evidence. Psychoanalysts following Freud have continued
the developmental motif while taking radically different perspec-
tives on both child development and psychopathology. Recent psychoanalytic models, such as relational theories
(Mitchell, 2000) or psychoanalytic schema theories (Stern, 1993)
focus their explanations on psychosocial development and the
parent–child relationship.

Despite this unequivocally developmental perspective, most
psychoanalytic theorists have done little directly to explore the
nature of early development through research or to incorpor-
ate empirically tested modern findings into their approaches,
preferring instead to speculate about infancy on the basis of
largely adult clinical experience.

Historical and Current Traditions

The field of psychodynamic child psychotherapy was histori-
cally established by Melanie Klein (1932) and Anna Freud
(1946). Klein assumed that play in the consulting room was
motivated by unconscious fantasy, activated by the child’s
relationship to the analyst (the transference). This generated
deep anxiety which required verbalization if it was to be
addressed. The child’s relationship with external figures (e.g.,
parents, teachers) was considered far less relevant. By under-
standing the child’s perception of him or herself as a person,
the clinician could gain an understanding of children’s experi-
ence of themselves. A highly influential psychoanalyst working
in this tradition, Bion (1959) described how such projections
could be evocative: they could impact upon the “container.”
The capacity of the container of the projection to understand
and accept these is seen by Kleinian analysts as critical to suc-
cessful therapy as well as normal development.

A highly influential psychodynamic therapist emerging from
the Kleinian tradition was the pediatrician Donald Winnicott.
Winnicott (1971) introduced drawing techniques into child
psychotherapy, highlighting his interest in what was beyond
verbal experience. The idea of an intermediate space between
the subjective and the interpersonal has become a central notion
in the work of relational therapists. Winnicott elaborated a
developmental model within which the caregiver is committed
to the infant but imperfectly, so that the child has gradually
to sacrifice infantile omnipotence. This gave rise to a therape-
utic attitude where the therapist’s constancy and tolerance
create a sense of being understood and accepted that provides
the patient with an important figure for internalization and
identification.

At the other end of the spectrum, Anna Freud introduced
only minor modifications to Freud’s classic theories but dramat-
cally reorganized the clinical situation of child psychotherapy,
 focusing on the child’s developmental struggle with the social
as well as the internal environment (Edgcumbe, 2000). She
viewed pathology as a disturbance of normal developmental
processes and therapy with children as aimed at returning to
normal developmental lines. Not in content but in structure,
Anna Freud’s approach shares some ideas with modern devel-
opmental psychopathology. The aims of the developmental psy-
chodynamic approach have some similarities with cognitive
therapy; however, the means by which these improvements are
considered to be most readily achieved are often quite differ-
ent. For example, a psychodynamic psychotherapist working
to enhance affect regulation may feel that working with the
child’s feelings about his or her therapist is the best way to
assist the child in acquiring the capacity to regulate emotion
in the context of intense attachment relationships. Similarly,
clarifying the child’s thoughts and feelings in relation to the
therapist has the effect of strengthening mentalizing or reflect-
ive function.

Modern Psychodynamic Therapy: Relational and
Attachment Theory Approaches

More recently, the Kleinian, Winnicottian and Anna Freudian
traditions have all to some degree been superseded, especially
in the USA, by an interpersonal relational perspective (Altman,
Briggs, Frankel, Gensler, & Pantone, 2002). In a relational
approach, conflict is no longer seen as within the individual
but as produced by conflictual and contradictory signals and
values in the environment. The relational therapist, like the
therapist offering developmental help, does not work to impart
understanding. The relational therapist’s style is more active
and participatory and aims to explore and correct maladapt-
ive patterns of relating.
Importantly, the intersubjective relational approach does not privilege early developmental periods at the risk of overlooking current relationship needs (Greenberg, 1991). Interpersonal therapists therefore tend to be active, to work with current relationships of the client, rather than focusing on a deeper layer of reality beyond the surface. Relational ideas form the basis of the psychodynamic model underpinning interpersonal therapy (IPT), which has a strong evidence base in the adult literature on depression and a somewhat more meager one for its adolescent adaptation (Mufson, Dorta, Wickramaratne et al., 2004; Young, Mufson, & Davies, 2006). In some people’s eyes, IPT might have moved too far from its origins to be genuinely considered a psychodynamic approach, yet the clearly psychoanalytic adaptations of the interpersonal psychodynamic tradition retain the focus on the relationship-seeking aspect of human character and a pragmatic focus to the child’s life and the therapeutic relationship in the context of this.

Attachment theory (Bowlby, 1980) overlaps with both the relational tradition and Winnicottian object relations theories. Attachment theory implements selected aspects of psychoanalytic theory, using a general systems model and an ethological approach, with the additional virtue of openness to empirical scrutiny. Bowlby’s work on separation and loss focused developmentalists’ attention on the importance of the security (safety and predictability) of the earliest relationships. It is postulated that safety and predictability give the child the capacity for relatively problem-free later interpersonal relationships. Bowlby assumed that representational systems (internal working models) evolve based on a template created by the earliest relationship of the infant to the caregiver. If the expectation that need and distress will be met by comforting is encoded into these models, the child will be able to approach relationships in a relatively non-defensive way. If this is not the case, if the child’s caregivers lacked sensitivity, the child’s representational system will be defensively distorted to either minimize or heighten experiences of arousal, and dismiss or become entangled in the response of others. Longitudinal work confirmed Bowlby’s emphasis on the formative nature of early relationships and the pathological significance of the disorganization of the attachment system (Lyons-Ruth, 2003; Sroufe, Egeland, Carlson, & Collins, 2005), although the child’s subsequent experience is also important in determining outcome (Rutter, 1987). Further, recent work has also demonstrated the relative independence of the attachment system from genetic influence (Fearon, van IJzendoorn, Fonagy et al., 2006; O’Connor & Coft, 2001). However, clinical approaches rooted in attachment theory are only beginning to emerge.

Recently, a group of workers have focused on an application of attachment theory that goes beyond Bowlby’s original rationale framed in the context of the quality of the infant-caregiver relationship. It is suggested that the attachment relationship has a key role in the development of social intelligence and meaning-making. The key evolutionary role of attachment in human development is in the opportunity that it confers for the development of social cognition (Fonagy, 2003). The relationship to the attachment figure has a long-term developmental impact through facilitating the emergence of complex psychological processes. In interaction with the infant, the caregiver tends to “reflect” the infant’s emotional states back to him, instinctively “mirroring” his feelings in a way that helps the child to feel that they are contained and not out of control. Such interactions enable the child to learn how to represent his own thoughts and feelings. The capacity for mentalization builds upon affect regulation as well as attentional control. For example, the capacity for pretend play has been found to be associated longitudinally with the mother’s ability to mirror the infant’s affects (Koos & Gergely, 2001). Weak affect regulation, attentional control and mentalization leave infants vulnerable to the impact of trauma (maltreatment), which undermines mentalizing capacities (Cicchetti, Rogosch, Maughan, Toth, & Bruce, 2003). The therapeutic approach to emanate from this developmental model may be particularly appropriate for more severe conditions, such as emerging personality disorder and multiple comorbidities that include an emotional disorder diagnosis. The therapeutic focus is no longer on enhancing insight but rather on strengthening social-cognitive capacities, particularly mentalization.

**Brief Psychotherapy, Group, Dyadic and Family Psychodynamic Therapy**

In the child literature, brief therapy has not been systematically studied even though this may be the form of individual dynamic therapy that is most commonly delivered in community settings (Kennedy, 2004). The one exception to this is interpersonal psychotherapy for adolescent depression (Young & Mufson, 2004), which is based on identifying maladaptive interpersonal patterns, making these patterns explicit and helping the patient to disrupt these patterns during the course of the treatment. These generally fall into one of five categories: grief, interpersonal disputes, role transitions, interpersonal deficits or single-parent families (Young & Mufson, 2004). There are some open trials and randomized controlled trials (Mufson, Dorta, Wickramaratne et al., 2004; Young, Mufson, & Davies, 2006) showing the effectiveness of the technique.

Group therapy is frequently employed for children and adolescents, particularly in school and residential settings. Group therapy offers several advantages beyond economy. For children and adolescents the group format reflects the developmental priority of finding and integrating into a peer group. Process research in group therapy (Schechtman, 2001) suggests that children benefit from cathartic experiences and sharing. In adolescence, the group process may help with separation–individuation and identity formation. A range of processes that take place in group therapy facilitate developmental goals: identification through recognizing commonalities, a refinement and calibration of social perceptions, a benefit from social support, a counteracting of social isolation and improved feedback to enhance self-esteem. There is some evidence that group therapy with medically ill children is beneficial (see systematic review by Plante, Lobato, & Engel, 2001). Many other factors may assist change: the instillment of hope; altruism through assisting others; corrective recapitulation of the primary family group;
the development of social skills; group cohesiveness; and interpersonal learning through developing positive relationships with another. The improvements seen can also be accounted for within other theoretical frameworks such as cognitive–behavioral or social learning models. Although psychodynamic psychotherapy groups are quite heterogeneous in character, in most group work it is assumed that conflicts and concerns within the group in some ways mirror those in the children’s lives outside of the group. Further, group members are frequently exposed to discussions that may foster new ways of dealing with personal or interpersonal issues and they are afforded an opportunity to exercise empathy capacity and perspective taking. Psychodrama offers a frame for group treatments and a method for creating a structured awareness-producing milieu. It has been used with a range of problems including middle school girls coping with trauma (Carbonelli & Partelno-Barechmi, 1999), adolescents with developmental problems (Oezbay, Goeka, Oeztuerk, & Guengoer, 1993) and as an adjunct to family therapy (Blattner, 1994). The efficacy of these forms of group therapy needs to be evaluated through properly conducted randomized controlled trials.

Increasing recognition of the formative character of aspects of early childhood has led to increasing concern with child mental health issues. Epidemiological and prevention studies have highlighted the prevalence of early maltreatment and other trauma that may impact on subsequent mental health (Pynoos, Steinberg, & Piacentini, 1999). The now generally accepted transactional model of early childhood development (Sameroff & Fiese, 2000), highlighting the complexity of the early caregiving environment, has offered a focus for therapeutic interventions in the child–caregiver relationship. Therapeutic interventions are directed not at the child who is presented as bringing a problem but at the child–caregiver relationship and its entire cultural, social, family, marital and parent context.

Child–parent psychotherapy (CPP; Lieberman, 2004) is based on the premise that the attachment system is the main organizer of children’s responses to danger and safety in the first years of life and a therapeutic relationship can be mutative. Weekly joint child–parent sessions over 1 year are interspersed with individual sessions for the mother, with the aim of changing maladaptive parenting behaviors and supporting developmentally appropriate parenting while guiding the child–parent couple to create a joint narrative of traumatic events working towards their resolution. Two randomized controlled trials have demonstrated the effectiveness of this method (Lieberman, Weston, & Pawl, 1991; Lieberman, Van Horn, & Ippen, 2005). When compared with case management, including community referral for individual treatment, child–parent psychotherapy was associated with significantly more improvement in parent-rated measures of child symptomatology (Effect Size = 0.840). This runs counter to the finding of van IJzendoorn, Juffer, and Duyvestyn (1995) in their review of attachment-oriented interventions with relatively low-risk samples without major psychiatric symptomatology. This review suggested that brief treatment was more effective than long-term treatment in increasing attachment security, but psychiatric symptomatology was not assessed. A dyadic narrative-oriented therapeutic approach similar to Lieberman et al.‘s has been demonstrated to be effective for toddlers of depressed mothers (Cicchetti, Rogosch, & Toth, 2000) and neglected and maltreated preschoolers (Toth, Maughan, Manly, Spagnola, & Cicchetti, 2002).

Psychodynamic psychotherapy now normally includes some “family work” or help for the parents. This is of course not the same as formal family therapy, which has a theoretical frame that is often antagonistic to or at least divergent from psychodynamic approaches. However, there are psychodynamically oriented implementations of family therapy that combine systemic approaches with psychodynamic ideas (Johnson & Lee, 2000). There is a move from both sides towards an integration between family and psychodynamic therapy. Thus, many more recent variants of structural family therapy recognize the relevance of aspects of the psychodynamic approach (e.g., attachment theory) as a core component of systemic family interventions. There is a spectrum, from more clearly psychodynamic approaches such as attachment-based family therapy (Diamond, Diamond, & Siqueland, unpublished data), to those that have taken only particular aspects of a psychodynamic perspective, such as multidimensional family therapy (Wood, Klebba, & Miller, 2000).

From the other direction, there are examples of traditional psychodynamic therapy taking on a family dimension. In the psychodynamic implementation of family therapy, intrapsychic problems are considered alongside characteristic family dynamics. The family is viewed as a system whose process determines adolescent development. Psychodynamic family therapy focuses on communication and negotiation, challenges problematic coalitions and supports the appropriate roles of parents and children in a family hierarchy. It also concerns itself with family narratives, helping families to understand the way they deal with the child’s problems at both conscious and unconscious levels (Lock, 2004). Treatment focuses on increasing parental self-efficacy but also on diminishing parental guilt. This is postulated to help parents to become more authoritative and able to manage problems while still being both warm and understanding. The therapist acts as a consultant, there to empower family members to solve their own problems. In narrative family therapy, the therapist relies on the creativity and playfulness of children with words and other activities. The therapist can facilitate the creation of coherent and lasting alternative stories by, for example, eliciting and developing a counterplot to a problem-saturated story. In emotion-focused family therapy (Johnson & Lee, 2000) techniques such as the family puppet interview, mutual storytelling and different forms of art therapy are used to set up a safe environment in which attachment needs can be identified and expressed. There is evidence for the effectiveness of emotion-focused family therapy, principally from couples research (Dunn & Schwebel, 1995). There is also empirical support for the efficacy of explicitly psychodynamic family therapy from studies with anorexia nervosa (see p. 1086).
Empirical Basis of Psychodynamic Child Psychotherapy

Randomized Controlled Trials

Comprehensive reviews of outcome studies of psychodynamic approaches to child and adolescent mental health difficulties are few. Surveys focus on the treatment of children with mental health problems in general (Fonagy, Target, Cottrell, Phillips, & Kurtz, 2002; Kazdin, 2004; Target & Fonagy, 2005) or psychosocial interventions limited to “evidence-based treatments” (Hibbs, 2004; Weisz, 2004). The most comprehensive survey of outcome studies specifically concerned with psychoanalytic approaches was that undertaken by Kennedy 2004. The conclusions are more optimistic than the current state of empirical evidence justifies, which is reviewed below.

There are no really good randomized controlled trials of psychodynamic psychotherapy with children. The few controlled trials are underpowered and suffer from other methodological limitations (Robin, Siegel, Moye et al., 1999; Sinha & Kapur, 1999; Smyrnios & Kirkby, 1999; Szapocznik, Rio, Murray et al., 1989; Trowell, Kolvin, Weeramanthri et al., 2002; Trowell, Joffe, Campbell 2007). All but one of these trials contrasted individual child psychotherapy with another treatment. In no case did child psychotherapy emerge as superior to the contrast treatment. These trials are all considered further below. Several studies employed quasi-randomized methods of assignment such as postcode (Moran, Fonagy, Kurtz et al., 1991) or therapist vacancy (Moran, Fonagy, Kurtz et al., 2001, Muratori, Picchi, Casella et al., 2001, Muratori, Picchi, Bruni et al., 2003). Six studies reported on findings with matched comparison groups (Fonagy & Target, 1994; Heinicke & Ramsey-Klee, 1986; Reid, Alvarez, & Lee, 2001; Target & Fonagy, 1994a,b). Three studies used experimental single-case methodology (Fonagy & Moran, 1990; Lush, Boston, Morgam, & Kolvin, 1998; Moran & Fonagy, 1987). On the basis of these studies, the evidence base for child psychotherapy is quite poor.

Indications of Differential Effectiveness of Psychodynamic Approaches for Specific Clinical Problems

Anxiety disorders

There is only very preliminary evidence that psychodynamic psychotherapy may be effective in the treatment of anxiety disorders (Target & Fonagy, 1994). In this chart review study, children with anxiety disorders (with or without comorbidity) showed greater improvements than those with other conditions, and greater improvements than would have been expected on the basis of studies of untreated outcome. Muratori, Picchi, Casella et al. (2001) examined the efficacy among 58 children with depression and anxiety, of 11 sessions of psychodynamic therapy based on the Parent–Child Model involving work with the parents for 6 of the 11 sessions. This was contrasted with treatment as usual in the community (poorly described in the report). Allocation was based on therapist vacancy at referral. At 2-year follow-up only 34% of the treated group were in the clinical range on the Child Behavior Checklist (CBCL), compared with 65% of the controls. Unusually for trials of psychotherapy, treatment effects increased during the 2-year follow-up period (the so-called “sleeper effect”): the average child with emotional problems moved from the clinical to the non-clinical range in the psychodynamically treated group only (Muratori, Picchi, Bruni et al., 2003). In the control group, the average child remained at the same level of severity through the follow-up period. The conclusions from this trial are limited because of the small sample size and the lack of random allocation. However, it is encouraging that psychodynamic psychotherapy patients sought mental health services at a significantly lower rate than those in the treatment as usual comparison condition over the 2-year follow-up period.

A very small randomized controlled trial (n = 30) of adolescents showed a surprisingly strong statistically significant benefit from 10 sessions of psychodynamic psychotherapy in a school setting in India. The vast majority of young people improved in psychodynamic psychotherapy (over 90%, reported effect size 1.8; Sinha & Kapur, 1999). Notably, young people with disruptive behavior were specifically excluded from this sample. Therapy outcome was independently, but not blindly, assessed by teachers.

Childhood Depression

A multicenter European trial compared family therapy with brief individual psychodynamic psychotherapy (Trowell, Joffe, Campbell et al., 2007). At 7-month follow-up none of the moderately to severely depressed young people who received psychotherapy met diagnostic criteria, whereas 29% in the family therapy group did. This trial did not have an untreated control group, so it is uncertain how far these results are superior to no treatment, although the results with individual treatment are comparable to children treated with a combination of fluoxetine and cognitive–behavior therapy (Goodyer, Dubicka, Wilkinson et al., 2007).

Smyrnios and Kirkby (1993) investigated the therapeutic effects of a therapy combining psychodynamic and systemic principles with 30 school-age children. The children were randomly divided into three groups of 10:

1 One group received “time-unlimited” psychoanalytic therapy using a Kleinian model (on average 28 sessions, with a range of 3–62 sessions);
2 Another group received short-term therapy (on average 10.5 sessions, with a range of 5–12 sessions); and
3 A third group was offered a three-session consultation.

All three groups showed significant improvements from pre-test to post-test on a number of individual and family ratings, but the effect size was greatest for the time-unlimited treatment. Effect sizes for target complaints at post-treatment, relative to consultation: 0.76 (95% confidence interval [CI], 0.28–1.3) for time-limited; 1.23 (95% CI, 0.84–1.6) for time-unlimited. At 4-year follow-up, the effect sizes for target complaints were no longer significantly different from the control group, who are likely to have had other treatments. In line with this, the consultation group caught up with the treated groups and reported significant improvement relative to post-treatment on
 CHAPTER 66

follow-up, severity of target problems and measure of family functioning. However, a high proportion (up to 50%) of the very small numbers in the original groups was lost to follow-up.

Disruptive Disorders
In the Anna Freud Centre retrospective study (Fonagy & Target, 1994), whereas children and young people treated for major depression were likely to improve even if they remained in the dysfunctional range after treatment, diagnoses related to conduct problems appeared particularly resistant to psychodynamic therapy (CD and ODD).

Family Involvement
In a comparison of family therapy and individual psychodynamic psychotherapy with a mixed behaviorally and emotionally disordered sample of Hispanic children, both treatments were found to be effective in reducing behavioral and emotional problems, relative to a no-treatment control group (Szapocznik, Rio, Murray et al., 1989). The symptomatic improvements were maintained at 1-year follow-up, but the control group caught up with these improvements over the follow-up period. It should be noted that there was considerable attrition in the control group and the analysis was not on the basis of intent-to-treat. A total of 16% of families dropped out of family therapy compared with 4% who abandoned individual psychodynamic therapy, but family functioning improved following family therapy and deteriorated following individual psychodynamic psychotherapy (i.e., between end of treatment and follow-up).

Individual child psychotherapy is now rarely carried out without family work. In the Anna Freud Centre retrospective study, concurrent work with parents was a predictor of good outcome (Target & Fonagy, 1994). With younger children, particularly preschool age, a mother–child dyadic therapy where the parent and child are jointly seen appears to be an effective psychodynamic intervention. For example, in Lieberman, Van Horn, & Ippen (2005) study, 75 children who had been exposed to marital violence were treated in child–parent psychotherapy weekly for 1 year and this was contrasted with individual treatment and case management. The dyadic work yielded superior outcomes in terms of behavioral problems, traumatic stress symptoms and diagnostic status and post-traumatic stress disorder (PTSD) symptoms and general distress for the mother.

Pervasive Developmental Problems
Non-directive play is often used to try to promote communication skills in children with autism (Cogher, 1999). Although such interventions have common components they are not specifically psychodynamic. The Tavistock Clinic has developed a specialized psychodynamic approach to the treatment of individuals with autism (Reid, Alvarez, & Lee, 2001), but this has not been evaluated in a controlled trial.

Eating Disorders
A further specific diagnostic group for which some trial data are available is anorexia nervosa. Randomized controlled trials of behavioral family systems therapy aimed to contrast this therapy with an “inert” treatment and they chose ego-oriented individual therapy, a specially designed treatment with a clear psychodynamic basis (Robin, Siegel, & Moye, 1995; Robin, Siegel, Moye et al., 1999). Each patient received 10–16 months of therapy and was assessed at post-therapy, and followed up at 1, 2.5 and 4 years. Improvements were equivalent in both treatments; two-thirds of the girls reached their target weights by the end of treatment, and at 1-year follow-up 80% of those receiving family therapy and 69% of those treated individually had reached their target weights (a difference that was not statistically significant). As is often found, the non-psychodynamic approach produced changes faster but in this instance carried the cost of a somewhat higher rate of hospitalization. Both therapies produced equally large improvements in attitudes to eating, depressed affect and family functioning (Robin, Siegel, & Moye, 1995). Robin et al. concluded that parental involvement was essential to the success of their interventions for younger adolescents with anorexia nervosa.

The comparability of the effectiveness of family and individual approaches in the above studies is somewhat in contrast to the long-term superiority of family therapy for a group of young adult anorexics using a similar psychodynamic approach (Dare, Eisler, Russell, Treasure, & Dodge, 2001; Eisler, Dare, Russell et al., 1997; Eisler, Dare, Hodes et al., 2000; Russell, Szmukler, Dare, & Eisler, 1987). In these studies at the Maudsley Hospital, individuals who were relatively older generally benefitted more from individual treatment while younger individuals benefited more from family-based approaches (for further details of these studies see chapter 41).

Chronic Physical Illness
There is a tradition of psychodynamic work with individuals with chronic physical conditions such as asthma and diabetes (Shaw & Palmer, 2004) but trial data are hard to come by. In a series of experimental single-case studies, individual psychodynamic therapy was found to improve several growth parameters probably associated with improvement of diabetic control (Fonagy & Moran, 1990).

Trauma
Goenjian, Karayan, Pynoos et al. (1997) reported a naturalistic study on the outcome of psychotherapeutically treated and untreated earthquake victims at 1.5 years (pre-treatment) and 3 years (post-treatment) after the earthquake. While the severity of PTSD symptoms significantly decreased among recipients of trauma/grief-focused brief psychotherapy, symptoms significantly worsened among untreated subjects. Layne, Pynoos, and Cardenas (2001) have developed a program for adolescents who experienced or witnessed violence. The UCLA School-Based Trauma/Grief Intervention Program for children and adolescents includes a systematic method for screening students, a manualized 16–20 week group psychotherapy protocol which addresses current stresses and conflicts not limited to the
A package, the protocol is a skills-based cognitive–behavioral therapy program and is very far from a prototypical unfocused insight-oriented group psychotherapy, but the attention to developmental considerations and the model of traumatic stress within which the treatment is rooted (Pynoos, Steinberg, & Wraith, 1995) make the intervention deserving of consideration under a general psychodynamic heading. Controlled trials are now needed.

More directly relevant is a multicenter randomized trial of the treatment of sexually abused girls treated in individual psychotherapy and psychoeducational group therapy (Trowell, Kolvin, Weeramanthri et al., 2002). A total of 71 sexually abused girls were randomized to either 30 sessions of individual psychoanalytic psychotherapy or 18 sessions of group psychotherapy with psychoeducational components. These young people presented with a range of psychiatric problems, most commonly PTSD and depression. Psychodynamic treatment was no different from psychoeducation in terms of overall levels of psychopathology measures and psychosocial functioning measures. In relation to PTSD, however, there were greater gains in the individual psychotherapy group; the between-treatments effect size ranged from 0.6–0.79 for specific symptoms. Trials are now needed comparing dynamic psychotherapy with other proven treatments such as cognitive–behavioral therapy and exposure.

**Summary**

The empirical status of all psychodynamic approaches remains controversial. The body of rigorous research supporting psychodynamic therapies for both adults and children for most disorders remains limited, particularly relative to research supporting pharmaceutical treatments and even other psychosocial approaches such as cognitive–behavioral therapy (Roth & Fonagy, 2005). There are both practical and theoretical difficulties in mounting trials of dynamic therapies, which go some way to explaining the lack of evidence. These include, for example, the bias against research by many practitioners of psychodynamic therapies, their epistemological problems with the canons of modern scientific studies, the reluctance of funding bodies to invest in research on clinical problems considered “solved” by a combination of drug and cognitive–behavioral treatments, the expense of mounting trials sufficiently powered to yield information on what treatments are appropriate for which disorder and the failure to manualize psychodynamic treatments. Currently, there is some modest evidence to support the use of psychodynamic psychotherapy for children whose problems are either emotional or mixed. There is also evidence that the support and inclusion of parents are important aspects of this treatment, that effects tend to increase following the end of treatment and that behavioral problems are more resistant – at least to a classic insight-oriented psychodynamic approach.

Those who argue (correctly in our view) for continued investment in this approach point to the limitations of the evidence base in childhood supporting cognitive–behavioral therapy (Westen, Novotny, & Thompson-Brenner, 2004) or pharmacological approaches (Whittington, Kendall, Fonagy et al., 2004). Notwithstanding the general weakness of the evidence base of mental health treatments for children, this weakness is particularly strong for psychodynamic treatments and the shortage of research studies needs to be addressed urgently.

In the light of the limitations of cognitive–behavioral therapy with severe disorders in comparison with medication (Goodyer, Dubicka, Wilkinson et al., 2007; March, Silva, Petrycki et al., 2004; Swanson, Arnold, Vitiello et al., 2002), it behoves us to investigate the effectiveness of alternative treatment approaches.

### Integration of Psychodynamic Psychotherapy into Child and Adolescent Mental Health Services

This section addresses the place of psychodynamic child psychotherapy within child and adolescent mental health services (CAMHS). This will be described from the UK perspective, in which child psychotherapy is delivered mainly within the National Health Service (NHS), but many of the principles probably also apply elsewhere.

In the UK, psychoanalytic psychotherapy for children and young people is usually delivered within a multidisciplinary CAMHS. A considerable part of child psychotherapists’ work is consultation with and supervision of other CAMHS professionals and paraprofessional staff, as well as contributing to thinking within the team and the network about the situations and emotional development of children referred. Working long-term and/or intensively with individual children has been shown to occupy only about one-third of the employed time of these specialized staff. Their perspective should complement rather than compete with systemic, biological, cognitive–behavioral or other frameworks. The range of contexts for child psychotherapy work has also very much extended, particularly the proportion of work focused on children who are being looked after by local authorities (child protective services); other areas to which child psychotherapists contribute include education, forensic services, pediatric liaison, perinatal services and parent–infant community settings.

The perspective of psychoanalytic psychotherapy appears to be used in several distinct ways; the following approximate proportions of time are based on consistent data from three large-scale surveys (Rance, 2003):

1. To treat individual children (usually once weekly; 36%);
2. To provide training, supervision (8%), assessment (14%) and consultation (14%) using a psychoanalytic framework (e.g., to support treatment carried out by other professionals in a team or their trainees);
3. Working using a variety of techniques other than individual psychotherapy (e.g., family therapy, work on parenting, group therapy with young people, parent–infant therapy); this is often joint work with colleagues in other disciplines (18%); and
CHAPTER 66

4 To inform discussion and understanding of a child’s behavior and the impact a child or family is having on relationships between the agencies involved (approximately 10%).

Individual psychotherapy is often carried out by other staff with teaching and supervision from a child psychotherapist. Medium- or long-term one-to-one work is a scarce, intensive and expensive resource that tends to be reserved for situations where other perspectives have been tried or are ongoing, but there are still serious problems. This is commonly where there are chronic and complex difficulties, often in the context of trauma and disrupted or abusive caregiving. Qualified child therapists can often help another colleague to do this work in the relatively less disturbed and disturbing cases. An interesting study by Kam and Midgley (2006) of one large inner city service found that almost all children referred for individual child psychotherapy were referred by other members of the CAMHS team after an average of 3 years of contact with the service and input from an average of 3–4 other CAMHS professionals. They tended to have the most complex developmental and social problems (e.g., parental mental illness, maltreatment histories). Individual therapy is often a last resort for children who are particularly hard to help.

Surveys and audits show that parent, foster carer and whole family work is usually carried out while therapy is provided for an individual child; this is not routine in the treatment of older adolescents. The parent or family work may be carried out by a colleague from another discipline, another child psychotherapist or the therapist who is treating the child. There are very often concerns about child protection in cases considered for referral to a child psychotherapist and this can raise difficult issues; psychotherapy for a child currently being emotionally, physically or sexually abused is clearly not a solution to the abuse. The first priority then is the child’s safety. Some therapists may look for that to have been achieved before beginning therapy, while others may try to establish a relationship with the child while steps are being taken to make sure that the child is safe. However, this risks disruption of the new therapeutic relationship if the child is removed from the current home or care environment to live outside the area. Child psychotherapists often carry out assessment work with the courts, and mostly carry out their ongoing therapeutic work with children who – even if still in unsatisfactory or disrupted care arrangements – are at least in a safe environment. The therapist may sometimes be the only consistent figure in the child’s life over a considerable period, and may effectively become an advocate for the child’s feelings and perspective.

We suggest that, in general, child psychotherapists – who are relatively few in number and expensive to train – should be kept for the more intractable cases where a briefer symptom-focused approach has been tried and failed or seems inappropriate. This is particularly important when the child’s attachment history places them beyond the reach of therapists without extensive relational training. However, to sustain this position will require controlled trials assessing effectiveness and cost-effectiveness.

A developmental psychodynamic approach includes a model of attachment processes and the ways in which the development of (for example) the social cognitive capacities of regulation of emotion and attention, and social understanding are shaped by early experiences particularly within the family. This framework also gives a rationale for relatively long-term work with a child to help build more positive capacities and to help the child to develop more coherent and effective social and mental functioning, and to increase resilience to cope with often ongoing trauma and dislocation (e.g., from disrupted care placements). Research needs to be designed that can include the type of children often seen by child psychotherapists, and that can follow up their outcomes in the longer term.

Finally, we come to issues of training, treatment integrity and monitoring. In the UK, psychoanalytic child psychotherapists have a 4-year full-time training, usually based in a multidisciplinary CAMHS team, which includes supervised clinical practice, theoretical work and intensive personal psychotherapy. Trainees are required to have considerable work experience with children prior to starting. A masters-level preclinical course is followed by 4 years of clinical training. Most available training courses are accredited as professional doctorate programs. Personal therapy is required because child psychotherapists’ work with profoundly disturbed and disturbing children and parents will often be distressing or unnerving to the therapist. The therapist is thought to gain two advantages from personal therapy: the first is resolution of disturbances in the therapist’s own personality, which might complicate the relationship with patients, and the second is to give an intensive and direct experience of the process that the patient will later experience. Without such personal experience, intensive work with highly vulnerable and disturbed children could be damaging rather than therapeutic. Close awareness of the phenomena involved not only helps the qualified therapist to tolerate, conceptualize and work with profound disturbances of development and functioning, but also helps him or her to teach and supervise other workers who have not had psychoanalytic training or therapy but who wish to gain experience with the techniques.

Every child psychotherapy post in the NHS has a set of skills and competencies (covering clinical, management and research knowledge) established within the knowledge and skills framework. This skill-set is individually reviewed annually and modified as needed. Maintenance of competence is through the registration requirements for continuing supervision and continuing professional development.

Conclusions

Psychodynamic psychotherapy is one of the oldest theory-driven forms of psychological treatment of mental disorders. The personal meaning of the discourse concerning the subjective world behind behavior has inspired many generations of clinicians. Psychodynamic ideas are applied in contexts well beyond the treatment of psychiatric disorders, including
psychology, other social sciences, literature and the arts. Sadly, empirical investigations of both its underlying constructs and its therapeutic outcomes are still in their infancy.

The shortcomings of the psychodynamic approach are considerable and include:
1. Shortage of operationalization;
2. Uncritical application of a relatively uniform approach to a wide range of disorders;
3. Limited amount of good evidence supporting its efficacy;
4. Over-reliance on individual case reports for helping theory and technique develop;
5. Common vagueness of treatment goals;
6. Possibility of unnecessarily prolonged treatment and even iatrogenic effects;
7. Significant heterogeneity of theoretical and linked clinical approaches calling themselves psychodynamic almost defying integration and rationalization; and
8. Antagonism on the part of many psychodynamic practitioners to the idea of systematic evaluation and scrutiny.

Notwithstanding these limitations, we remain convinced of the unique value of the psychodynamic approach, not only as a methodology for the study of the psychological difficulties of childhood, but also as a method of clinical intervention with children who are hard to reach using other methods. Considerable work remains to be done but a new culture of research is now emerging within the psychoanalytic community. It is, we believe, a realistic hope that over the next decade a substantial evidence base will emerge for child treatment. This would delineate the specific value of the approach for the long-term development of children with psychological disorders. Work is already under way at a number of centers internationally and will in time show whether psychodynamic treatment works for children and, if so, for whom.

Physical Treatments

Stanley Kutcher and Sonia Chehil

In the final analysis, all psychiatric treatments are biological. That is, whatever their mode of delivery, theoretical basis or assumed mode of effect, they modulate, change or otherwise alter the brain functions of behavior, cognition or affect. They do so in many ways, directly through their impact on neural networks (see chapter 16), and indirectly through altering attitudes and ideas.

There is no ascribed nobility, precedence or honor to either psychological or physical interventions. There is only the moral imperative to improve the lives of those who suffer, to do more good than harm and to adhere to three fundamentals of knowledge acquisition and application: developmental neurobiology, evidence-based care and the systematic application of sound therapeutic principles. Thus, although this chapter deals with physical (predominantly chemical) treatments, they hold no a priori primacy of place over non-physical interventions.

This chapter addresses the third of these fundamentals – the systematic application of sound therapeutic principles – using physical interventions as the model. Developmental neurobiology (see chapter 12) can be expected to inform our understanding of both patho-etiology and therapeutic response. Evidence-based care is woven into each of the chapters of this book in which interventions for specific disorders are discussed, and the details of somatic treatments for specific disorders are dealt with there. This chapter provides the clinician with a useful framework that can be applied to any therapeutic intervention. This framework has five components: selecting a treatment target; selecting a treatment; assessment and measurement; evaluating and maximizing treatment outcome; and the human interface.

Selecting a Treatment Target

Medical treatments are usually applied to three target conditions: illnesses/disorders, symptoms or risk factors. The target condition may be simply the illness/disorder (e.g., hypertension), it may be a symptom, such as pain (e.g., a “tension” headache), or it may be both (e.g., pain associated with arthritis). In some cases, treatment may be targeted towards a risk factor or constellation of factors, the effective treatment of which may prevent the onset of a known mental illness. Psychiatric treatments share the same contingencies. The target condition may be an illness/disorder (e.g., panic disorder), it may be simply a symptom (e.g., self-injurious behavior) or it may be both (e.g., panic attacks occurring only in the context of a major depressive disorder). In other cases, treating a risk factor (or constellation of risk factors) may prevent the onset of a mental illness (e.g., the prodrome in schizophrenia).

It is imperative that the clinician (and by extension the patient, family or responsible caregiver) understands what the treatment target is. Otherwise, treatments may be wrongly prescribed, wrongly understood or wrongly expected to produce a particular outcome. Furthermore, efforts should be made to ensure that all treatment participants (patient, clinician and others) agree on what the treatment target(s) is/are. Often there may be more than one treatment target, but at least one of these targets needs to be of significant importance to the patient. Put simply – if the patient does not buy into a treatment target it is not a treatment target.

The first step in the identification of a treatment target is determining if the patient has a psychiatric diagnosis. This is performed using standard DSM or ICD criteria, applied by a trained clinician in a systematic and reliable manner. The use of idiosyncratic diagnostic criteria makes it impossible to use the generalized experience of the profession. While interviewing creativity and the use of clinically suitable yet personally unique methods of data collection are to be encouraged, in the final analysis the information collected by the clinician must allow for a reliable application to determine diagnostic classification so that other clinicians obtaining information from the patient will arrive at similar diagnostic conclusions most of the time.

As psychiatric diagnoses are syndromal and are not yet based on independent objective methods of validation (e.g., laboratory tests), the clinician must be aware of the problems inherent in their use. These problems fall into two categories: composition and threshold problems. Composition difficulties arise when diagnostic categories can be realized by different combinations of their components. For example, in major depression, the DSM demands that five of nine components be present in order for the category to be confirmed. The difficulty that arises is that the composition of the category can be quite different, depending on the combination of the components being used. It is not yet clear that in all cases, similar
therapeutic interventions are useful for all combinations. In child and adolescent psychiatry, this potential confounding effect may be even greater as developmentally determined expression of individual components (symptoms) may differ depending on age, pubertal status or cognitive capacity.

Threshold problems occur at the level of the components (symptoms) of the category (diagnosis). For example, sleep difficulties, such as problems falling asleep, are a symptom used to make a diagnosis of depression. The issue facing the clinician is how much sleep difficulty must be present for that problem to be considered a symptom. This is obviously a crucial issue as difficulty falling asleep can be part of usual life, a response to a stressor or a symptom of a disorder. Thus, threshold considerations must be kept in mind whenever a diagnostic interview is being conducted. If the threshold is set too low, too many components will be classified as symptoms and individuals will be diagnosed as having a disorder when the reality is rather that they may be distressed or dysphoric. In these cases, unnecessary somatic interventions may be applied. If the threshold is set too high, individuals may be incorrectly classified as not requiring medical intervention.

These problems can be alleviated somewhat by the use of standardized diagnostic interviews; for example, the Kiddie Schedule for Affective Disorders and Schizophrenia (K-SADS), the Diagnostic Interview for Children and Adolescents (DICA) and others (see chapter 19). However, these standardized interviews are too cumbersome for everyday application and are unlikely to be used in most clinical settings. An alternative approach is to utilize a simple diagnostic checklist, to ensure that each of the components of the diagnostic category has been addressed and occasionally to apply one of the diagnostic interviews (e.g., K-SADS) to ensure continued reliable use of threshold criteria.

However, the determination of a diagnosis is not an act of clinical finality. A diagnosis is merely a hypothesis that predicts a particular outcome and leads to a specific intervention. As new information becomes available the hypothesis may need refinement or revision, or may even need to be completely discarded. As much treatment research is based on diagnostic categories, diagnostic classification can assist the clinician in choosing a particular treatment by referencing their patient’s condition to the research data. Similarly, diagnostic classification can assist the clinician in the risk–benefit evaluation pertaining to treatment. Simply put, does the risk–benefit ratio of the treatment available for the condition outweigh the risk posed by not treating the condition? The diagnosis then helps the clinician to select a particular intervention, one that has been demonstrated to be effective in ameliorating the problems for which the intervention is being sought.

However, choosing a diagnosis as a treatment target, while useful and necessary, is not without problems. Given that diagnoses are syndromal, it is possible that any particular intervention may improve some components of the syndrome while not affecting others, or perhaps even worsening some. For example, a particular medication taken to treat major depressive disorder may improve mood but may worsen sleep and enhance anxiety. Furthermore, some components of the syndrome may exhibit different phase effects in response to the same intervention. For example, in a young psychotic patient, an antipsychotic medication may show a positive effect on agitation within 3 days but not demonstrate a positive effect on delusions until 3 weeks of continued treatment.

Additionally, some patients may have significant problems that in and of themselves may be legitimate treatment targets, regardless of diagnosis. For example, aggressive outbursts or self-harming behaviors may be treatment targets in an individual with autism, although neither of these symptoms is necessary for the diagnostic category. In other cases such as borderline personality disorder one component of the diagnostic category (e.g., self-harming behavior) may be a target for medication treatment while another component (e.g., chronic feelings of emptiness) may not. In other words, both diagnoses and symptoms can be legitimate treatment targets. It is essential that both the clinician and the patient know and agree on what the treatment targets are.

Whatever the choice for the intervention target, the physician must be aware of the social and regulatory issues surrounding the use of medications for treatment of disorders or symptoms that are “off-label.” This means that the physician elects to use medications to treat disorders or symptoms, although the particular medication has not been approved by the regulatory agency in that particular country. In some cases, this will be because of procedural or work load delays at the level of the regulatory agency or because of decisions by manufacturers to differentially submit products for registration. These factors lead to a medication being registered for a particular indication in one jurisdiction (e.g., the EU) but not in another (e.g., the USA). In other situations, medications may not have been studied in youth and are therefore not registered for use in that age group although they are registered for use in adults. In other situations, medications will not have been studied in enough detail to be considered for registration – and if the medication is used for the control of specific symptoms, and if registration is disease-specific then by definition it will not have been registered for the purpose of specific symptom control. In child and adolescent psychiatric care, most medication interventions are “off-label” (as are all psychological interventions as there is no regulatory process for those). This does not mean that medications should not be used for “off-label” purposes. It does mean that the clinician should have reasonable evidence to support the use of “off-label” prescribing and that the rationale for this use should be clearly communicated to the patient and family and noted in the medical record.

The choice of treatment target depends on three factors: patient need, clinician knowledge and weight of therapeutic evidence.

**Patient Need**

Patient need may be expressed in syndromal or symptomatic terms. A young person with a major depressive disorder requires an intervention that will address the entire syndrome.
A young person with Tourette’s syndrome complicated by severe obsessive-compulsive symptoms may require an intervention directed not only at the Tourette’s syndrome but also at the obsessive-compulsive symptoms. A young person with autism complicated by aggressive outbursts may benefit significantly from a treatment directed towards the aggressive outbursts alone. In some cases, treatment targets can be simultaneously syndromal and symptomatic (e.g., significant depressive symptoms in a schizoaffective disorder) and both somatic and nonsomatic interventions may be used – alone, concurrently or sequentially.

**Clinician Knowledge**

Clinicians must be informed about the unique strengths and weaknesses of each physical intervention, and of possible interactions (both therapeutic and adverse) amongst them. These include both pharmacodynamic (what the drug does to the body) and pharmacokinetic (what the body does to the drug) interactions (see chapter 16). For example, does adding an antipsychotic medication to a selective serotonin reuptake inhibitor (SSRI) enhance the treatment response in a young person with OCD? What are the potential drug–drug interactions associated with such a combination? How does the addition of the antipsychotic drug alter the serum levels and the half-life of the antidepressant?

**Weight of Therapeutic Evidence**

The field of physical treatments for child and adolescent psychiatric disorders is rapidly developing and reports of potentially effective somatic interventions for numerous syndromes or symptoms are frequently found in the literature. However, not all evidence is of similar value. Case studies and naturalistic studies (particularly those with small sample sizes) do not provide sufficient scientifically sound evidence to guide treatments. Meta-analyses that are based on inadequately conducted studies may lead to erroneous conclusions.

Additionally, as the field is early in its development, few properly conducted studies have been carried out so absence of evidence cannot be equated with evidence of absence. Efficacy studies in homogeneous patient groups do not always positively translate into large heterogeneous populations – where effectiveness studies are needed. Acute results cannot be extrapolated into long-term conclusions, and studies of relapse prevention and length of remission are required to answer important duration-of-treatment questions. Some adverse and therapeutic effects (particularly those that are rare or require long-term use for expression) can only be identified using population surveillance techniques for which large numbers of patients treated for long durations are needed.

Given this developing database it is sometimes difficult to address the issue of therapeutic evidence with complete confidence, and guidelines and algorithms for assisting the clinician have been devised (Emslie, Hughes, Crismon et al., 2004). Generally, these guidelines use levels of evidence, ranging from high to low, based on the quality of scientifically conducted research. Data from double-blind placebo-controlled studies are usually considered to be more robust evidence than data from naturalistic studies, which in turn are considered to be more robust than the opinions of “experts.” However, the thresholds used to define these levels of evidence can vary across guidelines and different authorities may support different guidelines.

Guidelines along these lines (evidence-based medicine) have been developed for some conditions by national agencies (e.g., the UK National Institute of Health and Clinical Excellence [NICE]) and professional bodies (e.g., American Academy of Child and Adolescent Psychiatry). These can be helpful to the practitioner but, as recent history has shown, they are not always free from ideological bias that colors their interpretation of the available scientific evidence. For example, the NICE recommendations for the treatment of depression in young people differ significantly from the guideline standards used in their own literature review. Levels of evidence that are meant to inform the recommendations are not consistently applied. For example, interventions for which there is no evidence (such as watchful waiting) are recommended over an intervention for which there is the highest level of evidence (fluoxetine) (NICE, 2005). Multiple factors come into play when choosing if and how to treat (see p. 1092), but the evidence for efficacy, the probability and type of treatment emergent adverse effects, and the severity of the condition always need to be considered by the clinician, and his or her own experience used in the risk–benefit interpretation of any guidelines.

Additionally, in a rapidly evolving field such as child and adolescent psychopharmacology, guidelines may lose their relevance not long after their publication. New compounds for a specific disorder may come on the market in rapid succession or new indications for older medications may be defined. Clinicians must therefore be able to apply basic principles of psychopharmacology to their practice of therapeutics and not rely simply on algorithms or guidelines to direct their practice (see chapter 16).

Social factors (such as stigma against mental illness, strongly embedded belief systems regarding the effectiveness or danger of somatic interventions, belief-driven organizations or groups who are advancing unique political agendas, the over-enthusiastic uptake of somatic interventions by professionals unskilled in their use prior to their systematic evaluation, pharmaceutical company marketing methods) combine with the deficiencies of the syndromal classification system of psychiatric medicine and with long-standing ideological differences amongst child and adolescent mental health practitioners may create situations that at times are confusing not only to patients and family members but also to practitioners. This situation can only be effectively addressed by frank, honest and open discussion between clinicians and their patients and their families about what is and what is not known about various somatic interventions for syndromes and for symptoms. The weight of scientific evidence, with all forms of possible interventions being equally evaluated (e.g., it is not valid to expect that somatic treatments be evaluated at the highest standard of evidence while non-somatic treatments are evaluated using a lower standard of evidence), must be reviewed by clinicians.
Addressing Treatment Needs – Physical or Non-physical Treatments

Physical treatments are not provided in a vacuum but are always provided within a specific social context – the relationship between the clinician and the patient. In many cases, this social contract between provider and recipient of the treatment is complicated by the legitimate interests of third parties (e.g., parents and institutions). The impact of all of these different interests on the application, operationalization and outcome of any physical treatment must be taken into consideration at every intervention stage. Additionally, there may well be non-specific “healing” impacts in the clinician–patient interaction, and this also needs to be recognized.

In some cases, physical treatments will clearly be much more useful in addressing symptoms than non-physical treatments. In other cases, non-physical treatments may be as effective or even more effective. If the latter are available, then the preference may be to use them, because, in general, adverse effects are less common. In many circles it has become almost fashionable to “prescribe” non-physical treatments for disorders in which the evidence for the effectiveness of physical treatments is high – particularly if the disorder is judged to be “mild.” However, in many cases, such as the NICE guidelines for the treatment of depression in youth, there is little or no evidence that the suggested non-physical interventions are any better than placebo or the standard non-specific healing properties inherent in the clinician–client relationship. While such arguments are not without merit, it is important not to oversimplify the complexities of treatment effects. For example, depression is regarded by some as a degenerative disorder involving the hippocampus perhaps an altered expression of brain-derived neurotrophic factor, with antidepressants but not other interventions slowing down or reversing that process (Hashimoto, Shimizu, & Iyo, 2004; Swaab, Bao, & Lucassen, 2005). If that were to be the case (and it is not yet established), then not providing the physical treatment even to “mild” cases would have negative long-term effects on the progression of the disease. Generally, just as we are usually better at ascribing causality to proximal rather than distal causes, so we may be equally poorly prepared to consider long-term outcomes rather than immediate effects of treatments.

This dilemma has no simple solution. It becomes a particularly vexing problem if our commitment to “first do no harm” has to challenge us with different types of possible harm, expressed in different ways at different points in time. How does the clinician address the difference between “harm” from tolerable but unpleasant side-effects (short-term effects) and “harm” from not intervening in the disease process (long-term effects)? To date, the research evidence to help address these concerns is still quite limited, but it would be professionally improper not to consider these complexities carefully, albeit in the face of imperfect data.

In many cases, providing a particular physical treatment together with a specific non-physical treatment (such as fluoxetine plus cognitive–behavioral therapy [CBT] in adolescent depression) may lead to a better outcome than either one alone. In other cases, providing interventions designed to enhance learning, social or other skills when physical treatments have brought symptoms under control is necessary to improve outcomes over the use of the physical treatment alone (e.g., mathematics tutoring or social skills training for children with ADHD effectively treated with methylphenidate). At other times, physical treatments may be used to enable non-physical interventions to be more effectively applied (e.g., short-term benzodiazepines in the behavioral treatment of phobia when excessive anxiety prevents the application of a desensitization procedure from being initiated). Judicious application of physical treatments includes knowing when to use them and when not to use them; both are equally important.

In the future, the ability of the clinician to select treatments – whether physical or non-physical – or to choose amongst various types of physical or non-physical treatments on the basis of genetic or other biological variables may supersede our currently imperfect and opinion-laden approaches to these topics. There is some promise in that direction, but for now there are no objective physiological guideposts to assist us; and best available evidence, clinical judgment and trial and monitoring still provide the decision-making triad from which we usually operate. Given this climate of uncertainty, it is necessary to address patient need using the best evidence we have, with humility and the willingness to modify or change our approach as science catches up with clinical care.

Selecting a Physical Treatment

Once the scientific evidence base has been reviewed, a target or targets selected and a treatment or treatments that meet(s) acceptable criteria for use has been identified, a further process of selection occurs. This process is driven by the following considerations: practitioner familiarity with the specific treatment; patient acceptability; comparative risk–benefit profile; ease of administration; cost and availability.

Practitioner Familiarity

Given all the possible somatic treatments available, it is not likely that the average clinician can become proficient in the use of every one of them. At the same time, it is essential that clinicians become very familiar with the treatment that they are using. It is therefore reasonable for the clinician to choose one or two compounds that will become his or her “personal” medication choices, which will be used in most cases in which that class of medication is indicated. This is also known as
CHAPTER 67

the “Personal” or “P drug” selection. This approach to therapeutic medication selection is essential for primary or even secondary care, but even tertiary care physicians may find this approach useful (WHO, 2000; 2001).

The “P drug” should have the following characteristics:
1. It should have good experimental evidence (placebo-controlled trials) supporting its therapeutic effect;
2. Its side-effect profile should be well-known;
3. It should be relatively well tolerated by most patients;
4. It should be reasonably priced;
5. It should not have any significant disadvantages compared with other medications in its class;
6. It should be readily available; and
7. It should be relatively familiar to most clinicians.

Applying these criteria to medications in every class or subclass should allow the clinician to select a “P drug” for any target syndrome or target symptom. For example, and as illustration only, fluoxetine would be a reasonable “P drug” for adolescent depression; methylphenidate would be a reasonable “P drug” for childhood ADHD; and risperidone would be a reasonable “P drug” for youth-onset schizophrenia.

Once the “P drug” is selected, the clinician should become fully versed in its pharmacodynamics and pharmacokinetics. Repeated usage of the “P drug” will increase familiarity with its unique characteristics. Physicians in both primary and secondary care settings may find it useful to select two or three “P drugs” for each commonly treated condition using similar criteria to those noted above. This will allow greater flexibility in dealing with patients who may not have experienced therapeutic success with a previously used medication or who wish to have options in their choice of medications. Knowledge of the “P drug” also entails knowing its limitations, when others may be preferable and when a tertiary center should be consulted. Tertiary care physicians need to have a much wider familiarity with various therapeutic modalities.

Patient Acceptability
Patients and their families (as appropriate) should be active partners in their care and their acceptability of any treatment is important, not only for adherence but possibly also for therapeutic outcome. Patient (and family) participation in the choice of treatment (see p. 1104) is an important process of treatment selection. Patient preference for a specific intervention should be carefully considered whenever reasonable and may be driven by one or more of the following: previous experience with a medication (positive or negative); experience of a friend or relative with a medication; cost; and media coverage. Many young patients may find it difficult to swallow medications. For them, the type of preparation (tablet or capsule) or size of tablet is often an important consideration.

Comparative Risk–Benefit Profile
No medical treatment is risk-free. Every choice of medical treatment uses a risk–benefit approach. Risk–benefit can be analyzed by comparing the number needed to treat (NNT) with the number needed to harm (NNH). This creates a method for assessing the risk–benefit ratio of any treatment – regardless of its type. Such information may not be easily available for all somatic interventions (and is not available for most non-somatic interventions) but when it is, it should be used to guide treatment choice. As a rule of thumb, the number 10 is often taken as a “cut-off point” in treatment decisions using the NNT.

How many individuals does the clinician need to treat with a given intervention before he or she can be sure that at least one individual is getting better because of the intervention and not because of other reasons? In the Treatment of Adolescent Depression Study (TADS), the NNT was calculated for each of the four treatment arms. The combined fluoxetine and CBT treatment arm was found to have an NNT of 4, compared with fluoxetine alone which was 5 and CBT alone which was 12 (TADS, 2004). (Of course, single studies cannot by themselves provide sufficient assurance that NNT or NNH calculations based on their results alone are representative.) Clinicians should assess risk–benefit on the basis of likely therapeutic effect; likely adverse effects; rare adverse effects; likely outcome without treatment; and other available treatments. While there is no simple statistical or other method by which the individual practitioner can calculate the risk–benefit ratio for any single treatment for any single patient, the process of addressing the various domains will in itself raise issues that will need to be considered by both clinician and patient.

For some individuals, certain treatments may be contraindicated (they should not be used because their risk far outweighs their potential benefit) or contra-advised (they should generally not be used but for some specific patient reason they may be considered). For example, a medication that is known to demonstrate significant negative interactions with another medicine that is being used would be a contraindication for treatment. Treating an agitated psychotic manic male with a history of ADHD with methylphenidate alone would be contraindicated. Contra-advised selection would be a treatment that may raise the risk for an untoward outcome because of patient or treatment characteristics (or both). For example, the use of benzodiazepines to treat anxiety in a young person who has a strong family history of alcohol addiction would be contra-advised (Evans, Levin, & Fischman, 2000).

Ease of Administration
Ease of administration is a vital criterion for treatment selection. The easier a treatment is to administer, the more likely adherence is to be high. Considerations include the number of times the treatment is given (e.g., number of doses per day) and method of delivery (oral, parenteral, rectal). Additionally, the presence or absence of other associated features such as the necessity for periodic venipunctures (to monitor serum levels) and ancillary investigations because of possible negative drug effects (e.g., electrocardiograms [ECG]; lipid and glucose monitoring) need to be considered in treatment selection. As a general “rule of thumb,” when effectiveness and adverse events are similar, medications that are more convenient for the patient to use are preferred to those that carry greater inconveniences.
Cost and Availability

The cost of somatic treatments is an important factor in treatment selection. In this assessment, the availability of personal insurance or public health system coverage should be considered. As many pharmacological treatments will be long term (a year or longer), clinicians and patients should consider the cumulative and not just the single-dose costs of a treatment. In situations where individuals do not have coverage of costs, careful consideration needs to be given to the assessment of comparative benefits between medications that are less costly but “traditional” and those that are more costly and novel. Higher cost does not always mean better medication.

Additionally, the indirect costs of any specific medication must also be considered. For example, a medication may increase the likelihood of other medical problems for which later treatment will be needed (e.g., tardive dyskinesia or metabolic syndromes), or which entail frequent laboratory monitoring, either for serum levels of the medication (e.g., carbamazepine) or for medication-induced changes in physiology (e.g., prolactin, glucose or lipid levels which may be induced by some “atypical” antipsychotics). These “indirect” medication costs can have a substantial cumulative impact in both private and public payment systems.

In some settings, medication availability is an important issue. In many low-income countries, the supply chain of psychotropic medications is vulnerable to a variety of negative impacts often not considered by practitioners working in wealthy countries. A patient who cannot rely on a consistent supply of needed medications may be at risk for a variety of negative outcomes associated with supply discontinuation – including but not limited to relapse and withdrawal. If that is the case, then the clinician may choose to treat using a medication that in circumstances of reliable supply may not be preferred. For example, a long-acting injectable antipsychotic may be chosen instead of lithium carbonate for the maintenance therapy of a patient with bipolar disorder.

Assessment and Measurement

Once treatment targets have been identified, treatment goals (amount of expected change and expected timeline for change) need to be defined. These will vary depending on the treatment target and the intervention chosen. For example, panic disorder may be selected as a syndromal treatment target. Within that framework, panic attacks may be selected as a specific symptom target, with anticipatory anxiety and phobic avoidance also being chosen as symptom targets. In this case, assessment and measurement will need to be directed at both the syndromal and the symptom targets. This will lead the clinician to select a number of different measurement tools. For example, the syndrome can be assessed using ICD or DSM criteria; the panic attacks can be assessed using a diary that captures the number and severity of attacks weekly; the anticipatory anxiety and phobic avoidance can be assessed using a visual analog scale.

The expected timeline of effect will vary with the drug, not all treatment targets can be expected to show similar time courses of improvement. For example, in panic disorder, expected decreases in anticipatory anxiety may require 2–3 times longer to achieve than expected decreases in panic attack frequency. Phobic avoidance may similarly require a longer duration for a similar proportional improvement. In some cases, application of complementary concurrent interventions (e.g., behavioral therapy) may be required to achieve the treatment goals.

Treatment goals may be response or remission. Response can be defined as symptomatic improvement that is clearly experienced by the patient accompanied by functional improvement across a variety of domains (e.g., interpersonal, vocational, academic). Remission can be defined as a return to premorbid conditions (both symptomatic and functional). These outcomes may vary amongst treatment targets, as not all syndromes or symptoms show equal potential for response or remission with currently available somatic interventions. In some cases, addition of non-somatic interventions (e.g., CBT added to SSRIs for youth with OCD) may enhance the probability of improved outcomes.

Relapse prevention is also a treatment goal. Exacerbation of initial symptoms after treatment discontinuation is known as rebound, and the emergence of previously not experienced symptoms is known as withdrawal. Neither rebound nor withdrawal is synonymous with addiction, but either can occur in addictive states.

One of the many areas of therapeutics that require extensive additional research is that of the continued effectiveness of interventions that have shown positive short-term effects with acute treatment (e.g., methylphenidate in ADHD). There is a dearth of long-term studies of continued effectiveness of treatments (both physical and psychological) that can be used to guide clinical practice. So, in many cases (e.g., in the treatment of depression) we have to use data extrapolated from studies in adults. While this is not optimal information (and depression in adolescents does not follow the same expectations for treatment as in adults), it often is the only treatment available and so is still used to inform clinical practice for young people. It is hoped that future editions of this textbook will be able to draw on child- and adolescent-specific research that can address this issue.

Treatment emergent adverse events (commonly known as side-effects) are also treatment targets. However, here the target is to avoid or mitigate treatment emergent adverse events, not to achieve them. Treatment emergent adverse events are defined as any phenomena that have their onset during a treatment and are directly attributable to that treatment. For example, a specific medication can cause physical side-effects (e.g., nausea or diarrhea) by its effect on either the digestive system or the central nervous system. Similarly, behavioral side-effects (e.g., agitation, impulsivity), cognitive/perceptual side-effects (e.g., suicidal ideation or hallucinations) and affective side-effects (e.g., depressed mood) may occur as treatment emergent adverse events.
At times it may be difficult for the clinician to determine if patient complaints of adverse events are truly side-effects (i.e., they occur during treatment as a direct result of that treatment), or if they are reflections of another phenomenon. One such potentially confusing scenario is the onset of concurrent but unrelated events (e.g., the patient develops a flu-like illness during the flu season). Another potentially confusing scenario is attributional in nature. For example, the patient has had a long history of headaches, for which no cause has been established, but now is convinced that it is the treatment that is “causing” the headaches. In addition, negative outcomes occurring during treatment may also be the result of the natural history of the disorder and may be serendipitously linked to treatment application. For example, an increase in depressed mood that occurs a week after beginning an antidepressant may be a result of the natural progression of the illness prior to the onset of the therapeutic action of the treatment rather than a result of the application of the treatment. In such cases, the propensity for patients and clinicians alike to ascribe causality to proximal rather than distal factors may lead to the termination of a potentially effective intervention.

Thus, prior to any somatic intervention, a thorough assessment of treatment targets (syndrome, symptom, side-effect) must be conducted by the clinician. The initial application of this comprehensive evaluation is commonly known as the “baseline assessment.”

**Baseline Assessment and Measurements**

The baseline assessment takes place during a specified period of time prior to the initiation of a specific somatic treatment. It is carried on concurrently with patient (and where appropriate, family or responsible other) education about the disorder and its treatment (see p. 1103). In psychiatric treatments, emergency or life-saving interventions are usually not the norm and in most cases an appropriate window of time exists for the baseline assessment to be properly conducted. The baseline assessment addresses all of the treatment targets, provides specific measurements of those targets and sets outcome and evaluation process expectations.

Treatment targets can be syndromal, symptomatic, adverse effect or overall functioning. Syndromal targets are predefined by syndromal criteria (either ICD or DSM). Symptomatic targets can be directly defined by the disorder (e.g., hyperactivity, panic attacks, hopelessness). Functioning targets can be defined by assessing the effect of the disorder or symptom(s) on the individual’s functioning (e.g., interpersonal conflict, academic success). Adverse effects can be somatic, behavioral, cognitive/perceptual or affective.

Measurements of targets have three complementary components: frequency, severity and duration. For each target on which a measurement is conducted, each of these components should be noted. For example, for an aggressive boy: how many fist-fights (frequency) occurred during the last week (duration); and how intense were they (pushing, hitting, using a weapon at three different levels of severity)? Each of these components should be consistently noted at each measurement point.

Syndromal targets tend to be binary—that is, the syndrome is either present or it is not. They are therefore measured categorically. Syndromes may be measured in a variety of manners including the use of diagnostic rating scales such as the K-SADS and the DICA. These measurement tools are generally thought to be too cumbersome and time-consuming for routine clinical use but extensive training in their use may be associated with more comprehensive clinical assessments even when they are not being directly applied. Therefore, clinician training in one or more of these diagnostic instruments may be useful in a general sense for assessment and measurement purposes. Some authors suggest that syndromal checklists are a reasonable tool that can assist the clinician both in validating a clinical interview (does the patient clearly meet a syndromal diagnosis?) and in improving rater reliability over time (repeated application of the diagnostic checklist at designated intervals may enhance certainty in diagnostic outcome monitoring by ensuring that all the components of the diagnosis are appropriately considered each time the tool is applied). Application of a symptom checklist, which can be created directly from the diagnostic manuals for any psychiatric disorder, should be conducted at baseline.

Symptom treatment targets can often be ordinarily defined and thus lend themselves to measurement by scales. Sometimes these can be measured as symptom clusters which relate strongly to diagnostic categories (e.g., depression rating scales which include many of the symptoms found in major depressive disorder or obsessive-compulsive symptom rating scales). At other times, one or two symptoms will be the target of treatment (e.g., tics, aggressive outbursts; Storch, Murphy, Geffken et al., 2005). In many of these cases, a well-validated scale such as the Yale Global Tic Severity Scale (Storch, Murphy, Geffken et al., 2005) may not be available, or the clinician may prefer to use simple clinically useful measurement tools such as a Visual Analog Scale or an ordinal 0–3 scale where 0 equals none, 1 equals mild, 2 equals moderate and 3 equals severe. If this type of “shorthand” clinical measurement is used, the clinician must ensure that both he or she and the patient (or responsible other) understand the meaning of the different measurement points on the scale.

Symptom measurement tools can be either self- or other-administered, with the “other” being a clinician, parent or a specified responsible observer (e.g., a classroom teacher). There are pros and cons associated with the use of each type of tool and different informants may rate differently. When parents and patients rate differently on similar instruments (e.g., for ADHD symptoms), the astute clinician may use the occasion to explore the different perceptions of the problem, its treatment and the hoped for results. Thus, quantitative tools may also facilitate qualitative assessment.

For many mental disorders in children and adolescents, a variety of validated symptom rating scales are available. These often come complete with instructions for use and some may
be commercially available. The choice of measurement tool will depend on the realities of the clinician’s practice, the costs associated with their use and the acceptance of patients and responsible others. The routine application of 2–4 h of rating scales prior to therapeutic prescription is unlikely to find favor amongst patients and their families (nor is it necessary) outside of tertiary care or clinical research settings. However, routine application of some clinically useful standardized measurement tools at baseline and at appropriate times thereafter will improve clinical care.

As functional improvement should be a target of every somatic intervention, there must be some baseline assessment and measurement of functioning in various domains. The Global Assessment of Functioning Scale found in the DSM is helpful in this regard but different clinicians may prefer to use different tools. Some functional assessment tools have been developed for specific syndromes (e.g., the Kutchner scale for Social Anxiety Disorder; Brooks & Kutchner, 2004). In many cases, application of the Visual Analog Scale methodology to one or more functional targets will suffice. For example, level of family discord in the past week, success in getting homework completed prior to class. For some targets, simple counting is appropriate (e.g., number of fist-fights in the past week). The “best” choice of measurement tool will depend on the target.

Side-effects should be measured using standardized techniques that cover a wide variety of somatic dimensions (for examples see Kutchner, 1997) and must be applied at baseline before a somatic intervention is initiated. This will allow for appropriate identification of treatment emergent adverse effects, which can be either phenomena that arise for the first time during treatment or exacerbations of phenomena already existing at the onset of treatment.

Appropriate medical assessments may also be indicated at baseline. These include laboratory and other investigations, which may be diagnostic of a medical condition (such as a thyroid-stimulating hormone [TSH] test for hypothyroidism or a magnetic resonance imaging [MRI] scan for pituitary adenoma) suggested by information obtained during the history and functional enquiry (see chapter 22). Routine laboratory screening is not indicated given its low positive predictive value. Additionally, those laboratory or other physiological parameters (such as heart rate/rhythm) that can be affected by the somatic treatment used (e.g., thyroid function for lithium, prolactin for risperidone, metabolic indices for olanzepine, ECG for tricyclics) should be assessed at baseline. Pubertal females should have a pregnancy test and high-risk teenagers may be strongly considered for sexually transmitted disease (STD) investigations.

**Evaluating and Maximizing Treatment Outcome**

Following the baseline and at the time of expected outcomes, evaluation of each target should be conducted, using the same measurements that were obtained at baseline. The timing of these will vary depending on the target being evaluated, the treatment being applied and the expected time course for change to occur. For example, if syndromal outcome is being measured in a teenager with major depressive disorder, a checklist for major depressive disorder should be repeated following 8–10 consecutive weeks of treatment if an SSRI is being used. Syndromal assessment for ADHD in a 9-year-old boy could be conducted following 2–4 weeks if a psychostimulant is being used. For panic disorder (PD) it is reasonable to conduct a syndromal evaluation following 4–6 weeks if a benzodiazepine is being used. Conversely, depressive symptoms in major depressive disorder measured using either a self-rating or clinician-rating scale should be conducted at week 4 and weekly thereafter, while both ADHD and PD symptoms should be monitored weekly following treatment initiation. Side-effects should usually be evaluated within 2 days of initiation of treatment and weekly thereafter.

In acute agitated psychotic states, both therapeutic and side-effects may need to be evaluated hourly if clinically indicated. School functioning in OCD may be next assessed at 3 months and every 2 months thereafter. Serum carbamazepine levels can be assessed weekly for 4 weeks and then every 6–8 weeks following hepatic calibration to steady state levels.

In chronic treatments, similar criteria apply. For institutionalized children or teenagers, frequent evaluation of all target conditions will help ensure that appropriate clinical care is being provided, and institutional policies and procedures should be developed to ensure that such careful and standardized ongoing evaluation is in place.

Once maximal treatment outcome has been obtained (remission or recovery), treatment evaluation becomes treatment monitoring. In this scenario, regularly scheduled visits should be structured to ensure that syndromal, symptomatic, functioning and side-effect targets can be parsimoniously evaluated. Additionally, qualitative evaluation becomes increasingly important in the face of insufficient scientific data on the potential risks and benefits of long-term treatments. Evaluation tools should therefore be supplemented by more open-ended dialog. Patients and their families should be instructed to report any untoward adverse events immediately. Always check with the treating physician if other medications are being prescribed (in case of drug–drug interactions). Patients and families should be instructed in the earliest signs of relapse so that potentially useful interventions are not delayed.

**Maximizing Treatment Outcome**

The ideal goal of treatment outcome is recovery, which is remission followed by a prolonged sense of well-being. Unfortunately, our therapeutics are not perfect and in many cases, because of either individual or therapeutics reasons, neither recovery nor remission occurs. The aim is then an optimal outcome—achieving the best improvements possible in all treatment targets. For this purpose, somatic treatments are often necessary but insufficient, and should be linked with various other interventions, including psychological, social and...
vocational components, guided by the same principles of evidence and application as are used to direct somatic treatments. They should be chosen on the basis of patient need rather than clinician preference or ideological commitment.

In many cases, somatic treatments may differentially affect chosen targets in a manner that limits their ability to address patient needs effectively. For example, the same dose of a “P” medication that maximizes symptomatic improvement may lead to intolerable side-effects, thus limiting its dose. This may require the use of a different medication or “layering” of medications (the use of a lower dose of the “P” medicine with the addition of another medication, usually from a different class of drug). These different strategies are known as substitution and augmentation. While there is often anecdotal evidence for these strategies, and in some cases there is reasonable scientifically supported evidence from adult populations, neither of these two sources of information provides the necessary weight of scientific evidence required to clearly guide clinical practice in young people. In such situations, clinicians will need to rely on their best judgment and must discuss the limits of evidence and the basis for their further treatment advice with their patient and his or her family or responsible caretaker. The rationale for choosing either substitution or augmentation strategies should be noted in the clinical file.

Achieving therapeutic outcome with the initial “P” drug is based on two factors – dose and duration of treatment. The dose must be one that provides the greatest positive benefit with the fewest side-effects and it must be maintained for the necessary length of time – in both acute and long-term conditions. In dose determination, three factors are important: dose initiation, dose target and dose duration. The dose must be properly initiated; doses that are too high to begin with or which are raised too rapidly will not usually hasten symptomatic improvement but will often lead to significant side-effects. Sometimes there is a significant possibility of an individual showing adverse effects at an ordinary dose. For example, some individuals are slow metabolizers of atomoxetine (see chapter 16). A low dose may then be given as a check on sensitivity, with patient and family aware of the rationale. Choosing an initial dose target that is too low is unlikely to lead to optimal benefit, while choosing an initial dose target that is too high is unlikely to improve outcome over side-effects. Up-titration, the process of dose increases to achieve the initial target dose, should be carried out slowly – giving time for the patient to acclimatize to each stepped increase.

Medications that achieve their initial dosing targets but are not maintained for a sufficient length of time are unlikely to provide optimal treatment response. It is essential that the clinician allow sufficient time for the treatment to demonstrate its effect. This time to response will differ depending on the condition and the medication used. For example, a young person treated with an SSRI for major depressive disorder should be maintained at the initial target dose for a period of 8 weeks. For a youth with OCD being treated with an SSRI the time to response is about 12 weeks. Discontinuation of treatment prior to the expected time to response may not only negate the therapeutic effects of an effective treatment, but may also lead to negative perspectives about the value of a particular intervention on the part of patient, family and clinician alike.

Both dose initiation and dose duration must be based on the pharmacokinetics and pharmacodynamics of the medication chosen and the known response of a syndrome or symptom to the medication. For example, an SSRI used to treat OCD may require a higher therapeutic target dose level for a longer duration than the same SSRI used in the treatment of major depressive disorder. However, both will require similar rates of dose titration to reach the initial target dose. In general, for most medications, a “start low and go slow” dose titration model is to be preferred. Of particular importance in acute psychosis is that the expected course of clinical outcomes should be used to inform dose titration. For example, initial dosing strategies should target agitation and restore a “normal” sleep–wake cycle. Improvement in socialization and psychotic thinking can be expected later in the treatment course. Over-medicating by using higher doses of antipsychotics to treat agitation and sleep difficulties is to be avoided. The layering of medications (such as adding short-acting benzodiazepines to address agitation) is preferred to using larger (and potentially more problematic) doses of non-sedating antipsychotics.

Possible drug–drug interactions must be considered whenever multiple medications are being used in the same individual. While it is unlikely that any clinician can remember all such interactions, it is possible to keep in mind the most common that could be expected for children and adolescents. Up-to-date resources containing P450 level drug–drug interaction tables are readily available and any physician treating young people with medications should routinely consult these references. Some are free of charge (Flokhart, 2007) and others require a subscription (GeneMedRx, 2007). Every patient and responsible caregiver should be informed about the possibility of drug–drug interactions and asked to notify the treating physician before beginning any new medication. Over-the-counter and herbal compounds may also interact with prescribed medicines (Hu, Yang, Chan et al., 2005). Therefore, as a general rule, patients and responsible others should be informed (and repeatedly reminded) that any medication (including cold remedies, pain modulators and oral contraceptives) should be discussed prior to their use. Encouraging patients to have their prescriptions filled at reputable pharmacy outlets that maintain personal medication profiles is recommended.

At a predetermined time (set by the known expected time course for therapeutic improvement) the therapeutic intervention should be systematically evaluated. Ideally, this should include a comprehensive review of the initial presentation, all treatment targets, the outcome in every target, newly emerging problems (including side-effects), functioning and a diagnostic re-evaluation. At that time one of three outcomes can be determined:

1. Remission has occurred;
2. Response has occurred but some difficulties remain; or
3. Insufficient therapeutic response has occurred or the situation has worsened.
If the outcome is recovery, the usual strategy is to continue the somatic treatment for an appropriate length of time following remission prior to deciding if treatment discontinuation is warranted. Although insufficient scientific literature exists to direct clinical decision-making on this point, practice should in general be guided by the answers to the following questions: what are the known or suspected negative outcomes of continuing medication treatment; what are the known or suspected positive outcomes of continuing medication treatment; what is the evidence for relapse if medication treatment is discontinued? Open discussion of these issues with a patient and responsible others can be used to guide continued treatment.

In the situation where response has occurred but some significant problems remain, the clinician should reconsider the treatment targets and the known therapeutic gains that can be expected with available somatic interventions. For example, in cases of severe OCD treated with an SSRI, a 75% response in OCD symptoms may be the best that can be expected (see for example March, Biederman, Wolko et al., 1998). Additionally, a search for other factors that could contribute to insufficient improvements such as treatment adherence difficulties; the presence of significant comorbid conditions; the effect of ongoing psychosocial stressors or the possibility of heretofore unrecognized substance misuse should be explored. Following from that, the initial treatment should be optimized.

Pharmacologically, treatment optimization may require increasing the dose beyond the initial target dose. If adverse effects are tolerable, this may be initiated using dose increments similar to those used during the period of up-titration to the initial target dose. Once a new target dose is reached, this should be maintained for a reasonable period of time to determine if therapeutic response improves. This pattern of gradual step increases, interspersed with appropriate periods of waiting, can continue until either the patient no longer continues to demonstrate expected treatment gains or side-effects that are not tolerable to the patient occur.

In some cases, the patient may be genetically predisposed to rapid metabolism of the medication. These “ultra-rapid metabolizers” are more common in African and Middle Eastern populations and demonstrate highly efficient CYP2D6 hepatic enzyme activity. Such individuals may rapidly metabolize various antidepressant and antipsychotic medications. However, a small percentage of the population demonstrates slower than usual metabolism of medications. These “poor metabolizers” as they are called, may have genetic differences of either the CYP2D6 or CYP2C19 hepatic enzyme systems (Destá, Zhao, Shin, & Flockhart, 2002). Now that a relatively simple test for genotyping of 2D6 and 2C19 has received Food and Drug Agency (FDA) approval, patients whose clinical presentation suggests a problem with drug metabolism could be tested in locations where that test is available (de Leon, Armstrong, & Cozza, 2006).

Optimization of response may also be achieved with the addition of psychological treatments with well-demonstrated efficacy, such as CBT added to fluoxetine in depressed adolescents (TADS, 2004) or CBT added to sertraline in OCD patients (POTS, 2004). In other cases, augmentation with another class of medication (e.g., adding lithium to an antidepressant in the treatment of depression) may be indicated (Hughes, Emslie, Crismon et al., 1999). Another alternative is to switch medications, either to a compound in a similar class or to a compound from a different class (Hughes, Emslie, Crismon et al., 1999). In some circumstances, the clinician may choose to substitute a non-somatic intervention for a physical treatment that has not led to good therapeutic results. This should only be considered where the research evidence for the effectiveness of the non-somatic is substantial and if the patient and/or family concurs (e.g., in OCD; O’Kearney, Anstey, & von Sanden, 2006). If this course of action is contemplated, then a graduated medication withdrawal strategy should be put into place to minimize the potential for a withdrawal syndrome.

Given the lack of substantive scientific evidence for any of the above strategies in the child and adolescent literature, treatment options will need to be discussed with the patient and responsible others and a jointly acceptable decision will need to be made as to the direction taken. Once that decision has been made, similarly rigorous assessments and treatment target selection and monitoring are necessary.

In cases where improvement has been unsatisfactory or the situation has worsened, the diagnosis should be critically reviewed and the social ecology of the therapeutic situation critically addressed (including treatment adherence, family and peer factors, and possible substance abuse). Then a new conceptualization of the problems and treatment targets needs to be undertaken and the systematic assessment, measurement and application once again initiated. A consultation with an experienced colleague is often useful in such situations.

The “N of One” Assessment Methodology

For some conditions and with some medications, an “N of One” treatment trial can be effectively and relatively simply initiated (Kutcher, 1986). This approach has stood the test of time and is appreciated by patients and families alike (Kent, Camfield, & Camfield, 1999) and can be implemented over the telephone (Nikles, Mitchell, Del Mar, Clavarino, & McNairn, 2006). Ideally, the medication should be paired with an identical placebo which can be made up by a pharmacist (or a non-identical comparison with blind raters). Then an on–off cycle (3–5 days on the medication followed by a similar length of time on the placebo) is initiated. Ideally, this cycle should be repeated so that an ABAB model is applied (A = medication phase; B = placebo phase). Ideally, multiple raters of the patient’s symptoms, blind to the treatment condition and all using the same rating scale in the same manner across the entire ABAB sequence provide the assessments on which therapeutic decisions will be made. A positive trial demonstrates a repeated therapeutic effect of the medicine that is not found with the placebo.
CHAPTER 67

This assessment method is well suited for a medication that demonstrates a rapid therapeutic onset and rapid therapeutic offset. Of all the child and adolescent disorders, ADHD is most amenable to this type of evaluation, using immediate-action medications and standard measures such as the SNAP (Pelham, Gnagy, Burrows-Maclean et al., 2001; Swanson, 1992) with a methylphenidate specific side-effects scale (Kutcher, 1997). If therapeutic response is limited or side-effects are substantial, the “N of One” can suggest that a non-stimulant alternative be considered, thus saving the time and expense of an initial unsuccessful clinical trial.

Variations on this design can be used to answer other important clinical questions – for instance, of the need for different doses as a child with ADHD grows. Other, less rigorous “N of One” approaches to test hypotheses about medication treatments are less well supported by evidence and less well grounded in scientific validity. For example, some clinicians may choose to stop a medication to “see if it is still working.” While the intent may be honest this suggests that the initial approach to the treatment was weak on assessment and evaluation. It is not necessary to stop a treatment to see if it is working. That question can be answered by comparing current assessments of symptoms and functioning against the baseline. Furthermore, discontinuation of treatment is not without its risks – for example, in bipolar patients, continuation of lithium treatment is highly correlated with lower rates of suicide (Baldessarini, Tondo, Davis et al., 2006).

Polypharmacy

The increasing rate of psychotropic medication use in young people has been well documented (Thomas, Conrad, Casler, & Goodman, 2006). In some jurisdictions those increases (e.g., the use of SSRIs to treat depression) may be reasonably justified (Hunkeler, Fireman, Lee et al., 2005) while in other jurisdictions the choice of medications used (e.g., the use of tricyclic anti-depressants and herbal preparations to treat depression) is not supported by the available data on safety and efficacy (Fegert, Kolch, Glaeske, & Janhsen, 2006). Many reasons to explain this increase have been suggested, including but not limited to: changes in clinical practice (from inpatient to outpatient care); increased treatment of heretofore untreated populations; better diagnosis and case identification of mental disorders in young people; availability of less toxic and less dangerous medications; pharmaceutical industry promotion of medication use; and better data on the effectiveness of medication treatment. Given the complexities of this issue, it is reasonable to conclude that multiple factors have come together to create this phenomenon.

As part of this increase, there is a general perspective that polypharmacy – the use of many medications concurrently – has become relatively commonplace, up to half of the populations studied in some reports (Russell, George, & Mammen, 2006), even though the evidence to support this use is not always robust (Lopez-Larson & Frazier, 2006). There may be a number of reasons for this increase. For example, some medications are routinely prescribed to counter possible adverse events caused by others (e.g., anticholinergic medicines used concurrently with “typical” antipsychotic compounds to limit extrapyramidal side-effects). Such clinical use is reasonable and consistent with both the pharmacodynamics and pharmacokinetics of the concurrently prescribed compounds. Another example of rational polypharmacy is the combined short-term use of a sedating benzodiazepine with an antipsychotic in the initial stages of an acute agitation psychosis.

However, there are a number of concerns about the use of polypharmacy. These include but are not limited to: an increased risk of side-effects caused by drug–drug interactions; decreased treatment adherence; increased treatment cost; and using two medications when one will do in the treatment of comorbid conditions (e.g., depression and panic attacks). Therefore, it is necessary to consider carefully the rationale for combining psychotropic medications and to monitor their use closely.

The following are issues that the clinician should consider prior to combining medications:

1 Why is the combination being considered? If it is for subtherapeutic response to a monotherapy, has the necessary review of the case and monotherapeutic optimization been conducted?
2 Is there a clinical and pathophysiological rationale for the combination?
3 Is there a scientific literature that addresses the combination being considered?
4 Are there known or likely drug–drug interactions?
5 If the combination is being used to treat a number of different symptoms or conditions, is there one medication that can be used instead?
6 How long will the combination be used and what are the evaluations that will be put into place to monitor therapeutic outcomes and adverse events?

When combining medications (and when changing medications) it is advisable to add (or subtract) only one compound at a time, ensuring that enough time passes to allow for appropriate evaluation of the effects of the medication addition (or subtraction). Careful monitoring will also be necessary as insufficient research data are available on possible adverse reactions to medication combinations.

The Human Interface

No medical treatment takes place in a social vacuum. Every interaction includes a host of individual, group and society factors, which influence, color and impact on the interaction between clinician and patient. Indeed, this interaction in and of itself may have therapeutic effect and thus, by implication, may have a negative effect. In some disorders, specific psychological or social therapies may extend some of the activities found in the clinician–patient interface but do not substantively alter or necessarily even improve on them. For example, the best estimation of the effect size of CBT for major depressive disorder in adolescents is 0.3–0.4 (Weersing & Brent, 2006; Weisz, McCarty, & Valeri, 2006), which is strikingly similar.
to the placebo rate found in strictly conducted studies of somatic therapies (Cheung, Emile, & Mayes, 2006). In other disorders (such as OCD), however, a similar type of psychotherapeutic intervention shows a greater effect size, suggesting a unique positive effect of that specific treatment.

The foundation of the clinician–patient interaction is based on two important principles: clinician responsibility to the patient and respect for the autonomy and rights of the patient. Each of these principles can be used to inform and direct the clinician–patient interaction in the delivery of somatic treatments.

**Clinician Responsibility to the Patient**

This value is arguably the basis for all physician–patient interaction, has its roots in centuries of medical history and is the framework on which the Hippocratic oath is built. In the provision of somatic treatments this value has certain specific applications.

First, the clinician is obligated to provide the therapeutic intervention for which the best and strongest scientific evidence for safety and effectiveness is available. This means that in some cases the clinician may advise against the use of somatic interventions if equally effective, inexpensive, safer and readily available non-somatic modalities are available. Conversely, it means that any responsible clinician should advise the use of somatic treatments when these are clearly indicated. Personal adherence to a particular “school” of therapeutics is not the criterion upon which patient care is based. Ideology should not trump science. The tradition of offering the “least restrictive” treatment as the preferred intervention in child psychiatry is still very strong and has important human rights foundations which should not be ignored. In days when therapeutic interventions were both all very much of a kind and all with a minimal evidence base, that framework as the primary guide to treatment selection was at least partly defensible. Currently, it is not a sufficient criterion for treatment selection. Not only must treatment be as minimally restrictive as possible, but it must also be as safe and effective as possible.

Additionally, clinicians must be honest with the patient and family about the strength of the scientific evidence used to guide their interventions. In a rapidly changing and imperfect world clinicians work with the best evidence that is available, not necessarily with the best evidence that should be available. Often therapeutic decisions need to be made on the basis of weak or even contradictory evidence. Sometimes, the available evidence is inconsistent. For example, we have a reasonable understanding of the acute therapeutic and side-effects of antidepressants but limited knowledge about their long-term therapeutic and side-effects. Long-term safety information can only be obtained from long-term use with ongoing surveillance. Apart from methylphenidate in the treatment of ADHD, this level of uncertainty is actually the norm and not the exception. A fair and reasonable discussion about the limits of the scientific knowledge is to be preferred to dogmatic statements about the prescriptions being offered. This of course applies to all therapeutic interventions, not just somatic treatments. Best clinical judgment means applying best available evidence to address the needs of the patient. Physicians are expected to ply their craft at the limits of certainty.

Second, clinicians are obligated to be as up-to-date as possible regarding all aspects of the diagnosis and treatments for the population that they are serving. There is no excuse for “not knowing.” If the clinician is unsure, or uninformed, then referral should be made to a colleague who has the up-to-date knowledge needed to provide proper patient care. In child and adolescent psychiatry, it is still too common to find practitioners who practice what they learned as residents or house officers. Every clinician treating mentally ill children and adolescents either needs to have a solid working knowledge of diagnosis and somatic treatments, or else must discharge the obligation to the patient by referral to one who does. Furthermore, this requirement of life-long learning must be driven by appropriate educational activities. It is not appropriate to base one’s understanding of somatic treatments on information solely supplied by the pharmaceutical industry. Similarly, it is not appropriate to base this understanding on the basis of the opinions of colleagues alone. Ongoing critical reading of the evidence and constructive, unbiased peer discussion of the scientific literature form the foundation of continuing self-education.

Third, the clinician is obligated to inform others, often within the wider society, of the values, risks and benefits of somatic treatments for child and adolescent mental disorders. Societies are complex organizations, comprised of many subgroupings, some of which are more certain of the truth than others. In some situations, social criticism of medical practice is well warranted and provides an independent and necessary counterpoint to medical tradition and self-certainty. In other situations, social criticism of medical practice is the result of certain ideologies or socioeconomic agendas, which may make great theater and sell newspapers or lead to wealth accumulation in some of the members of the legal profession. Responsible physicians need to become involved in proactively countering such negatively driven social discourse, as the outcome of some of these social processes, if not appropriately addressed, may lead to negative outcomes for patients and their families. At times, clinicians must discharge their obligation to their patients by active participation in the public debates of civil society. Here again this participation is to be driven by the scientific and not the ideological prerogative.

Fourth, clinicians must discharge their obligation by doing no harm. This does not mean “Do not treat.” Nor does it mean “Do not treat using an intervention that may be harmful if used incorrectly or if inappropriately applied.” As chemists, alchemists and sorcerers have known for centuries, toxicity is mostly an issue of dose! The obligation is to ensure that the therapeutic intervention does not do more harm than good and that it does not do more harm than the unchecked progression of the disease and that it does not do more harm than an available, equally effective intervention. The clinician is obligated to use treatments that have a positive benefit–risk ratio, and to use them in a way that maximizes benefits and minimizes risks. In order to do this properly, the three obligations described above must be effectively discharged.
CHAPTER 67

Clinician Respect for the Autonomy and Rights of the Patient

In many religious and philosophical traditions, the “golden rule” is “Do unto others as you would have them do unto you.” This is a useful dictum for clinicians to follow, regardless of their personal beliefs. Treating your patient as you would like to be treated means that you respect the autonomy and rights of your patient. In practical consideration this includes such activities as ensuring that the patient provides informed consent to treatment. Younger patients (perhaps as young as 7–8 years of age) may be able to provide informed assent while all patients under the age of majority should (apart from exceptional circumstances that could be professionally or legally defended) receive parental or responsible other’s consent prior to treatment (De Lourdes, Larcher, & Kurz, 2003).

The treatment contract between care provider and patient includes the framework of active patient participation in decision-making pertaining to care. This means that treatment decisions need to be shared with patients and responsible others and that treatment choices should be made mutually. There may be exceptional circumstances in which such collaborative decision-making may not be possible – such as a psychotic disorder with no insight from the patient – and in those cases, the legal framework governing physician–patient interaction must be followed. Psychoeducation, the provision and comprehensive review of information pertaining to the illness, its treatments and its treatment options should be provided to patients and their families in language that they can understand. Many such resources (including web-based materials) are easily available from reputable sources – such as the American Academy of Child and Adolescent Psychiatry and the National Institutes of Mental Health (or, e.g., World Health Organization, 1998). The patient and family should be given hard copies of “best information” and referred to other sources that they can review on their own. Following this, time should be spent answering questions and addressing specific concerns. This educational process should be ongoing and may require additional time at both baseline and follow-up visits.

It is not clear whether good psychoeducational interventions can improve adherence to treatments, which may be especially problematic during the adolescent years (Staples & Bravender, 2002). Compared with adults, treatment adherence issues may be more complex in children and adolescents (Gau, Shen, Chou et al., 2006) for many reasons, including but not limited to: the input of parents; input of teachers or other institutional representatives; family conflicts; and peer pressures. The importance of treatment adherence is not to be overlooked, as it may not only impact on therapeutic outcome, but may also be linked to adverse effects – such as suicidality in depressed youth treated with antidepressants, in which it has been postulated that poor treatment adherence may explain “suicidality” (Weiss & Gorman, 2005).

Additionally, the clinician and any others participating in the care of the mentally ill young person must be aware of the sociocultural aspects of their interaction. In this multicultural and global environment, not to understand and consciously consider the cultural, religious and social frameworks that the patient and family bring to the care interaction is to be disrespectful to the patient and his or her sense of self. Thus, the clinician cannot prescribe somatic treatments by “giving a prescription.” Somatic treatments are a science, dispensed in the form of an art.

Juvenile Delinquency

Sue Bailey and Stephen Scott

The term *delinquency* is a legal one and refers to antisocial acts that could result in conviction, although most do not. The term *juvenile* refers to the age of the perpetrator. This extends from the age when they are first deemed able to be criminally responsible, through an age range when they are processed in a legal system for youths, until an upper age when they are dealt with in courts for adult crimes (see chapter 8). These ages vary between countries and states, and also may vary according to the offense (Cavadino & Allen, 2000; Justice, 1996). In England and Wales the juvenile age range is currently 10–18 years, although some have proposed the minimum age should be older (e.g., 14 years). Juvenile delinquency is a major public concern because of the damage inflicted on property and people, and the wasted unproductive lives of the young people themselves (Surgeon General, 2001).

The legal term delinquency should be distinguished from scientific concepts in developmental psychopathology such as antisocial behavior and aggression, and from clinical psychiatric diagnoses such as conduct disorder (see chapter 35; Frick, 2006). There is a considerable degree of overlap because all involve antisocial behaviors that fail to conform to societal norms. However, they are not the same; for example, a child under 10 with conduct disorder in England cannot be a delinquent, and a single delinquent act by an otherwise well-adjusted 15-year-old would not qualify for a diagnosis of conduct disorder. A major role of the forensic psychiatrist in the youth justice system is to bring the benefits of modern developmental psychopathology to illuminate the assessment and management of offenders.

This task is helped by important advances in understanding the epidemiology, longitudinal course and treatment of antisocial behavior in recent years. Understanding is growing of how risk factors combine to both precipitate and maintain antisocial behavior (see chapter 35). Progress has been made in the development of validated screening, needs assessment and risk assessment tools for this specific population (Bailey, Doreleijers, & Tarbuck, 2006; Grisso, Vincent, & Seagrave, 2005) and in the development of promising interventions (Harrington & Bailey, 2003).

This chapter has three sections. First, the contribution of psychiatric disorders to delinquency is reviewed. Second, three aspects of assessment are covered: determining the personal needs of delinquents; assessing the risks they pose to others; and judging their mental capacity with regard to their fitness to stand trial. Third, treatment of special groups is covered, and interventions for youths displaying delinquent behaviors are reviewed. Because of the trend to treat antisocial youth outside of expensive formal court proceedings where possible (AACAP, 2005; Bailey & Williams, 2005), this last section includes general treatment of offending youths whether or not they have come to the attention of justice systems.

**Historical Context**

The need to control a small group of very persistent recalcitrant youth, perhaps 1–2% of the population, is perennial. In the 18th and 19th centuries, offending children were seldom distinguished from adults and were placed in prison. In the England of 1823, boys as young as 9 years were held in solitary confinement in ships retired from the Battle of Trafalgar. Over the last 50 years, both community and secure residential interventions in youth justice have been characterized by a pattern of reforming zeal, followed by gradual disappointment as the results of evaluations have become available (Hagell, Hazel, & Shaw, 2000).

Throughout the 20th century, concern about levels of juvenile offending has absorbed the attention of the public, politicians, practitioners and researchers (Burt, 1925; Glover, 1960; Rutter, Giller, & Hagell, 1998). Throughout the western world (Junger-Tas, 1994) there has been a widespread and growing perception that juvenile crime is inevitable, a fact of life in an increasingly violent society (Shepherd & Farrington, 1993). However, this has been accompanied by increasing urgency to curb the spread of serious juvenile crime. A century ago, the plan underlying the juvenile justice system in the USA had as its purpose, through the juvenile court, the creation of a whole new system of law for responding to youthful offending based on the developmental premise that young people were still malleable and could be saved from a life of crime. This philosophy held its ground for nearly 100 years, until the USA experienced an increasing tide of youth violence from the late 1980s (Zimring, 1998). Grisso (1996) commented that in its wake the “rehabilitative approach to juvenile justice has all but disappeared in the USA in an avalanche of massive legislative efforts to transform it.” These changes are echoed...
in the overhaul of the youth justice system in England and Wales (Bailey, 1999).

This more sobering view of whether delinquents naturally improve is supported by recent advances in developmental psychopathology. Increased understanding of the continuities between child and adult life (see chapter 13; Maughan & Kim-Cohen, 2005) has served as a timely reminder that many childhood disorders once thought to resolve with age are known to cast long shadows over later development (Moffitt, 2003). This is especially true with regard to the trajectory from antisocial behavior in childhood, through adolescence and on into antisocial personality disorder (ASPD) in adult life where the prevalence is approximately 2% (Coid, 2003; Torgersen, Kringle, & Cramer, 2001). ASPD is associated with a high degree of social handicap and increased risk of death through accidents, suicide, substance abuse and murder (Robins & Rutter, 1990; Tremblay & Pare, 2003). Once established, it is very hard to treat. Nonetheless, recent studies suggest that there are several promising interventions for juvenile offending, as reviewed below.

**Psychiatric Disorders and Offending**

Rates of psychiatric disorder in detained juveniles vary, according to study, from 50% to 100% (Lader, Singleton, & Meltzer, 2003; Lederman, Dakof, Larrea, & Li, 2004; Sailas, Feodoroff, Virkkunen, & Wahlbeck, 2005; Vermeiren, De Clippele, & Deboutte, 2000; Vreugdenhill, Vermeiren, Wouters, Doreleijers, & van den Brink, 2004). A survey in England and Wales by the Office of National Statistics (ONS) of 590 young offenders (aged 16–20 years) found that 80% had two or more disorders (Lader, Singleton, & Meltzer, 2003); broadly comparable figures were found in two large Finnish cohorts (Sailas, Feodoroff, Virkkunen et al., 2005). The most common disorders, unsurprisingly, are conduct disorders (CD), but other disorders such as substance abuse disorders, attention deficit/hyperactivity disorder (ADHD), mood and anxiety disorders and post-traumatic stress disorder (PTSD) are common; psychoses are significant, and autistic spectrum disorders are being increasingly recognized.

**Conduct Disorders and Attention Deficit/Hyperactivity Disorder**

High rates of physically aggressive behavior are found in children and adolescents with CD, and particularly those with comorbid CD and ADHD. They are at substantially greater risk of delinquent acts in adolescence and continued violence and offending into adulthood; many develop ASPD (Loeber, Pardini, Homish et al., 2005; Seagrove & Grisso, 2002; Soderstrom, Sjoedin, Carlstedt & Forsman, 2004; Sourander, Elonheimo, Niemela et al., 2006). Factors that may be protective for other outcomes may not necessarily reduce offending; thus, having a partner in itself does not appear to reduce criminality (indeed, juvenile delinquents with a partner commit more offenses); however, if the partner is supportive, this is associated with less offending (Meeus, Branje, & Overbeek, 2004). CD are discussed in more detail in chapter 35.

**Psychopathic Traits and Antisocial Personality Disorder**

Psychopathic traits are being increasingly recognized in children and adolescents (see chapter 51). Youths with these traits are commonly seen in justice systems as a result of the combination of deceptiveness and antisocial behavior. Factor analyses typically find three sets of characteristics (Cooke & Michie, 2001):

1. An arrogant, deceitful interpersonal style, involving dishonesty, manipulation, grandiosity and glibness;
2. Defective emotional experience, involving lack of remorse, poor empathy, shallow emotions and a lack of responsibility for one's own actions; and

Delinquent offenders with these psychopathic traits have an earlier onset of offending, commit more crimes, re-offend more often (Forth & Burke, 1998) and more violently (Spain, Douglas, Poythress, & Epstein, 2004) than non-psychopathic criminal youth. In addition, they exhibit insensitivity to punishment cues irrespective of whether or not they have conduct problems, making them especially hard to treat (O'Brien & Frick, 1996). ASPD (using DSM-IV criteria) was found in 81% of sentenced 16- to 20-year-old males in the ONS survey (Lader, Singleton, & Meltzer, 2003). However, overconfident predictions about poor outcomes for youth with these traits should be avoided, as knowledge about the nature, stability and consequences of juvenile psychopathy is still very limited. There is only one published longitudinal study of its stability and it remains unclear to what degree the antisocial behaviors in callous-unemotional youths change over time.

**Autistic Spectrum Disorders**

Autistic spectrum disorders are being increasingly recognized in general populations (Baird, Simonoff, Pickles et al., 2006), and at a clinical level in adolescent forensic populations, although there have not yet been thorough surveys. Jones, Forster, and Skuse (2007) found high rates of impaired social cognition in young offenders, but they did not fully assess autistic spectrum disorders. Suspicion should be raised if an offense or assault is bizarre in nature, the degree or nature of aggression is unaccountable or there is a stereotypic pattern of offending. Howlin (1997) proposed four reasons for offending and aggression in autistic persons:

1. Their social naivety may allow them to be led into criminal acts by others;
2. Aggression may arise from a disruption of routines;
3. Antisocial behavior may stem from a lack of understanding or misinterpretation of social cues; and
4. Crimes may reflect obsessions, especially when these involve morbid fascination with violence – there are similarities with the intense and obsessional nature of fantasies described by some adult sadists (Bailey, 2002).
Autistic spectrum traits share some characteristics with the callous-unemotional and interpersonal aspects of psychopathy: in both a lack of appreciation of, or concern for the feelings of others is prominent. Future studies need not only to disentangle these emotional dimensions of autistic spectrum disorders and psychopathy, but also to determine how the behavioral dimensions of impulsiveness and recklessness of psychopathy overlap with the same traits in ADHD. We need phenomenological, etiological and longitudinal studies to characterize these symptom clusters, and intervention trials to see what works in ameliorating them, and how they moderate response to treatment.

Substance Misuse
Drug and alcohol misuse are strongly associated with offending. The ONS survey (Lader, Singleton, & Melzter, 2003) found that 70% of male and 51% of female young offenders had misused alcohol in the year before coming to prison (Alcohol Use Disorders Identification Test scores over 8), and that in the same period 30% of men and 26% of women had used heroin. Rutter, Giller, & Hagell (1998) describe three mechanisms that operate. First, both sets of behaviors share common antecedent risk factors, including individual characteristics such as impulsiveness with lower IQ, environmental characteristics such as harsh parenting with poor supervision, and associating with a deviant peer group. Second, while under the influence of substances, youths are more disinhibited and commit more offenses, including violent assault and driving offenses. Third, once addicted, some youths commit crimes to pay for their habits; for the same reason, a substantial proportion of female addicts turn to prostitution. Additionally, use of cannabis is associated with psychosis, which also increases the likelihood of offending (Arseneault, Moffitt, & Caspi, 2002; Henquet, Krabbendam, Spauwen et al., 2005).

Early Onset Psychosis
Of the juvenile population in the youth justice system, 5–10% have psychoses (Chitsabesan, Kroll, Bailey et al., 2006; Lader, Singleton, & Melzter, 2003) compared with around 1% of the general juvenile population. As in adult life (Taylor & Gunn, 1999), most young people with schizophrenia are non-delinquent and non-violent. However, about 10% of adults with psychoses commit offenses (Soyka, Morhart-Klute, & Schoech, 2004) and the juvenile proportion is likely to be similar. Non-psychotic prodromal behavioral disturbances precede full-blown psychotic symptoms in about half of cases of early-onset schizophrenia, and can last between 1 and 7 years. They include disruptive behaviors, ADHD and CD. Therefore, the forensic psychiatrist needs to carry out mental health assessments repeatedly over time, to be able to detect changes in social functioning (often from an already disorganized baseline level) and mental state changes including perceptual distortion, ideas of reference and delusional mood.

There is an increased risk of violence to others when youths with psychoses have active symptoms, especially when exacerbated by misuse of drugs or alcohol. The risk of violent acts is related to subjective feelings of tension, ideas of violence, delusional symptoms that incorporate named persons known to the individual, persecutory delusions, command hallucinations, fear of imminent attack, feelings of sustained anger, and fear and passivity experiences that reduce the youth’s sense of self-control. Protective factors include responding to and ongoing compliance with physical and psychosocial treatments, good social networks, a valued home environment, no interest in or knowledge of weapons as a means of violence, good insight into the psychiatric illness and any previous violent aggressive behavior, and a fear of their own potential for violence. These features require particular attention during assessment, but full general psychiatric assessment remains essential, as the best predictors of future violent offending in young people with mental disorder are the same as those in the general adolescent population (Clare, Bailey, & Clark, 2000).

Depression, Anxiety and Post-Traumatic Stress Disorder
These disorders are also very common in young offenders. The ONS survey, using the Clinical Interview Schedule, found 41% of men and 67% of women scored above the cut-off score of 12 for symptoms of “neurotic” (emotional) disorders, compared with 11% of the general population. The combination of depression, anxiety and severe PTSD is being increasingly recognized in the child literature as one pathway into adult ASPD (Harrington & Bailey, 2003; Pliszka, Stienman, Barrow, & Frick, 2000). In depression, as well as feelings of low mood, there may also be irritability, hostility and anger, which increase the risk of defensive aggression (Harrington, 2001), a pattern seen in juvenile justice populations (Harrington, Kroll, Rothwell et al., 2005).

Anxiety and PTSD (see chapter 42) are relatively common in children who have experienced violence in war-torn countries and those who live in a context of “urban war zones” (Fletcher, 2003). Exposure to brutalizing violence can then lead the victims to be violent themselves. Garbarino (2001) has set out an ecological framework to explain the process and conditions that transform the “developmental challenge” of coping with violence into the “developmental harm” of meting it out to others. He proposed an accumulation of risk factors for understanding how and when children who suffer the most adverse consequences of exposure to community violence then have the limits of their resilience overwhelmed. Emotional symptoms such as these can easily be missed, so it is essential to enquire about them during the mental state examination.

Suicide and Deliberate Self-Harm
Deliberate self-harm and completed suicide are particular problems for both out-patient and incarcerated young offenders. In the community, youths with more severe conduct symptoms are more likely to have comorbid depressive symptoms, and rates of deliberate self-harm have long been recognized to be elevated to levels higher than in either condition alone. Thus, Kovacs, Goldston, and Gatsonis (1993) found 22% of adolescents with depression, 9% with CD, but 45% of those
with both had attempted suicide; Fombonne, Wostear, Cooper, Harrington, and Rutter (2001) found a similar pattern. Mechanisms to explain this include a higher genetic loading and also increased psychosocial risk factors.

Rates are especially high amongst incarcerated youths. Because they are a more severely antisocial subsample, they tend to have more of the genetic and environmental risk factors mentioned above. Additionally, immediate proximal risk factors are elevated: self-harm is often a serious attempt to escape from unbearable feelings or situations (see chapter 40), and youths in prison often feel, and are, powerless and trapped. In England and Wales, the number of self-inflicted deaths in prison in 2006 was 99 per 100,000 prisoners per year, compared with 18 in the general community (Safer Custody Group, 2007). A total of 20% were by under twenties, 95% were by males (reflecting the prison population make-up), and over 90% were by hanging, with half occurring within the first month of imprisonment (Safer Custody Group, 2007). Violent and sexual offenders are at highest risk. Triggering factors include being bullied and being locked in a cell for long periods. These worryingly high rates led in 2004 to the Safer Custody Group being formed for England and Wales, and attempts are being made to ameliorate the risk factors within prisons. However, there is still a long way to go. It is incumbent on psychiatrists working with these youths to assess suicidal tendencies thoroughly and plan interventions accordingly; this can be overlooked when the focus is on the offending record.

Assessment

General Principles
Assessment of need and risk are two separate but intertwined processes. The former has improving the health of the young person as its goal, the latter concerns the danger the young person poses to others, and is often more prominent in public debates about policy and legislation. Both types of assessment contribute to risk-management procedures (Bailey & Dolan, 2004).

Needs Assessment
While carrying out a traditional clinical psychiatric assessment with multiaxial diagnosis should form the backbone of a needs assessment, additionally using a formal needs assessment instrument can help because there are specific issues for the forensic population, and often a formal report is required for court in which it is essential to demonstrate that all key issues have been addressed (Bailey, Doreleijers, & Tarbuck, 2006). As there is rather little literature about needs assessment instruments for adolescent offenders (Knight, Goodman, Pulerwitz, & DuRant, 2001), the first author (S.B.), with colleagues, developed a new interview-based instrument called the Salford Needs Assessment Schedule for Adolescents (SNASA; Kroll, Woodham, Rothwell et al., 1999). This follows the design of the Cardinal Needs Schedule (Marshall, Hogg, Gath, & Lockwood, 1995), which is widely used with adult populations and has well-established reliability and validity. It covers 21 different domains, including individual behaviors (such as aggression), social relations and living situation (Kroll, Rothwell, Bradley et al., 2002). A clinical version is available, as is a shortened form (including a screening questionnaire) developed for use by youth offending teams (Youth Justice Board, 2007).

A recent study in the UK used the SNASA. It adopted a cross-sectional design and investigated 301 young offenders: 151 in custody and 150 in the community. Participants were found to have high levels of need in a number of different areas, including mental health (31%), education/work (48%) and social relationships (36%), but these needs were often unmet because they were not recognized. One in five young offenders were identified as having intellectual disability (IQ <70; Chitsabesan, Kroll, Bailey et al., 2006).

Risk Assessment
Risk assessment has a theory and methodology separate from needs assessment. Most instruments combine factors from various areas of risk (e.g., individual, family, neighborhood) in order to predict the probability of future offending. A number of instruments have been designed for application in the juvenile justice system (Barnoski & Markussen, 2005; Borum & Grisso, 2007; Corrado, 2002; Desai, Goulet, Robbins et al., 2006; Ogders, Burnette, Chauhan, Moretti, & Reppucci, 2005). For better reliability and validity, items should refer to multiple contexts of behavior and use multiple sources of independent information (Farrington & Loeber, 1999). They should tap into not only static risks, but also dynamic factors that can be changed by interventions. To maximize predictive power, information on risks should be complemented by data on protective factors and strengths; however, this is rarely done.

Fitness to Stand Trial
In the UK, a young person’s age, level of maturity and intellectual and emotional capacities must be taken into account when they are charged with a criminal offense, and appropriate steps taken in order to promote their ability to understand and participate in the court proceedings (T&V v United Kingdom, 1993). A responsibility therefore falls on the defense lawyer to be aware of the possibility that a young person may not be able to participate effectively in the trial process, particularly if they are under 14 years old, or have learning problems or a history of absence from school (Ashford, Chard, & Redhouse, 2006). Ashford and Bailey (2004) stated that all young defendants, regardless of the offenses they are charged with, should be tried in youth courts with permission for adult sanctions for older youths if certain conditions are met. The idea was to enable a mode of trial for young defendants that would be subject to safeguards that can enhance their understanding and participation.

Assessment of cognitive and emotional capacities should occur before any decisions on venue and mode of trial take place. It needs to be borne in mind that a distinction is made...
in criminal law between conditions that negate criminal liability and those that mitigate the punishment deserved (see chapter 8). Very young and mentally immature children, and the profoundly mentally ill, may lack the minimum capacity necessary to be criminally liable. Those exhibiting less profound impairments may meet the minimum conditions for some punishment but qualify for a lesser level. It should also be borne in mind that capacity is not a generic skill that a person either has or lacks; rather, it is specific to the issues in question and is multifaceted, with four key elements:

1. The capacity to understand information relevant to the specific decision at issue (understanding);
2. The capacity to appreciate one’s situation as the defendant when confronted with a specific legal decision (appreciation);
3. The capacity to think rationally about alternative courses of action (reasoning); and
4. The capacity to express a choice among alternatives (choice).

In addition to these facets, capacity is also situation-specific, and open to influence.

Evaluation of capacity should include assessment of all possibly relevant psychopathology, emotional understanding as well as cognitive level, the child’s experiences and appreciation of situations comparable to the one relevant to the crime and to the trial, and any particular features that may be pertinent to this individual in this particular set of circumstances (Barnum, 2000; Grasso, 1997). Particular attention needs to be paid to developmental background, emotional and cognitive maturity, trauma exposure and substance misuse. Appropriate sources for obtaining information relevant to assessment of a juvenile’s competence to stand trial will include a variety of historical records, a range of interviews, a variety of other observations and, in some cases, specialized tests. Records of the child’s school functioning, past clinical assessment, treatment history and previous legal involvements need to be obtained.

In coming to an overall formulation, there should be a particular focus on how both developmental and psychopathological features may be relevant to the forensic issues that have to be addressed. Potentially relevant problems include: inattention, depression, disorganization of thought processes that interfered with the ability to consider alternatives, hopelessness, such that the decision is felt not to matter, delusion or other fixed beliefs that distort understanding of options (or their likely outcomes), maturity of judgment and the developmental challenges of adolescence (Ashford, Chard, & Redhouse, 2006).

**Interventions for Particular Crimes and Groups**

**Juvenile Homicide**

Youths who have been prosecuted for murder or manslaughter are similar in background to other juvenile delinquents on points such as age, gender and ethnic background, but usually have more risk factors (Crespi & Rigazio-DiGili, 1996; Myers & Scott, 1998). However, there are differences – murder and manslaughter are more often committed alone rather than in a gang, and on average the perpetrators start their criminal activities at a later age and are much less likely to have previous convictions than other minors taken into judicial youth institutions. Nevertheless, there is great variety in terms of motives, victims and modus operandi – each case stands on its own.

The majority of young persons who have killed initially dissociate themselves from the reality of their act, but gradually experience a progression of reactions and feelings akin to a grief reaction. In these early stages, while the young person is still facing an adversarial and public trial process, they may move through processes of disbelief, denial, loss, grief and anger/blame.

Therapeutic work with juveniles who have killed needs to include an understanding of the role of violence and sadism in a young person’s life. The therapist has to understand the depth of the young person’s sensitivity and reaction to perceived threat, and how their past maladaptive behaviors may have allowed them to feel in control of their lives. There may be expression of considerable anger and distress in sessions as the young person comes to terms with their rage, and also when they are exploring feeling empathy for their victim and saying sorry for their actions and reattributing blame. PTSD arising from the participation in sadistic acts (either directly or observing the actions of co-defendants) has to be treated, as does any trauma arising from past personal emotional, physical or sexual abuse. Later, considerable work is likely to be needed to prepare the young person for the transition from long-term incarceration to re-entry into the community; preferably, this should be followed by extended aftercare (Heide, 1999).

**Sexually Abusive Behavior**

Sexually inappropriate behavior in children and adolescents constitutes a substantial health and social problem (Quinsey, Harris, Rice, & Cormier, 2006). Young abusers who have been charged come within the criminal justice system but should also be considered in their own right within the child protection framework (see chapter 32). Most, but not all, abusers are male, often come from disadvantaged backgrounds with a history of victimization, sexual and physical abuse (Bentovim & Williams, 1998; Skuse, Bentovim, Hodges et al., 1998) and show high rates of psychopathology (Hummel, Thomke, Oldenburger, & Specht, 2000; van Oost, Beckett, Bullens et al., 2006). Of particular concern are a significant subgroup with mild learning disability, for whom treatment programs have to be tailored to their level of development and cognitive ability. Most adult sexual abusers of children started their abuse when adolescents, yet neither ICD–10 nor DSM-IV has a diagnostic category for pedophilia in those under 16 years (see chapter 52). Langstrom, Grann, and Lindblad (2000) advocated the development of empirically based typologies for this offender group.

A structured, carefully planned multiagency approach is required when working with sexually aggressive younger chil-
Firesetting/Arson

Arson can have a devastating impact on the victim and more widely. Juvenile arsonists are not a homogeneous group, with a wide range of familial (Finein, 1980), social (Patterson, 1982), developmental, interpersonal (Vreeland & Lowin, 1980), clinical and “legal” needs. Kolko and Kazdin (1992) highlighted the importance of attraction to fire, heightened arousal, impulsivity and limited social competence. Compared with one-off firesetters, recidivists show more covert antisocial behavior, have greater interest in fire and fire-related activities, are more likely to be male and have poorer social skills and more family dysfunction (Kennedy, Vale, Khan, & McAnaney, 2006; MacKay, Henderson, Del Bove et al., 2006). In addition to the general assessment of antisocial behavior, the specific domains to be considered include: history of fireplay; history of hoax telephone calls; social context of firesetting (whether alone or with peers); where the fires were set; previous threats/targets; type of fire, single/multiple seats of fire setting; motivation (e.g., anger resolution, boredom, rejection, cry for help, thrill-seeking, fire-fighting, crime concealment, no motivation, curiosity and peer pressure).

As with other forms of serious antisocial behavior, no single standard treatment approach is appropriate for all individuals (Repo & Virkunen, 1997). For recidivistic firesetters, therapy may include psychotherapy to increase the understanding of the behavior, including antecedents defining the problem behavior and the environmental or intrapersonal triggers, and establishing the behavioral reinforcers. Skills training may help to promote adaptive coping mechanisms, and carers will need to be trained in how to supervise the adolescent closely. However, to date there have been no randomized controlled trials of treatments.

Female Delinquents

Any framework offering treatment for young offenders must consider appropriate provision for the special needs of young females who constitute an important minority of offenders (Bailey, 2000a; Miller, Trapani, Fejes-Mendoza, Eggleston, & Dwiggins, 1993; Zoccolillo, 1993). Whereas the overall level of offending is far lower in girls, in general similar risk factors operate (Gorman-Smith & Loeb, 2005; Moffitt, Caspi, Rutter, & Silva, 2001) although early physical aggression seems not to predict later delinquency in girls (Broidy, Nagin, Tremblay et al., 2003). As well as external risk factors, the thinking patterns of violent girls are similar to those of violent boys (Jasper, Smith, & Bailey, 1998; Lenssen, Doreleijers, Van Dijk, & Hartman, 2000). Longitudinal data demonstrate that girlhood aggression often contributes to a cascading set of negative outcomes as young women move into adolescence and adulthood. Young girls who engage in disruptive behavior and fight are at risk for several negative outcomes, including being rejected by peers and feeling alienated and unsupported in their relationships with peers and adults; struggling academically; affiliating with other peers prone to deviant behavior and with them becoming involved in more serious antisocial behaviors; choosing antisocial romantic partners, and hence initiating and receiving partner violence; becoming adolescent mothers who are less sensitive and responsive as parents, and who have children with increased physical and mental health problems. A downward spiral can ensue in those who are sufficiently antisocial and violent; for example, if they are incarcerated, opportunities for stable employment and relationships may be much diminished. If they are also mothers they may lose custody of their children.

In treatment, while similar general principles should be applied as for boys, specific consideration should be given to sexual and reproductive health— including education,
CHAPTER 68

contraceptive advice, information about help for sexually transmitted diseases, appropriate support for problems around menstruation, and support and access to relevant resources in the event of a pregnancy. For those who have been abused, when the adolescent female is ready to engage in it, post-abuse counseling from an appropriate adult should take into account the gender of the therapist. Where there is parasuicidal behavior, medical and psychiatric assessment should be followed by appropriate treatment, remembering that the distraction and attention provided by the emergency may be an important component in reinforcing the use of this behavior as a coping strategy. Recognizing that eating problems are far more common in girls is important. Girls seem to respond as well as boys to evidence-based treatments. The trial of Multidimensional Treatment Foster Care (MTFC) by Leve, Chamberlain, and Reid (2005) randomized 81 girls to MTFC or usual care and found 1 year later that those in the experimental group had fewer days locked up and 42% fewer criminal referrals, a similar success rate to that in boys.

Early identification of girls at risk is an important step for prevention and intervention programs but can get overlooked given the low base rates of girls engaging in physical aggression and violence. As well as the usual risk factors, high-risk groups of girls to consider for early intervention include those girls who are temperamentally overactive as well as antisocial as toddlers and preschoolers (fewer than boys) and those who have early pubertal development.

Interventions for Offending Behavior

A large number of different treatments have been used to try to reduce antisocial and offending behavior. These include psychotherapy, pharmacotherapy, school interventions, residential programs and social treatments. A decade and a half ago, Kazdin (1993) documented over 230 psychotherapies that were available, the great majority of which had not been systematically studied. In this review, focus is on treatments with a testable scientific basis and which have been evaluated in randomized trials (Sukhodolsky & Ruchkin, 2006) and applied to populations of young offenders. This section is concerned with the treatment of youth who offend, whether or not they have been formally apprehended by the criminal justice system. There is increasing interest in using community-based interventions for young offenders, because incarceration on its own is barely effective in the longer term, and for intervention to be effective, the young person has to learn not to offend once released back into the home environment. Prevention is considered to be more effective, the young person has to learn not to offend once released back into the home environment. Prevention is covered in chapter 61, and treatment of younger children with CD is covered in chapter 35.

Rational Targets for Intervention Derived From Longitudinal and Causal Research

There is an abundance of research describing risk and protective factors influencing delinquency (Loeber, Pardini, Homish et al., 2005; Rutter, Giller, & Hagell, 1998), so a rational starting point when considering intervention is to consider the main causal factors and processes, and then design interventions around them. However, in practice many other considerations have shaped interventions, from the desire to punish offending youths, to making use of what is currently available at relatively low cost. These different motives may conflict with what is effective for the young person and what works in reducing the damage they cause to society. One of the best examples of this is shock incarceration in military style boot camps, which, although recommended in the 1990s by the US Office of Juvenile Justice and Delinquency Prevention, and satisfying the desire for retribution and somewhat lower running costs, have repeatedly proven at best ineffective, and often positively harmful (see p. 1119; Benda, 2005). We now turn to consider factors that may be modifiable.

Factors Within the Young Person

On their own, temperamental and personality factors with high heritability and little malleability would seem poor candidates for intervention (e.g., being male or having a low IQ). However, even when this is the case, treatability is not ruled out. Thus, part of the effect of being male on delinquency is associating with more violent peers, which is potentially treatable; low IQ has many effects such as poorer understanding of social situations, lower empathy (Jolliffe & Farrington, 2004) and lower academic attainments, which in turn affect, for example, propensity to violence and employability. Social skills training and remedial education may moderate some of the impact of low IQ. There are other individual risk factors for which there is good evidence of modifiability; for example, hyperactivity and inattention are eminently treatable (see chapter 34), and hostile attributional styles can be changed (see chapter 63). Even psychopathic traits can be improved through treatment (Hawes & Dadds, 2007).

Factors in the Environment

Family factors have repeatedly been associated with delinquency (see chapter 25). Parenting styles are characterized by low warmth and involvement, high hostility, inept discipline and poor supervision (Stouthamer-Loeb, Loeb, Wei, Farrington, & Wikstrom, 2002), and these are not just reactive to irritating child behavior, but also have a causal role (Patterson, 2002; Snyder & Stoolmiller, 2002) and are modifiable (see chapter 64). More distal parental characteristics such as having a criminal record and being alcoholic may be impossible or hard to treat, but the mechanism through which they convey risk is likely to be partly through inherited temperament, and partly through parenting style and values (Rutter & Quinton, 1987), which may be modifiable.

Beyond the family, peers have an important role through two mechanisms: peer rejection and deviant peer association (Gifford-Smith, Dodge, Dishion, & McCord, 2005). Again, both of these are potentially modifiable. A particularly harmful aspect of the latter is membership of a gang, although the evidence suggests that part of the poor prognosis accrues from gang members being worse than other antisocial youths before
they join, but nevertheless being in a gang promotes further antisocial acts (Gatti, Tremblay, Vitaro, & McDuff, 2005). The neighborhood a youth lives in can exacerbate delinquent tendencies, with low ties to the neighborhood, poor social control of irregular behavior and exposure to risky activities such as drug-taking (Sampson, Morenoff, & Gannon-Rowley, 2002). Whereas community-wide interventions to improve neighborhoods are beyond the scope of this chapter, they are mentioned because they are a potentially modifiable risk factor.

Implications for Treatment of Mechanisms Through Which Risk Factors are Postulated to Work

Social learning theory proponents (Patterson, 1982) suggest that the immediate proximal environment is crucial in engendering antisocial behavior, with the contingencies provided by parents, and then later peers, shaping delinquency. By ignoring prosocial overtures, and inadvertently rewarding aggression (e.g., by giving in to threats or tantrums), parents and peers reinforce deviant behavior. This has formed the basis of parenting programs for antisocial behavior (see chapter 64) that try to change these contingencies; some peer-relationship programs also take this approach (Frankel & Myatt, 2003). Other processes implicated by social learning theorists are imitation and identification (Bandura, 2004), although interventions addressing these mechanisms are not well developed. Parenting also involves the transmission of values, and some treatment approaches specifically address these (e.g., attempting to dissuade parents from believing in the effectiveness of excessive corporal punishment).

Within the individual at a psychological level, different theories lead to different intervention approaches. Thus, cognitive theory has led to cognitive therapies that concentrate on the way the youth perceives threats and cues; whereas if the causal theory postulates that the fundamental problem is one of emotional over-reactivity, then teaching youth to become more aware of their own emotions and develop strategies to control these may be tried, as in anger-management programs. Likewise, where a deficit in empathy has been postulated, “restorative justice” programs have attempted to reduce recidivism by confronting perpetrators with their victims, so they have sympathy for what they have done. Each of these treatment approaches is discussed below.

Within the individual at a biological level, rather few findings on mechanisms have led to treatment approaches so far. Low autonomic reactivity (as seen in resting and reactive pulse rates) has not led to any well-validated drug treatment, and no neurotransmitter abnormalities have been identified, so the use of neuroleptics is not based on solid etiological theory.

At a simple level, risk factors appear to operate in a cumulative fashion that is not simply additive, so that increasing numbers of risk factors appear to confer disproportionately higher risk. The Minnesota group (Appleyard, Egeland, van Dulmen, & Stroufe, 2005) recently reconfirmed Rutter’s (1979) findings that multiple risks had a disproportionally harmful association with poor outcomes and, taking a cluster analytic approach, Stattin and Magnusson (1996) found that antisocial behavior alone did not carry substantial risks unless accompanied by several other risk factors. A clinical implication of this would be that to get a reasonable effect, several risk factors need to be tackled or, alternatively, tackling only one is unlikely to lead to much change. At a rather more sophisticated level, risk factors also do not co-occur randomly. Moving a child experiencing harsh parenting to a different family with parents who are calm, could reduce his or her experience of hostility. However, impulsive children evoke harsher, more critical parenting than controls (Schachar, Taylor, Wieselberg, Thorley, & Rutter, 1987), so this mechanism needs to be borne in mind when planning interventions. Even if there is placement within a foster family, the new parents may need training in techniques of delivering calm discipline. Finally, there may be active selection of environments, so that an impulsive youth might, for example, positively seek out peers and neighborhoods where drugs are sold. Understanding these mechanisms has practical implications, because simply removing a youth from a high-risk neighborhood in the hope that he or she will not get into trouble will not help if the child actively seeks the troublespots.

Beyond this, interactions between environmental and constitutional factors may play a part, rather than risk factors operating in a linear fashion. Thus, the MAOA gene confers an increased risk of antisocial behavior only in the presence of adverse parenting (Kim-Cohen, Caspi, Taylor et al., 2006), and adoption studies indicate that whereas having biological parents who are criminal or alcoholic raises the risk of delinquency two- or three-fold, the odds increase to four to five times if the adoptive parents are also criminal or alcoholic (Bohman, 1996). The implication then is that children who are constitutionally at risk may be more susceptible to adverse environments. A therapeutic sequel of this is the potentially optimistic point that if the environment can be substantially changed, youths with greater constitutional risk factors may show the greatest improvements.

Intervention is not solely the removal of risk, but also the enhancement of protective factors. Simply conceived, a protective factor may only be the positive end of a risk factor. However, in clinical intervention terms, conceptualizing a factor as protective can lead to a different approach from directly reducing risk factors for antisocial behavior. This could take the form of encouraging parents to build a positive relationship for the young person outside the home, or helping the youth find an activity or hobby in which they can take pride and develop self-esteem. Longitudinal studies suggest that protective factors may be especially important in high-risk individuals. Stattin, Romelsjo, and Stenbacka (1997) found that having physical, emotional, social and cognitive personal resources at age 18 was associated with far lower later conviction rates in high-risk individuals, but made little difference in low-risk cases. Other experiences along the life path found to be protective in the follow-up of delinquents to age 70 by Laub and Sampson (2003) included marriage and military service; in both cases it seemed the changes in practical external circumstances and contingencies were the
crucial change agent, rather than any shift in internal motivation or intention. Although not immediately relevant for the treatment of delinquents, perhaps a learning point is that it can be effective to change the context and contingencies around these youths.

Given these theoretical considerations, treatment is more likely to be effective if it alters several risk variables for the youth. It follows that, ideally, these risk mechanisms should be measured during treatment to see if they alter. In the past, therapy has often been carried out with only one approach, for several months, and then progress in achieving the end goal (e.g., offending) has been reviewed. It would be preferable to measure progress regularly (say, weekly or monthly) and include risk mechanisms such as quality of parental monitoring and school attendance so that the proximal mechanisms as well as end targets of treatment can be monitored. Then, if there is no change in the youth offending, it would be possible to see whether this was because the mechanisms had been changed and the youth failed to respond, or whether no change in mechanism had occurred. For example, hostile cognitions or negative parenting or teacher rewards could be monitored. If they do not change, they can be addressed and more therapeutic effort directed at them; if they do change, but the youth is not changing, then other barriers to improvement can be explored and a different formulation made. A number of the interventions described below do this more or less formally.

**Interventions in Practice**

**Political and Social Context**

The major challenge of altering the trajectories of persistent young offenders has to be met in the context of satisfying public demands for retribution, together with welfare and civil liberties considerations. Treatment of delinquents in institutional settings has to meet the sometimes contradictory needs to control young people, to remove their liberty and to maintain good order in the institution, at the same time as offering education and training to foster future prosocial participation in society and meeting their welfare needs. In England and Wales, over 3000 juveniles aged 13–18 are locked up at any one time, out of a total population of around 3.5 million, a rate approaching 1 in 1000 overall but around 1 in 300 late teenage boys. In 1998, the Crime and Disorder Act led to an overhaul of youth justice systems, mandating practitioners to improve community treatments and so fill the gap before and after institutional detention by involving families in the use of new Youth Offending Teams (YOTs). The use of empirically validated interventions by YOTs is gradually increasing but still has a long way to go. As well as leading to better provision of community treatment, the 1998 Act introduced instruments to enable magistrates to make control orders for lower level disruptive behavior in the community, called Antisocial Behaviour Orders (ASBOs).

**Prevention**

Prevention is discussed more fully in chapter 60. This chapter does not discuss crime prevention, which is a wide subject. However, it is worth noting that as well as prevention being aimed at individual propensities, environmental factors can also be altered. For example, target hardening refers to the strengthening of the security of premises with a view to minimizing the risk of attack. Such deterrence aims to reduce the opportunity for the juvenile to steal from or vandalize the premises. Examples include fitting grilles over windows, installing cables on computers or fitting stronger locks on doors. Evaluations show that these simple measures can be relatively cost-effective (Bowers, Johnson, & Hirshfield, 2004).

**Need for Assessment**

Because multiple factors affect antisocial behavior, and each case is different, giving the same treatment to all cases would seem likely to be less effective, although there do not seem to be studies comparing “one size fits all” interventions with those in which a thorough assessment has been conducted. Nonetheless, it seems logical to know which youths have a low IQ or a high one, particular skills to build on, comorbid depression or hyperactivity, parents needing treatment for alcoholism before they can set limits, and so on. In contrast, if the family is taking all steps to manage their adolescent well, then an approach based on family management might not be very effective.

**Overviews of Intervention Effectiveness**

Belief in the effectiveness of treatments for offending behavior has oscillated between modest hope and downright pessimism. In the 1950s and 1960s, practitioners and scholars were optimistic about interventions. However, in 1974, Martinson reviewed the literature of the time and concluded “nothing works.” The early controlled studies later in the 1970s were more optimistic (Gendreau & Ross, 1979). The first meta-analysis of outcomes in residential or community settings was of studies between 1960 and 1983 in the USA. It found that psychoanalytically oriented residential treatment had an effect size of 0.01 on recidivism, behavioral approaches 0.18 and educational approaches 0.28 (Garrett, 1985); by 1990 it was possible to conclude “Some things work in some settings with some people” (Izzo & Ross, 1990). Lipsey and Wilson (1998) in their classic meta-analysis included nearly 400 programs with around 40,000 juveniles. The effect size for institutionalized offenders was 0.10, and 0.14 for non-residential or non-institutional (community) settings. Behavioral programs and those training interpersonal skills produced the highest effects, whereas group counseling, milieu therapy and programs focusing only on employment produced little or no effect.

An updated meta-analysis by Wilson, Lipsey, and Soydan (2003) concluded that the programs were equally effective for those from ethnic minorities as for White people. Lösel and Köferl (1989) carried out the first meta-analysis of studies outside the USA, focusing on 16 studies of sociotherapeutic prisons in Germany with around 3500 juvenile offenders. The aim of these is social training and encouragement of contacts in the outside world with preparation for release. Compared with normal prisons, the mean effect size was 0.21. Dowden
and Andrews (2000) included US and Canadian studies published after 1990 in their meta-analysis. Although the overall effect size was 0.09, effects were greater for high-risk (0.12) than for low-risk offenders (0.03); programs targeted at personal needs (e.g., academic achievement, enhancing self-esteem, supervision, affection from family members) were more effective (0.22) than those that were not (~0.01); those with behavioral methods (e.g., role play, modeling) had larger effects (0.24) than those that did not (0.04). An overview of meta-analyses is provided by Grietens and Hellinckx (2004), and in 2001 the Campbell Collaboration Crime and Justice Group was set up to make available reviews of criminological interventions (Farrington, 2001). Further work is needed using stricter inclusion criteria, because there is evidence that if one only includes the highest methodological quality, effect sizes reduce, sometimes to zero (Dowden & Andrews, 2003; Latimer, 2001).

What principles should guide interventions? Over a decade ago, McGuire and Priestley (1995) identified six principles for effective programs which still hold:

1. The intensity should match the extent of the risk posed by the offender;
2. There should be a focus on active collaboration, which is not too didactic or unstructured;
3. There should be close integration with the community from which the offender came;
4. There should be an emphasis on behavioral or cognitive approaches;
5. The program should be delivered with high quality and the staff should be trained adequately and monitored; and
6. There should be a focus on the proximal causes of offending behavior rather than distal causes.

In other words, the program should focus on peer groups, promoting current family communication, and enhancing self-management and problem-solving skills. There should not be a focus on early childhood or other distal causes of delinquency.

All of the reviews suggest that there are a number of promising targets for treatment programs, which include antisocial thoughts, antisocial peer associations, promotion of family communication and affection, promotion of family supervision, identification of positive role models, improving problem-solving skills, reducing chemical dependencies, provision of adequate living conditions and helping the young offender to identify high-risk situations for antisocial behaviors. Conversely, the systematic reviews have also suggested a number of approaches that are unlikely to be promising. For instance, improving self-esteem without reducing antisocial cognitions is unlikely to be of value. Similarly, it is unlikely that a focus on emotional symptoms that is not clearly linked to criminal conduct will be of great benefit.

Psychological Interventions with Individual Youths

On theoretical grounds, working with youths to control anger and promote more sociable interactions would seem a plausible approach. There are a number of programs, broadly based on cognitive–behavioral principles. Elements include:

1. Attributional retraining;
2. Anger management;
3. Social problem-solving;
4. Social skills training; and
5. Helping the youth set targets for desirable behavior and negotiate rewards for achieving them.

While each of these elements can be separated out, most modern programs incorporate a number of these themes blended together.

Attributional retraining helps correct the cognitive distortions identified by Dodge (1993) whereby the youths tend to perceive threat and hostile intent even in neutral scenarios; work is done to help understand others’ points of view. The anger management aspect usually lasts several sessions and provides techniques to slow down instant angry arousal. Techniques include coping self-talk, distraction and relaxation; plenty of in vivo practice is needed because otherwise what is learned as a good idea in the clinic often does not generalize to the more emotionally arousing scenarios on the street (Kazdin, Siegel, & Bass, 1992). Social problem-solving programs follow classic lines:

1. Defining the problem;
2. Analyzing the intentions of the other party;
3. Generating a range of solutions;
4. Evaluating them;
5. Selecting the best and putting it into action; and
6. Reviewing how well it worked (see chapter 63 for further details).

The social skills element involves lots of practice in role plays and in real life, whereby the youth practices conversations, asking teachers for guidance, expressing disappointment, declining drugs without getting angry, and so on. The target setting is usually agreed in negotiation with teachers or parents, and involves starting with small achievable goals with strong immediate rewards to promote success.

Two of the best validated programs of the type described above are Problem Solving Skills Training (PSST), which lasts 22 weeks (Kazdin, Siegel, & Bass, 1992) and the Coping Power (CP) program, which lasts 18 weeks (Lochman & Wells, 2004). PSST was found to be effective in a randomized controlled trial with in-patients with severe conduct problems (Kazdin, Siegel, & Bass, 1992), but now needs independent replication. CP has been shown to have effects that lasted both at home and in school at 1-year follow-up (Lochman & Wells, 2004); independent replications in Holland and Germany are under way. More generally, a meta-analysis of randomized controlled trials of social skills training confirmed its usefulness, although studies with larger samples led to smaller effect sizes (Lösel & Beelman, 2003). Likewise, a meta-analysis of CBT with offenders found that it worked, and better effects were obtained for higher-risk offenders, higher-quality treatment implementation and a CBT program that included anger control and interpersonal problem-solving but not victim impact or behavior modification components (Landenburger & Lipsey, 2005).

More directly within the justice system, individual offenders
have had to take part in victim–offender mediation sessions, so-called “restorative justice” (Latimer, Dowden, & Muise, 2005). A meta-analysis of 15 studies concluded the approach was effective, with a rate of re-offending 70% of that of controls (Nugent, Williams, & Umbreit, 2004). Similarly, a meta-analysis of “reasoning and rehabilitation” programs by Tong and Farrington (2006) concluded that these reduced offending by 14%.

**Special Education**

Approaches to special education are covered in chapter 74. Here we simply note that because of the high rates of poor literacy and educational attainments in offenders, this is a crucial component of interventions. If formerly offending youths are expected to conform to societal norms and become employed and work within the system, then they need sufficient educational attainments and work skills to succeed in getting and holding down jobs. Without these, it is far harder even for well-motivated youths to avoid the apparently quick rewards crime appears to offer them (Hawkins, Herrenkohl, Farrington et al., 1998).

**Family-Based Interventions**

These typically attempt to alter the structure and functioning of the family unit, being based on systemic family therapy theories (see chapter 65). The best known in the context of delinquency is Functional Family Therapy (FFT), brought into being in 1969 by James Alexander and colleagues. It is designed to be practicable and relatively inexpensive: 8–12 1-h sessions are given in the family home to overcome attendance problems common in this client group; for more intractable cases, 26–30 h are offered, usually over 3 months. The target age range is 11–18 years. One of the attractive aspects of FFT is that it has evolved and changed over four decades. Thus, there is now a standardized assessment, including separate family and therapist perspectives on the issues, which the therapist monitors and updates regularly. Following assessment, there are four phases to treatment. The first two are the engagement and motivation phases. Here the therapist works hard to enhance the perception that change is possible, and to minimize perceptions that might signify insensitivity or inappropriateness (e.g., poor program image, difficult to access, insensitive referral). The aim is to keep the family in treatment, and then to move on to find what precisely the family wants. Techniques include reframing, whereby positive attributes are enhanced (e.g., a youth who offends a lot but does not get caught is labeled as bright), and the emotional motivation is brought out (e.g., a mother who continually nags may be labeled as caring, upset and hurt).

Families are encouraged to see themselves as doing the best they can under the circumstances. Problem-solving and behavior change are not commenced until motivation is enhanced, negativity decreased and a positive alliance established. Explicit attempts are made to reduce negative spirals in family interactions, by interrupting and diverting the flow of negative blaming speeches. Reframes do not belittle the impact of the negative behavior, but each family member should feel at the end of these two initial stages that:

1. They are not inherently bad, it is the way they have done things that has not worked;
2. Even though they have made mistakes, the therapist “sided” with them as much as with everybody else;
3. Even though they experience the problems differently, each family member must contribute to the solution;
4. Even though they may have a lot to change, the therapist will work hard to protect them and everyone else in the family; and
5. They want to come back to the next session because it finally seems that things might get better.

The third phase of FFT targets behavior change. There are two main elements to this: communication training and parent training. The success of this stage is dependent on the first two having been achieved, and is not commenced unless they have been (this differs from some programs where a predetermined number of sessions is allocated to each topic irrespective of the rate of family progress). This stage is applied flexibly according to family needs. Thus, if there are two parents who continually argue and this is impinging on the adolescent, the “marital subsystem” will be addressed, using standard techniques. These include using the first person voice rather than the second (instead of “you are a lazy slob,” “I find it upsets me when you leave your socks on the floor”), being direct (instead of complaining to partner “he never . . . ,” say it directly to the youth), brevity instead of long speeches, behavioral specificity about what is desired, offering alternatives to the young person and active listening. Parent training techniques are similar to those found in standard approaches, and include praise, rewards (called contracting in FFT; e.g., “If you come home by 6pm each night, I will take you to the cinema on Saturday”), limit setting, consequences and response-cost (e.g., losing TV time for swearing; for more details of these techniques see chapter 64).

The fourth and final phase of FFT is generalization. Here, the goal is to get the improvements made in a few specific situations to generalize to other similar family situations; to help the youth and family negotiate positively with community agencies such as school, and help them get the resources they need. Sometimes, this latter goal may require the therapist to be a case manager for the family. To do this therefore requires that the therapist knows the community agencies and how the system works, and be prepared to spend time engaging it – these characteristics are specified in the model. This is a very different approach from traditional therapies in which the therapist stays neutral with regard to outside agencies.

Beyond specifying the intervention, FFT has a formal schedule for training professionals, which over and above the initial 3 days, requires three 2-day follow-up visits in the ensuing year and supervision for 4 h per month with FFT supervisors for the first 2 years. There are four levels of worker: functional family therapist, FFT clinical team leader (who coordinates a site), FFT clinical supervisor (who takes clinical responsibility for therapists’ cases and provides individual and
group supervision) and FFT trainer, who is officially certified to run training. These personal training approaches to maintaining treatment fidelity are backed up by a tracking system of questionnaires filled in by the clients as well as the therapist. However, there is no insistence that supervision is by showing video or audio tapes of actual sessions, although the three on-site visits per year offer an opportunity for the developers to do this. The effectiveness of FFT is well established; there have been over 10 replication studies (Alexander, Pugh, Parsons, & Sexton, 2000), of which over half have been independent of the developers, and four are under way in Sweden. The trials published to date have all been positive, with typical recidivism rates being 20–30% lower than in controls.

Family programs can be delivered within school settings (e.g., as part of after-school programs). Thus, “Project Back-on-Track” included family therapy and diversionary projects for only 4 weeks (although for 4 days a week, giving 32 h contact time) and led to significant reductions in offenses 1 year later (Myers, Burton, Sanders et al., 2000).

Multiple Component Interventions
The example of Multisystemic Therapy (MST) is taken as it is one of the best developed treatments of this kind. MST was developed by Henggeler, Rowland, Randall et al. (1999) in the USA. There are nine treatment principles:

1. An assessment should be made to determine the fit between the problems and the wider environment: difficulties are understood as a reaction to a specific context, not seen as necessarily intrinsic deficits.

2. Therapeutic contacts emphasize the positive and use systemic strengths as levers for change. Already, the assessment will have identified strengths (e.g., being good at sports, getting on well with grandmother, the presence of prosocial peers in grandmother’s neighborhood), and the implementation of this principle means that each contact should acknowledge and work on these. The strengths may be in the young person (competencies and abilities), the parent (skills, friendliness, motivation), the family (practical resources such as nice house, affection between members, some good parenting practices, supportive friends locally, and so on), peers (any with prosocial activities or hobbies, with parents who monitor well), at the school (good classroom management, understanding of youth’s special needs, drama, music or sports facilities) and in the community (organized activities by voluntary or church organizations, parks, well-functioning social services departments, children’s centers). Each contact should reinforce these strengths and use a problem-solving approach to mobilize them.

3. Interventions are designed to promote responsible behavior and decrease irresponsible behavior. This principle is similar to other parenting programs, and is core: by increasing prosocial behavior and the amount of time during which it is carried out, then inevitably antisocial behavior is not being carried out. Eventually, the objective is more than the elimination of antisocial behavior, it is to help the youth become independent and to have prosocial life skills to make relationships, contribute effectively in work and so stay out of trouble and have a productive life. However, this goal is not just for the youth; parents too have their role in changing their practices and beliefs, which includes taking more responsibility for their youth’s behavior and making life changes to enable this to happen – which could include giving up a second job or helping with school work.

4. Interventions are focused in the present and are action oriented, and have specific well-defined goals. The approach is what can be done in the here and now, in contrast to some therapies which emphasize the need to understand the family’s and the youth’s past. By having clear targets, all family members are aware of the direction of treatment and the criteria that will be used to measure success. This also means that effectiveness can be monitored effectively and accurately, and there are clear treatment termination points when targets are met. In this respect MST is similar to behavioral and some other therapies, but differs from counseling and psychoanalytic approaches.

5. Interventions target sequences of behavior in multiple systems that maintain problems. This is an approach similar to systemic family therapy (see chapter 65), in that change is postulated to be mediated by interpersonal transactions rather than insight. What is different is that multiple arenas are explicitly assessed and, where appropriate, targeted (e.g., the youth’s peer group, extended family, school).

6. Interventions are developmentally appropriate. They should fit the life stage and personal level of the family members.

7. Interventions require daily or weekly effort by family members. This enables frequent practice of new skills and frequent positive feedback for efforts made; non-adherence to treatment agreements rapidly becomes apparent.

8. Intervention effectiveness is evaluated continuously from multiple perspectives, with the intervention team assuming responsibility for overcoming barriers to successful outcomes.

9. Interventions are designed to promote treatment generalization by empowering parents to address youth needs across multiple contexts.

Interestingly, the precise nature of the moment-to-moment content of intervention is not tightly prescribed, although in practice the greater part is not dissimilar to the approach used in behavioral family therapy. However, MST is not limited to work on psychosocial interactions; for example, when the program developers found that despite influencing the more distal risk factors for drug-taking, such as parental supervision and school attendance, drug use was not diminishing as much as they had hoped, they instituted daily urine tests and paid the young people if they were clear of drugs. What is noticeably different from many therapies is the explicit recognition of the multiple contexts in which difficulties may occur, and the need to influence these. In a sense, MST is a set of operating principles that draw on the evidence for whatever works (e.g., CBT, close monitoring of association with deviant peers, constructive teaching) rather than one specific therapy.

The way the therapy is delivered is closely controlled. Because of the weekly monitoring of progress, if there are barriers to improvement these should be rapidly addressed, and the
CHAPTER 68

hypotheses of what is going on in the family and systems around the youth should be revised in the light of progress. Clinicians only take on 4–6 cases because the work is intensive; there is close attention to quality control by weekly supervision along prescribed lines, and parents and youths fill in weekly questionnaires on whether they have been receiving therapy as planned. Therapy is given for 3 months and then stopped.

Given that MST makes good use of up-to-date evidence on the causes of antisocial behavior, and good use of effective treatment principles such as close measurement of effectiveness during treatment and close attention to implementation quality, one might hope that results would be encouraging. Indeed, the first raft of outcome studies by the program developers were positive. Thus, the meta-analysis of papers up to and including 2002 by authors that include one of the program developers, Charles Borduin, found that in seven outcome studies comparing MST with treatment as usual or an alternative with 708 youths by 35 therapists, the mean overall effective size across several domains was 0.55 (Curtis, Ronan, & Bourduin, 2004). Outcome domains ranged from offending (arrests, days in prison, self-reported criminality, self-reported drug use), where the mean effect size was 0.50, peer relations (ES 0.11), family relations (self-reported 0.57, observed 0.76), and individual youth and parent psychopathology symptoms (0.28). When these studies were subdivided into chronic offenders versus the remainder (youths who were abusing drugs, sex offenders and psychiatrically disturbed youths), no differences were found. However, the three studies using the developers’ own graduate students as therapists obtained noticeably larger effect sizes (mean 0.81) than when the developers were supervising local community therapists, where the mean effect size was 0.26. Long-term follow-up 14 years later (when the individuals’ mean age was 29 years) by the developers of one of the first trials, with 176 cases allocated to MST or usual individual therapy, gave recidivism rates of 50% versus 81%, respectively.

There have been at least 27 published reviews of MST (Littell, 2005), and the sorts of findings cited above have led MST to be cited as an effective evidence-based treatment by the US National Institute on Drug Abuse, the National Institute of Mental Health, the Office of Juvenile Justice and Delinquency Prevention, and others. However, in the process of evaluation, the next test of any therapy is its effectiveness when carried out by teams who have no financial or employment ties with the developers (although they may pay the developers for materials and supervision), with an independent evaluation team. The only independent evaluation was also the only one to see whether parenting practices continue to be strong after the intervention ceases, and whether this mediates relapse; or is it deviant peer association that leads to more offending? Some

rated, although here there was 40% missing data. Likewise, a totally independent trial by Timmons-Mitchell, Bender, Kishna, and Mitchell (2006) in the USA randomized 93 delinquents and also obtained substantial beneficial effects. The Canadian study (not published in a peer-reviewed journal but of high quality) was included in the Cochrane Library’s review of MST (2005), but the other two independent Norwegian and US studies were not. The Cochrane conclusion that “Evidence suggests that MST is not consistently more effective than other alternatives” is thus in our view unduly harsh; its general tone was very conservative, thus it also concluded that MST had no harmful effects and that nothing else was proven better than MST.

This conclusion is more cautious than the previously established view. A number of reasons are possible. First, the developers’ own studies did not do full intent-to-treat analyses, and may have been more favorable because some cases with worse outcomes (the dropouts) were excluded. Second, the degree of skill with which the intervention was delivered may have been higher in the developers’ sites. Evidence on treatment fidelity for MST is mixed—in the independent Ontario study, fidelity as rated on-site was unrelated to outcomes. Henggeler, Rowland, Randall et al. state that fidelity is crucial for effectiveness, and in their first paper on the subject they made 105 correlations between fidelity and outcomes, but only 11 were significant, with some being in the opposite direction to that predicted (i.e., better adherence leading to worse results). However, the same group (Huey, Henggeler, Brondino, & Pickrel, 2000) found that when they used a latent variable approach, therapist-rated fidelity improved family functioning and parent monitoring, both of which reduced youth delinquency, but that parent- and youth-rated fidelity had no effect. This rater effect could be because it requires a therapist to appreciate the complexity of fidelity, and also because therapists working across cases will be more consistent in their ratings than parents and youths, who may differ widely in their rating of the same phenomena. Third, the financial conflict of interest may have consciously or unconsciously led the developers to bias their results favorably. Henggeler and his associates direct and hold stock in MST Services Inc., which has the exclusive licensing agreement for MST. It serves around 10,000 families a year and total fees amount to around $500 per youth served (Littell, 2006). Fourth, the comparison treatment may have been different in Canada, where the justice system is perhaps better organized; however, the Cochrane reviewers (2005) point out that their conclusions would have been largely the same even without this study.

Given that MST is predicated on sound modern principles, why is it often hard to obtain consistently reliable effects? A further possibility is that 3 months of treatment is too short a duration. To disentangle possible explanations, we need good measures of mediators during treatment and, crucially, after the end of treatment. This would enable, for example, one to see whether parenting practices continue to be strong after the intervention ceases, and whether this mediates relapse; or is it deviant peer association that leads to more offending? Some
Interventions with Multiple Components that Put Youths into Foster Families

The best example of this approach is Multidimensional Treatment Foster Care (MTFC). It evolved at the Oregon Social Learning Center (OSLC), beginning in 1983 (Chamberlain, 2003), where parent training with families of delinquents proved extremely difficult, although reasonably effective (Bank, Marlowe, Reid, Patterson, & Weinrott, 1991), because of the inability of the family to cope with the extreme demands of having a delinquent youth. This led to the idea of placing them in a specially trained foster family. It has a number of similarities with MST: it is based on an interactive model, whereby the moment-to-moment interactions are seen as the key to change. However, it differs in that the regime in the foster home is based on the youth earning points from the moment they get up. They have to earn 100 points a day for privileges such as going to bed later, having time on the computer or extra time to phone friends. Points are awarded for day-to-day living and social skills, such as making the bed, being polite, getting to school on time. While at school points are awarded for good behavior in class.

Unlike some programs, in MTFC points are also taken away (e.g., for swearing or being unhelpful). Foster carers are carefully trained to take away points with the minimum of negative affect, and to quickly offer the young person the opportunity to make up points by doing a small chore. For the youth, the immediacy of experiencing a contingent response to their behavior is often a stark contrast to being left alone or having long coercive interchanges with their parents. In addition to close liaison with the school, close supervision is key—the young person loses a point a minute for all the time when they cannot verify their whereabouts, a sizeable fine. There is a relatively large team to carry out MTFC. The program supervisor oversees the case, and has a maximum caseload of 10. An individual therapist sees the youth once or twice a week, for problem-solving and to develop skills-based coaching of how to negotiate everyday situations—not for traditional psychotherapy. When the youth is in the community, there is a skills trainer, usually a young graduate, to help them negotiate prosocial activities and avoid dangerous situations.

MTFC lasts for around 6 months and then the young person returns to their birth family. However, crucial to the model is the birth family therapist who, while the youth is in the foster family, works with the birth family to inculcate the same regime. While the youth is in foster care, there is a weekly clinical meeting for all team members, and a weekly foster carer meeting attended by the program supervisor and other team members at which progress is discussed, support given to foster carers and the day-to-day management regime carefully adjusted. However, each youth’s progress is even more closely monitored, because every morning a team member calls the foster carer and goes through the Parent Daily Report, a simple 36-item checklist of antisocial behaviors requiring a yes/no answer. The clinical team plot progress graphically, so that any deterioration is quickly detected and remedial action put in place.

There have been two main trials completed with MTFC for delinquency: one in boys and one in girls, both by the program developers. With boys (n = 79), MTFC compared with group care led to a reduction in the number of arrests at 2-year follow-up (for two or more arrests, 5% versus 24%) and reduced self-reports of aggression and fighting (Eddy, Whaley, & Chamberlain, 2004). With girls at 1-year follow-up (n = 81), criminal referrals showed a trend (mean 0.76 referrals in MTFC, 1.3 for group care; P = 0.10), 22 versus 56 days locked up (P < 0.05) and a reduction on Child Behavior Checklist (CBCL) delinquency but none on Elliott delinquency. No report of CBCL aggression scales or other measures such as the Parent Daily Report (PDR) are given (Leve, Chamberlain, & Reid, 2005). Clearly, independent replications of MTFC are now needed, and are in progress. The model is being extended to younger children, and to less intensive forms.

Rather few intervention studies measure mediators of effectiveness, but the Oregon Social Learning Center (OSLC) staff did this for the male delinquency study (Eddy & Chamberlain, 2000). Three family process mediators and one relating to the youth’s peer group were found to be relevant. The three family mediators were harsh and inappropriate discipline, quality of the parent–youth relationship and supervision of the youth’s whereabouts; the peer dimension was association with deviant peers. When these variables were changed by treatment, then delinquency reduced. Here then is a model of how to measure mediators during treatment. Not only can these findings guide treatment targets, but they confirm important information about the causes and maintenance of antisocial behavior.

Interventions That Do Not Work

Harsh, military style, shock incarceration, so-called “boot camps” are still popular for young offenders in the USA, and were promoted by the Office of Juvenile Justice and Delinquency Prevention in 1992 when three pilot programs were set up. However, several reviews have concluded that they are ineffective (Benda, 2005; Cullen, Blevins, Trager, & Gendreau, 2005; Stinchcomb, 2005; Tyler, Darville, & Stalnaker, 2001), and a randomized controlled trial by the California Youth Authority that included long-term arrest data found no difference between boot camp and standard custody and parole (Bottcher & Ezell, 2005). In contrast, a meta-analysis of 28 studies of wilderness programs found an overall effect size of 0.18, with recidivism rates of 29% versus 37% for controls (Wilson & Lipsey, 2000). Programs with intense physical activity and a distinct therapeutic component were the most effective. Another approach is to attempt to frighten delinquents with visits to prisons in an attempt to deter them, as for example in the “Scared Straight” program. However,
of settings. However, Weiss, Caron, Ball et al. (2005) have led the group (Gifford-Smith, Dodge, Dishion, McCord, & Poulin, 1999; McCord, 1997). These lines of evidence have led the group (Gifford-Smith, Dodge, Dishion et al., 2003) to warn against “peer contagion” in a whole range of settings. However, Weiss, Caron, Ball et al. (2005) have questioned these findings and, in a fresh meta-analysis to address the question, found that in 17 of 18 studies group treatments for antisocial behavior did not support iatrogenic or deviancy training effects. In conclusion, it seems likely that unsupervised and prolonged contact with deviant peers is harmful, but well-supervised and well-supported contact during which youths are actively taught new skills can be effective.

Pharmacological Therapies

As for non-offenders, medication may be helpful in juvenile delinquents with diagnosed mental disorders for which it has been shown to be effective, such as schizophrenia, bipolar disorders, and ADHD (for details of appropriate treatment see the chapter covering the relevant disorder). The question arises whether medication has any role in the management of long-standing antisocial or aggressive behavior in offenders. Most authorities agree that, on present evidence, psychopharmacological treatments alone are unlikely to be an effective and acceptable treatment for behavioral problems in adolescents. However, in younger children with more unpredictable explosive aggression there has been a recent trend by some clinicians to prescribing a range of drugs, from mood stabilizers such as carbamazepine and lithium to newer antipsychotics such as risperidone; certainly reviews by employees of the drug manufacturers argue for their effectiveness and acceptability (Pandina, Aman, & Findling, 2006). However, the evidence for the effectiveness of these medications in straightforward antisocial behavior without comorbid diagnoses or intellectual disability over the medium to long term is minimal (for review see chapter 35); most trials to date have lasted under 2 months and have not been undertaken with teenage offenders (Pappadopulos, Woolston, Chait et al., 2006).

Conclusions

There is now a considerable body of knowledge about the causes of delinquency, how to assess the young people and what interventions are likely to be effective. Recent advances in genetics at a molecular and behavioral level have shown that certain genotypes predispose to antisocial behavior, but that it is likely that in many cases these interact with adverse environmental conditions to lead individuals towards antisocial and offending behavior. In future, genetic and longitudinal studies should further elucidate not only the mechanisms through which individuals embark on a pathway of crime, but also what is the crucial combination of influences leading to desistance in particular groups of cases. Person-centered analyses such as cluster analysis and its longitudinal variants should illuminate what is likely to be a heterogeneous picture, and take forward the majority of current findings, which have often lumped whole samples together when using multivariate statistics. Thus, the causal factors influencing a child born with callous-unemotional traits who is brought up in favorable circumstances may be very different from a child with hyperactive traits who is subjected to prolonged abuse and rejection. Studies will need to combine such an approach with consideration of wider societal influences such as the effects of valuing violence and criminal behavior that predominate in some youth subcultures.

It is to be hoped that treatments will be developed in tandem with increasing specificity according to the youth’s needs. For example, while at present psychopathic traits have the reputation of being associated with untreatable offending behavior, this needs to be tested out using treatments tailored to the psychopathology – thus, if these individuals are, as experimental studies suggest, punishment insensitive but reasonably responsive to rewards, then intensive reward programs need to be
devised and then subjected to trials. For the established treatments for general delinquency, again greater differentiation according to youth need is required, rather than a “one size fits all” approach. This should include trials where the intervention is given for reasonably long periods if necessary (say, 9–12 months) rather than for the more typical 3 months. While the studies envisaged above may lead to potential further improvements in outcomes for young offenders, there will be little improvement in their prospects unless high-quality services are implemented. To clarify what difference this could make, it would help to have trials of model forensic services. These would include preventive community services, thorough assessments of all apprehended youths and high-quality interventions based on the assessments. The issue of implementation quality is important, because with highly motivated and skilled teams, good effect sizes are repeatedly achieved with the better interventions. Such trials of model services would need thorough economic evaluations so that potential economic gains of good services could be clarified. Armed with the results of such trials, it might be easier to persuade policy-makers to invest in adequate services. In the meantime, there is a need for a change in culture at local and national governmental levels so that evidence-based interventions are demanded and their effectiveness regularly monitored. At present there are considerable opportunities in most countries to switch from currently used interventions to more effective ones without incurring extra expenditure. Finally, by way of prevention, we need further studies of how to better identify, screen and effectively intervene with young children at risk of antisocial behavior. If such studies are completed, and if (and only if) service improvements are made, there are grounds for definite optimism for the outlook for delinquent youths.

CHAPTER 68

The last decade has seen a rapid evolution in the structure and delivery of mental health services in many countries. The use of in-patient beds has generally declined in developed countries and there is an increasing interest in alternative models of intensive service delivery such as day provision or intensive outreach. In parallel, the context within which children’s mental health disorders are seen has progressively widened to encompass the context of family, school and wider community. The stage emphasis in personality and social development, which provided a rationale for intensive episodic interventions, has largely been replaced by a new appreciation of chronicity and long-term pathways in the evolution of many disorders (see chapter 13). Acute episodes of intensive treatment have therefore to be considered now in the wider contexts of family and local environment as well as in the longitudinal context of what is known about the natural history of particular disorders. This chapter reviews new developments in intensive mental health treatments for young people, the evidence base for intensive treatments in the light of these considerations and prospects for the future.

**In-patient Treatment**

**Historical Roots**

Two broad forms of residential mental health care for young people emerged in the early 20th century. The first was based on the idea that a self-contained environment could act as a “therapeutic milieu,” effecting personality and behavior change (Kennard, 1983). Examples in the UK were Homer Lane’s “Little Commonwealth” (Bazeley, 1928) and residential therapeutic schools such as the Mulberry Bush; in the USA, there was the work of Bettelheim (1955). The second historical root was the adaptations made for children within the asylums of the 19th century (Parry Jones, 1998) and the accelerated development of specialized medically based psychiatric units in the 1920s (Beskind, 1962). Such hospital units developed to provide a comprehensive approach to assessment and treatment based on a biopsychosocial model (Cameron, 1949). Here, the hospital environment was the location for assessment and treatment rather than its primary agent. The decades after World War II saw a rapid expansion of in-patient units, usually combining elements of both models. Recent decades have seen a plateauing or reduction in numbers of units and increasing specialization, alongside an awareness of the potential negative effects of residential treatment (Wolkind, 1974). However, the two historical themes remain a useful way of conceptualizing the in-patient treatment process.

**The Ward as a Therapeutic Milieu**

The “therapeutic milieu” is a term subject to numerous reinterpretations but little research (Green & Burke, 1998). Early psychodynamic formulations (Bettelheim, 1955) contained an assumption that the milieu substituted for a lack in the child’s previous experience – particularly, sensitive parental care. There was an emphasis on a closed environment and long treatments. Later, systemic models (Woolston, 1989) emphasized the ward as an “open system” mediating the “goodness of fit” between young person and their environment through collaboration with other agencies and the family; parents often taking an active part in the ward caregiving. Other models have emphasized the ward environment as a shorter-term “corrective emotional experience” with high levels of warm staff communication, peer contact and active behavioral control (Cotton, 1993). A few specialized developments have involved admitting whole families (Lynch, Steinberg, & Ounsted, 1975); these then can have some convergent roles with mother and baby units. Five-day residential patterns have become common (Green & Jacobs, 1998). Recent developments – notably driven by managed care in the USA (Nurcombe, 1989) – have in contrast reduced the ward environment to its most minimal form. The emphasis here is on symptom stabilization and “minimum necessary change” before rapid discharge. Stays are often under 2 weeks; a radically different form of milieu from the 3-year or more stays described by earlier writers. In this recent model, the “therapeutic milieu” as historically understood has essentially disappeared and in-patient care has returned to its root in acute hospital practice.
INTENSIVE TREATMENT

Social Functioning and Education

By the time of admission, a young person’s social adaptation in their community has often broken down, sometimes in all areas of school, family and community life. Widespread social difficulties were found in 58 consecutive general admissions in New Zealand, including a moderate to severe language handicap in 40% of cases (Paterson, Bauer, McDonald, & McDermott, 1997). In the USA, Luthar, Woolston, Sparrow, and Zimmerman (1995) similarly found severe impairments on Vineland social competency scores in 126 patients admitted with disruptive and mixed emotional-disruptive disorders. Social competency was associated with specific reading scores rather than broad intelligence quotient. These findings have practical implications. The traditional therapeutic milieu contains elements of group living, peer relationships and intensive staff–patient contact. Removal from social difficulties in the external environment and exposure to such a milieu can produce rapid gains in functioning and self-esteem. Nevertheless, young people with significant social impairments may not be able to make effective use of such a socially orientated therapeutic environment. Assessing and targeting social difficulties more precisely and defining the effective milieu char-
such decision-making will be the empirical evidence regarding the effectiveness of in-patient treatments in particular situations and for particular disorders (see pp. 1132-1133). Whereas the in-patient resource is rightly held in reserve for the most complex and severe cases, referral should not be over-delayed: a well-timed intensive treatment may often prevent further deterioration in an acute disorder.

Admissions generally fall into a number of broad categories:

1. The need for detailed assessment in complex cases where the formulation is unclear. The combination of the medical setting with the range of health professionals makes the ward particularly well able to address the interaction of biological, psychological and social aspects of disorders.
2. Assessment or treatment away from the family. This can be crucial when the role of family in a presentation may be unclear — for instance, in possible factitious presentations (see chapter 57), or when complex symptoms seem confined to home.
3. When psychiatric symptomatology is escalating despite the most intensive out-patient treatment available. This includes acute risk management of self-harm or family disruption associated with psychiatric disorder.
4. For controlled trials of specific interventions.

Pre-admission evaluation is a crucial area. The admission must be seen within the context of a continuum of service use and the developmental trajectory of the child, because it will be a brief episode in both these areas. Many of the key predictors of in-patient outcome lie in details of previous family adaptation, child social functioning and child symptomatology (see p. 1132); assessment should thus focus on these aspects as well as the needs and motivation of patient and family. Pre-admission evaluation may lead to a decision not to admit. For instance, many children with social and behavioral difficulties may be more appropriately cared for within the social care system with psychiatric input.

Emergency Admission
Studies of referrer attitudes emphasize the high priority given to the specialist unit’s responsiveness and capacity to admit emergencies (Gowers & Kushlick, 1992; Worrall & O’Herlihy, 2001). This is particularly the case in situations of acute risk management. Responsive consultation around the emergency may meet referrer needs without admission (Cotgrove, 1997). However, provision of emergency beds is likely to be an increasing priority and will shape service provision. Street (2000) found that even with a clear agreement between referrer, admitting in-patient unit and family, the time taken to actually acquire a UK child and adolescent mental health services (CAMHS) bed from time of acute referral averaged 3 days. Where facilities are not immediately available, young people may have to be temporarily cared for in inappropriate environments such as pediatric wards, adult psychiatric wards or out-of-district facilities (Street, 2000).

Discharge and Aftercare
Discharge planning should receive equal attention to admission planning. Many studies point to the crucial role of aftercare in the maintenance of treatment gains made during admission (Pfeiffer & Srzelecki, 1990). In a minority of cases, admission may prove to be a stepping stone towards longer-term alternative care or residential schooling. Because of the multifaceted nature of in-patient problems, the team liaises with a wide variety of local services in education, social services and mental health. A “care program approach” may be used along lines developed in adult mental health as an aid to transition into adult services. Hoagwood, Jensen, Wigal et al. (2000) showed that a limited period of intensive specialist treatment resulted in a more effective use of other services thereafter; this may explain some “sleeper” effects in outcome. There is evidence (Green, Jacobs, Beecham et al., 2007) that in-patient treatment can have a similar effect, but provision of post-discharge services is vital, and the same study showed that in the majority of cases the discharge plan recommendations were not carried out.

Potential Unwanted Effects
Theoretically, unwanted effects could derive from:

1. Loss of support from the child’s local environment;
2. Presence of adverse effects within the in-patient environment; and
3. The effects of admission on family life (Green & Jones, 1998).

However, there is no convincing research into their prevalence.

Losses Consequent on Admission
Reporting bias towards acute problems during pre-admission assessment could obscure hidden sources of support and resilience in the local environment — within the extended family, peers or school. Pre-admission assessment should therefore actively focus on strengths as well as difficulties and identify key areas of individual resilience. Admission may also result in the loss of important local professional input, which should be ameliorated by good communication between unit, referring teams and local services. These factors need particular attention from in-patient clinicians because they may be less obvious than active effects from within the in-patient environment itself.

Impact of the In-patient Environment
Some young people may enter the ward with a profound sense of relief but others may find it at least initially frightening or bewildering. Patient ratings after in-patient psychiatric care (usually collected by the units themselves) generally show positive evaluation of the treatment. However, parents are often concerned that their child may be negatively affected (“contaminated”) by other patients’ problems. There is additionally the stigma that is often attached to the prospect of in-patient psychiatric treatment. Units must be constantly vigilant to the possibility of the negative impact of peers on each other, the pooling of problems or abuse. To counter such potential problems, Newbold and Jones (1998) suggested a proactive emphasis on child welfare and rights, embodied in the appointment of a “welfare co-ordinator,” with a role to investigate any complaints. This is done in the context of
procedural agreements with local child protection agencies and a continuing program of awareness training and education of staff.

There have been no specific studies into institutionalization in child or adolescent psychiatry units. Well-publicized episodes of abuse in residential social care environments (Levy & Kahan, 1991) may be unreasonably generalized into attitudes towards residential psychiatry treatments by families, although the intensity of monitoring and supervision in the latter hopefully makes such disasters less likely.

**Effect on Families**

Some professional concern has focused on the effect of admission on family dynamics, for instance the reinforcement of “scapegoating.” This may indeed be a contraindication to admission, although equally a scapegoated child has a right to the best possible assessment and care – and this may involve admission. As the child engages with the ward there can also be a danger that the parents feel deskilled (Green, 1994). Good family contracting pre-admission and sustained family work can counteract these negative effects. A family’s commitment to intensive treatments can be disruptive and expensive. In a study of eight UK units, Green, Jacobs, Beecham et al. (2007) found that family borne costs averaged £2400 per admission, a good proportion of the average annual wage. It is essential to anticipate this by building support for family travel into the contracting around the case and actively to support the family in relation to employers.

However, there is a need for systematic study of unwanted effects rather than reliance on theoretical concerns or anecdote. Along with general standards of good practice, systematic procedures of anticipation, prevention, recognition and repair should minimize unwanted effects (Green & Jones, 1998).

**Day Units**

The concept of psychiatric day care developed in the USA in the 1940s with the therapeutic nursery school for very young children (Zimet & Farley, 1985). Relieved of the need to provide residential aspects of care, day unit environments have been able to evolve in a host of different directions. These have ranged from specific day programs for young children with developmental problems, as an adjunct to specialist school provision, to intensive 5 day a week treatment interventions with whole families. The range is now too great to summarize neatly and this is a difficulty in appraising the effectiveness of day units from published literature. Day hospital units are often associated with in-patient units in the UK (Green & Jacobs, 1998), Germany and Switzerland. In Finland, there is a high number of in-patient beds but only 8% of these units offered a day program (Ellila, Sourander, Valimaki, & Piha, 2005). Integrated in-patient and day units can share programming, staff and infrastructure; the advantages of independent day units relate to flexibility. The reduced need for a shift system to cover nights allows ward staff to work predictable hours and be available regularly for liaison sessions and outreach work. Partial attendance also means that staff can have days free for supervision and continuing education. Flexibility of in-patient, day and outreach is emerging as a priority; Street (2004) highlighted the need for more CAMHS to be able to offer outreach and/or day care before and after admission.

Amid the variety of day unit functioning, a number of broad themes may be distinguished:

1. **Day units for the treatment of disruptive behavior.** A number of programs have been developed, usually using multimodal treatment packages with a combination of individual family and liaison intervention alongside psychopharmacology. Grizenko (1997) and Rey, Denshire, Wever, and Apollonov (1998) reported the outcome of such programs.

2. **Units have specialized in the management of younger children with developmental disorders such as autism, speech and language disorders or attention deficit/hyperactivity disorder (ADHD).** These provide centers for comprehensive assessment and initiation of treatment management involving family and school liaison.

3. **Units whose prime aim is to influence family functioning in situations of family breakdown or child maltreatment.** A number of influential programs of this kind have been described (Asen, Stein, Stevens et al., 1982).

The partial milieu of the day unit shares care with family or local school to a greater extent than residential units. Thus, liaison takes up correspondingly more time and contact with parents may be more frequent. The day unit has the opportunity to generate treatment programs that link closely with parental care. The emphasis on education means that the academic focus of the milieu in day care can be fully exploited. Educationally, therefore, in-patient and day unit treatment can be identical. There are also opportunities to transfer learned skills in to the community and family setting (McCarthy, Baker, Betts et al., 2006) or to provide outreach into the community (http://www.swindonmarlborough.nhs.uk/departments/child/ beacon_under_8’s.htm).

Disadvantages of the day unit milieu mirror these advantages. Many stand alone day units do not have the critical mass of staff to mount a full educational program and make do with sessional teacher inputs. This may not in itself be enough to achieve the key academic goals necessary for a child failing in school. The day unit has to achieve a balance between adequate intense academic input on the one hand and the socialization and therapeutic experience on the other; they may find that they have insufficient time to do both properly with children with complex problems. The child may have to make multiple adaptations to different environments during the week and in many areas the daily transport to and from the unit can be complex and tiring. The opportunities for completeness and intensity of treatment and observation are less. There are some multiagency collaborative units (http://www.tavi-port.org/patient/tavistock-clinic/patient-services-and-departments/mulberrysvc.html?no_cache=1&sword_list%5B%5D=sh%5D=bush) using facilities from education, health or social care services to meet complex needs.
CHAPTER 69

Common Aspects of Day Unit and In-patient Treatment

Therapeutic Alliance

Therapeutic alliance is poorly researched in child psychiatry when compared with adult mental health treatments (Green, 2006), yet proxy measures of therapeutic alliance such as “parental co-operation” commonly provide the most significant predictor of in-patient and day patient outcome (Grizenko, 1997; Sourander, Helenius, Leijala et al., 1996). Kroll and Green (1997) reviewed the complexity of the therapeutic alliance in in-patient and day patient care. Alliances are necessary between child and parents separately and a complex in-patient team. The team acts in a number of different roles, ranging from a quasi-parenting role in relation to a child’s basic needs to a therapeutic role while undertaking specific programs; from a “collaborative” role with parents to a “patient” status for adults within family therapy. Adult studies find that therapeutic alliance relates to pretreatment social adaptation (Hougaard, 1994) and social competency is found to be a key variable predicting adaptation into an adolescent in-patient treatment environment (Luthar, Woolston, Sparrow et al., 1995). Such findings emphasize the importance of pre-admission work for building a therapeutic alliance. Techniques for maximizing alliance independently with both child and parent need consideration. Two studies (Green, Kroll, Imre et al., 2001; Green, Jacobs, Beecham et al., 2007) found that child and parental alliances were independent of each other and that the child alliance was a main predictor of health gain during admission.

Assessment Strategies

The ward environment creates opportunities for detailed assessment of biological and psychological aspects of disorder. Covert causes of behavioral difficulties can be elucidated – for instance, a study of unselected adolescent admissions (Szabo & Magnus, 1999) revealed 4% of patients with undiagnosed complex partial seizures. Wards need ready access to the full range of biological investigations, including scanning, electroencephalography (EEG) and clinical chemistry; a range of developmental assessments such as detailed speech pathology, occupational therapy and psychometric evaluation; and the opportunity for pediatric and neurological liaison. There are unique opportunities for observational studies in settings ranging from highly structured individual assessments to naturalistic observations during ward and school activities. Making best use of these opportunities requires good planning because important observations are often made by the least experienced staff and multiple assessments have to be integrated into a whole. One solution is to have structured assessment protocols for particular problems in which different staff have defined tasks towards a common end (Green, 1996). Assessments carried out in this way are always challenging – initial assumptions based on limited information can be examined critically in the light of different staff perspectives: this is one of the strengths of multidisciplinary working in the ward environment. Staff use specific skills from their core profession as well as skills developed within the team to serve these tasks – the team thus needs a program of generic skill development to meet the priorities of the unit.

Planning Treatment Goals

The concept of treatment goal planning was elegantly outlined by Shaw (1998) and has many attractive features. It acts to organize thinking and focus treatment in complex cases and counters therapeutic drift. However, it is deceptively simple and needs significant assessment and engagement with the family. Shaw suggested that treatment goals should be understandable, ideally framed in the child’s own words, achievable and measurable; they are distinguished from the staff hypothesis (a professional formulation of the case) and the treatment plan established by the staff group on the basis of this hypothesis. Rothery, Wrate, McCabe, and Aspin (1995) made an audit of treatment goals in admissions to four adolescent units. They found that the majority of treatment goals reflected relationship and maturational aims rather than symptom change alone. Improvement across such goals was noted during treatment. Goals should be flexible enough to be able to evolve in potentially unexpected directions when necessary during treatment.

Adapting Treatments to the In-patient and Day Patient Settings

In addition to individualized treatments, there remain generic aspects of ward management. Behavioral management on any unit is a key area, requiring ward policies on the management of aggression, use of seclusion or restraint, bullying and runaway behavior (AACAP, 2000). Minimization of problems begins with a thorough initial risk assessment and treatment planning, but equal emphasis needs to be placed on the overall culture of the unit, staff behavior and the ongoing use of social skills and anger-management programs (Cotton, 1993; Higgins & Burke, 1998). The AACAP review commented that the trend to brief treatment stays can undermine such a culture. Luiselli, Bastien, and Putnam (1998) applied a behavioral analysis to incidents of mechanical restraint in a US unit and concluded that such extreme measures were often the result of a failure of preplanning, unit policy or staff awareness. Antecedents to restraint were commonly an escalation of conflict initiated by staff behavior rather than child behavior and based on unrealistic staff expectations of child compliance. The authors advocated a comprehensive functional assessment, proactive treatment planning and the use of short time-out procedures in which the child has control as to duration. When prevention fails, crisis intervention techniques can range from de-escalation strategies and seclusion to brief carefully trained physical holding. More controversial techniques include use of medication and mechanical restraint (papoose boards or holding blankets) but these are contraindicated for younger children or when there is previous trauma related to confinement (AACAP, 2000). There are no comparative studies of the relative value of these techniques and the whole
area is relatively under-researched and subject to clinical fashion (Angold & Pickles, 1993). However, careful reviews of available evidence and explicit clinical guidelines such as those from the AACAP form the best current safeguard for patients and professionals alike.

Individual treatments such as cognitive–behavioral therapy (CBT) and individual psychotherapy are incorporated into individualized treatment planning. The trend towards shorter treatment stays favors brief and focal treatments such as CBT. The detailed assessments provided by individual psychotherapy have continuing value but there are particular challenges in adapting psychotherapeutic treatment techniques to the modern treatment milieu when stays are relatively short (Leibenluft, Tasman, & Green, 1993; Magnagna, 1998). The challenge of mounting family therapy in the context of a busy in-patient unit has been reviewed by Lask and Maynerd (1998). Pre-admission family functioning has been found to be a predictor of health gain during treatment in a number of studies (Pfeiffer & Strzelecki, 1990) but Green, Kroll, Imre et al. (2001) found in one study that family functioning did not improve during admission. An option may be for the formal family therapy to take place at the local site of referral in partnership with the in-patient team. The ward staff provide a form of psychological care which inevitably has elements of substitute parenting, especially for younger children, and have the opportunity to pioneer the development of specialized forms of care for extreme difficulties. In wards taking multiple diagnostic groups, flexibility and thoughtfulness are needed; the management of a behaviorally disturbed child with attachment disorder will be very different to superficially similar behaviors in a child with pervasive developmental disorder or obsessive-compulsive disorder (OCD).

Consent and Motivation
The United Nations Convention on the Rights of the Child (UNICEF, 1995) and national legislation with regard to children (e.g., the UK Children Act; White, Carr, & Lowe, 1990) have significant implications for practice. The trend is for consent to be increasingly explicit, treatment-specific and involving of the child. Developmental issues around competency have been reviewed (Shaw, 1998). Within residential units, the social and linguistic impairments of patients, described elsewhere in this chapter, need to be carefully considered. In a useful study of competency in a consecutive series of 25 psychiatric child in-patients, Billick, Edwards, Burget, Serlen, and Brun (1998) found that “legal competency” (the ability to understand legal rights and the principle of consent) was associated with the achievement of a 5th or 6th grade (year 12 equivalent) reading level.

Another principle of consent should be collaboration with parents. A generic consent to treatment can be obtained early in admission in conjunction with treatment goal planning, based on what is likely to happen within a particular program of care. Such an approach combines the best principles of both consent and treatment goal planning. In the case of enforced treatment, there is debate as to whether it is best to use various aspects of children's legislation or adult-orientated mental health legislation in particular circumstances (see chapter 8).

The Staff Team
As treatment approaches become more sophisticated, the staff team in both in-patient and day patient care have increasingly complex tasks to perform. In many countries, nurses with mental health and/or pediatric qualifications form the main ward staff group but play specialists, trainee psychologists and volunteers can also usefully add to the skill mix. Guidance from both the USA (AACAP, 1990) and the UK (Royal College of Psychiatrists, 1999) emphasized the wide variety of other professionals that should be represented in well-run in-patient or day patient units: consultant child and adolescent psychiatrists; social workers; psychologists; speech and language therapists; occupational therapists; family therapists; and psychotherapists. Attempts to operate with too few staff are a recipe for stress, burnout and institutional decay. Staff numbers are best discussed in “shift ratios” (number of staff per shift) or in sessional terms, because this allows application to diverse unit functioning. For nursing staff, factors influencing the shift ratio include skill mix, the task demands of a particular shift (from low-intensity observation at night to high-intensity active therapy) and patient dependency (Table 69.1). Units caring for those with diverse disorders need more intensive staff ratios. Furlong and Ward (1997) piloted a dependency measure that shows predictable weekly fluctuations and interactions with staffing levels and quality of care. American and UK guidelines (AACAP, 1990; Royal College of Psychiatrists, 1999) recommend nursing shift ratios of 1:3 for low-intensity activities rising to 1:2 for active treatment and 1:1 for intensive care. Recommendations for other staff include 1 whole time equivalent (WTE) consultant per 10–12 bedded unit, up to 1 WTE in clinical psychology and up to 0.5 WTE sessional inputs from social work, psychotherapy, family therapy and occupational therapy. The UK recommendation for specialized teaching is 1 teacher to 4 students per lesson.

Table 69.1 Factors indicating the need for higher shift ratios.

CHAPTER 69

Models of team management and functioning vary with the style of the unit. A popular current style is a model of “matrix management,” which combines different disciplines with multiple tasks in a flat hierarchy with task-focused “mini teams” (Maskey, 1998). Whatever the organization, responsive and adequate staff supervision is vital.

Effectiveness of In-patient and Day Patient Treatment

Generic Outcomes

In-patient and day units are considered as a single entity for the purposes of administrative planning and therapeutic organization, and most studies have investigated generic outcomes across a range of disorders. Pfeiffer and Strzelecki (1990) reported a meta-analysis of 34 such in-patient outcome studies; there have been subsequent reviews (Curry, 1991; Pottick, Hansell, Gaboda et al., 1993) and individual reports. These studies pointed to the overall efficacy of in-patient care and have been able to identify predictors of outcome. However, the reviews have also highlighted significant methodological limitations. Few early studies included control groups or standardized outcome measures and sample sizes have often been insufficient to overcome problems of patient heterogeneity. Pottick, Hansell, Gaboda et al. (1993) argued for more experimental designs to investigate the value of the residential component of care against other components, and prospective randomized trials of in-patient versus other forms of treatment for particular disorders are now beginning to appear (see p. 1136). Outcome measurement is also becoming more sophisticated with “triangulation” methods to measure multiple perspectives on outcome (Jensen, Hoagwood, & Petti, 1996). Use of change-sensitive common methodologies in the future will greatly help the field. It will also be necessary to be creative in the variables measured; markers such as social competency may be more relevant for treatment and outcome than diagnostic groupings per se. Grizenko, Papineau, and Sayegh (1993), in a study of multimodal day treatment for children with disruptive behavior problems, found that compared with a waitlist control group, day treatment produced significantly greater improvement in behavior, and that this was maintained at 6-month follow-up.

Predictors of Outcome

Pfeiffer and Strzelecki (1990) identified a number of predictors of in-patient outcome in their meta-analysis, which have received support and extension in subsequent studies. However, the design limitation of these studies must again be emphasized. By contemporary standards of evidence, these older studies do not robustly establish the causal link between admission and outcome or test predictor variables against other possible explanations. More recent study designs have begun to address these limitations. High levels of aggressive antisocial behavior and “organicity” of symptoms, as in schizophrenia, predict poor outcome; emotional disorders do better. Well-organized treatment, multimodal treatment, positive alliance and good aftercare are common predictors (Grizenko, Papineau, & Sayegh, 1993). Intelligence measured as IQ shows a moderate positive effect, but the study of Luthar, Woolston, Sparrow et al. (1995) suggested that functional achievement may be a more critical variable than IQ per se. Pretreatment family functioning is a strong predictor of outcome but the effects may be complex and disorder-specific. In a study of anorexia nervosa, North, Gowers, and Byram (1997) found that the child’s perception of family functioning was prognostic but parents’ perception was not. Gender, age and emergency or elective admission were found to have little predictive value.

Length of Stay (LOS) had only a modest association with outcome in Pfeiffer and Strzelecki’s (1990) review. However, interest in treatment lengths has been increased by the rapid progress in the USA and elsewhere towards managed care and very short hospital stays. Influences on LOS are complex. A retrospective case note study of pre-admission variables in 100 children in one private US unit (Gold, Shera, & Clarkson, 1993) found that longer LOS was predicted by greater global impairment, post-traumatic symptoms and psychosocial stressors; diagnosis of adjustment disorder predicted shorter stays. In contrast, Christ, Tsernberis, and Andrew (1989) found that LOS was predicted by funding constraints or unit philosophy rather than diagnosis. In a multi-unit study, Green, Jacobs, Beecham et al. (2007) showed that longer treatment stays were associated with improved outcome independent of diagnosis and when other factors were controlled using robust standard errors. Because of the size of the sample (n = 153) and the variation in LOS between the units, this may be a salient finding. The clinical lore that symptoms often decline rapidly early in an admission and then worsen – the “honeymoon” effect – was supported by LaBarbera and Dozier (1985), who showed symptom increase from early to late in admission. No measure of preadmission symptomatology was made here but the authors argued that shortening admissions beyond a certain limit might well produce spurious health gains based on symptom inhibition early in admission. Alternatively, the fact of admission may relieve contextual causes of symptoms in the young person’s environment and the early symptom reduction may be a valid effect – but the work needed to maintain these positive changes into discharge will take longer.

Outcome for Specific Disorders

Eating Disorders

There is unresolved debate on the value of in-patient treatment for eating disorders. The anxiety that these disorders induce, the issues around control and the significant mortality often combine to produce a desire for admission as a safe option. Adolescents themselves often resist admission and some of the extreme behavioral methods previously used on units to promote eating continue to cause anger when patients recount their experiences (Shelley, 1997). On the other hand, the residential experience can be therapeutically powerful. Studies of the outcome of in-patient treatment show widely
differing results. Steinhausen and Seidel (1993) followed 50 patients over 5 years and found a 68% recovery rate, with 14% still diagnosable with eating disorder. Saccomani, Savoini, Cirinicione, Vercellino, and Ravera (1998) followed 81 children over 9 years and found a 53% good outcome. A comparison of outpatient and inpatient treatment (Crisp, Norton, Gowers et al., 1991; Gowers, Weetman, Shore, Hossain, & Elvins, 2000) showed little additional benefit from inpatient care, and in a recent large randomized study no significant difference was found between inpatient and assertive outpatient arms in weight outcomes (Gowers, Weetman, Shore et al., personal communication).

Depression and Suicidality
Admission practice following suicide attempts shows great regional variation. A recent large study found that, for similar presentations, 39% of cases in the USA were admitted compared with 12% in Europe (Safer, 1996). There are no studies directly comparing hospitalisation with other forms of post-overdose care although an evidence-based review (Hawton, Arensman, & Townsend, 1998) recommended that psychiatric admission should not be the intervention of first choice for self-harm (see chapter 40).

A number of recent uncontrolled studies have investigated suicide risk following inpatient treatment of depression or suicidality. Of 111 emergency admissions, 20% remained depressed and suicidal at 2–4-year follow-up (Ivarsson, Larsson, & Gillberg, 1998), 18% of 100 patients admitted with depression reported suicidal behavior at 6-month follow-up (King, Segal, Kaminski, & Naylor, 1995) and 25% of 180 similar admissions attempted suicide within 5 years of discharge (Goldston, Sergent-Daniel, Reboussin et al., 1999). Predictors of ongoing symptoms were suicide attempts prior to hospitalization, high levels of depressive symptomatology and family dysfunction at inpatient assessment.

Psychosis
Adolescents with first-onset psychotic illness will commonly be admitted but there are no studies comparing admission with alternative forms of treatment at this stage. One study of 58 adolescents admitted with psychotic disorder showed that 78% were continuously ill at follow-up after 2 years (Cawthron, James, Dell, & Seagroatt, 1994).

Conduct Disorder
The presence of unsocialized aggressive or disruptive behaviors at presentation is a consistent predictor of poor outcome for inpatient treatment (Green, Jacobs, Beecham et al., 2007; Pfeiffer & Strzelecki, 1990). However, this reflects the general prognosis for these disorders. Conduct disorder is a specific exclusion criterion in some units but accounted for 25% of child admissions overall in a study of UK child psychiatry units (Green & Jacobs, 1998) and 15% of children and adolescents referred to Finnish inpatient units in 1990 and 1993 (Sourander & Turunen, 1999). In a recent UK study of eight units, conduct and aggression were associated with worsened ward milieu and shorter stays. Current evidence suggests that the management of conduct disorder is best seen in terms of long-term maintenance rather than episodes of care and the contextual basis of much of the symptomatology supports community intervention as a first-choice treatment. In spite of these arguments, and the often disruptive effect of such children on the milieu, there is good indication for admitting selected patients: for assessment when there are concerns about covert underlying comorbidity relevant to treatment (e.g., ADHD, emotional disorder, pervasive developmental disorder, specific learning disability or subclinical seizures; Jacobs, 1998); or when a trial of treatment is needed within a controlled setting.

Children with disruptive disorders receiving a multimodal day program showed improvements in adjustment at 5-year follow-up (Grizenko, 1997). Another multimodal day program (Rey, Denshire, Wever et al., 1998) also showed improvement over matched controls who had received other treatments; however, both groups showed poor outcome. In a study of inpatient treatment of adolescents with emotional and conduct disorder, patients who completed the treatment showed more progress 1 month post-discharge than patients who were early dropouts, but these differences had become insignificant at 1- and 2-year follow-up (Wells & Faragher, 1993).

Substance Misuse
A number of inpatient and day patient addiction programs have been evaluated. Of 280 adolescents treated in a substance abuse inpatient program (Dobkin, Chabot, Maliantovitch, & Craig, 1998), 67 subjects completed 1-month follow-up questionnaires; 19 had improved and 48 had not. The improvers tended to be older with better motivation for social adjustment and less emotional symptomatology; those who did worse were distinguished by more mental state abnormalities at admission. Cornwall and Blood (1998) compared inpatient with day patient programs in this area and found they showed similar outcomes. A random allocation trial comparing inpatient with intensive community treatment of adolescents with substance misuse and juvenile offending (Schoenwald, Ward, Henggeler, & Pickrel, 1996) showed additional benefits for the community treatment. Freeman, Garrick, Kreisher et al. (1993) report a matched study comparing long-term outpatient treatment with short-term inpatient treatment and found benefits in the longer-term outpatient treatment.

Obsessive-Compulsive Disorder
In a prospective naturalistic study, Wever and Rey (1997) examined the effectiveness of combined CBT and psychopharmacology in a group of 57 children and adolescents first diagnosed with OCD, 20% of whom received inpatient treatment. Factors leading to admission included the severity and type of OCD symptoms, the failure of past therapy, comorbidity, family factors and geographical isolation. The inpatient group had double the rate of comorbid diagnoses compared with the outpatient group and showed a poorer outcome.
CHAPTER 69

Alternatives to In-patient Care

Historical Development

Over the last 40 years changing philosophical beliefs among educators and health professionals (Bracken & Thomas, 2002) have led to a movement away from residential psychiatric care in the UK, Europe and North America (Smyth & Hoult, 2000). Reforms in US mental health policy (including the introduction of Medicare, Medicaid and the Supplemental Security Income program) encouraged policy-makers to discharge patients to the community and transfer state mental health costs to the federal government. Systematization of the Child and Adolescent Service System Program (England & Cole, 1992) opened up discussion among in-patient service providers about how best to meet the complex needs of children and young people (Burns & Friedman, 1990). A range of alternative community-based services were then developed, many now systematically evaluated (Henggeler, Rodick, Borduin et al., 1986). In general, evidence-based changes to mental health care have underpinned reform of psychiatric service provision for adults and young people, and intensive home-based treatments are central to these changes (McGorry, 2005).

In the UK, the development and evaluation of psychiatric intensive home treatment has somewhat lagged behind the US developments (Smyth & Hoult, 2000). However, a commitment to tackling the links between mental illness and social deprivation has been made explicit in the National Service Framework for Mental Health (Department of Health, 1999) and for Children (Department of Health, 2003), which challenge health professionals to widen their approaches to care. A review of home-treatment studies (Joy, Adams, & Rice, 2004) found that patient and relative satisfaction was higher in home care compared with admission in adults and that carers found home care less disruptive and burdensome. Recent surveys showed that young people and families want CAMHS to be delivered flexibly (Baruch & James, 2003) and in a variety of settings, including the home (National Service Framework for Children, 2004).

Current Developments

In adult mental health services a range of treatment models are now used, sometimes specifically to reduce the need for hospitalization, sometimes to allow more patient choice and active involvement in care (Department of Health, 1999; Priebe, Fakhoury, White et al., 2004). These include assertive community treatment (Wright, Burns, James et al., 2003), case management (Burns, Fioritti, Holloway, Malm, & Rossler, 2001a) and home treatment (Burns, Knapp, Catty et al., 2001b), all of which have the aim of providing increased support and care for the mentally ill within their own homes so that hospitalization can be avoided where possible. However, the disorders for which young people – especially children – are admitted vary greatly from those in adults, as does the developmental context. Thus, direct comparisons with adult psychiatry can be misleading. Assertive outreach, case management and wraparound models have been adapted for use in child services but there has also been the development of developmentally specific models, such as treatment foster care and multisystemic therapy. The heterogeneity of these initiatives makes comparison difficult, although they tend to share common features (e.g., the importance of the family and social context, the complex needs of young people and families, multimodal interventions and the understanding of outcomes as being multifaceted). The services with which home treatment is compared are often poorly defined as “standard care,” which can vary enormously from study to study (Burns, Knapp, Catty et al., 2001b). Furthermore, the majority of the studies focus on young people not at the highest risk (often the acutely suicidal or psychotic are excluded) and therefore results may not be generalizable outside of a specific and narrow patient group. While most studies report that effective systems of care can be developed in the community (Henggeler, Rodick, Borduin et al., 1986), other work suggests that outcomes may not always be substantially improved (Burns, Farmer, Angold, Costello, & Behar, 1996).

Models of Out-of-Hospital Care

Family Preservation

Family Preservation is a home-based intensive service for families who need additional support beyond typical out-patient services. It can be used as a transitional service for families with children returning home from psychiatric admission, or to prevent admission. The aims are to improve parenting skills, promote healthy child development, prevent out-of-home placement of children and provide or co-ordinate services needed to maintain family stability. The therapists make contact with the family several times a week, providing assessment and treatment, and access to educational and practical resources. Family Preservation services are usually limited to weeks in duration. However, family contact with therapists is intensive during this time, almost double that in residential units (Wilmshurst, 2002). A randomized controlled trial of young people allocated to either Family Preservation or a 5-day residential program found that at 1-year follow-up more of the Family Preservation group had sustained the improvements in behavior and the symptom reduction than had those in the residential program (Wilmshurst, 2002).

Home Treatment

Home treatment can be summarized as a service for young people with mental illness who are in crisis and are eligible for hospital admission. Features of an effective home treatment team are 24 h a day, 7 days a week availability; rapid response time; and the ability to work flexibly with families and their networks (Smyth & Hoult, 2000). In a series of studies from Germany, home treatment was compared with “standard” in-patient treatment. The first study (Remschmidt, Schmidt, Mattejat, Eisert, & Eisert, 1988) randomly allocated young people to home treatment or admission; it found that the baseline severity of symptoms was similar for both treat-
ment groups, and that immediate treatment effects were similar. However, only about 15% of young people could safely be diverted from in-patient to home treatment, exclusion criteria for the home treatment arm being severe psychosis, life-threatening eating disorders, families living more than 30 km from the therapeutic unit and risk-taking behavior. Mattejat, Hirt, Wilken, Schmidt, and Remschmidt (2001) conducted a re-analysis and 3-year follow-up of these data. They contacted 68 of the original 92 families (in-patient \( n = 33 \), home treatment \( n = 35 \)). Baseline symptom scores and psychosocial functioning were similar for both groups. Home treatment was found to be as effective as in-patient treatment across diagnoses in reducing symptom scores and improving psychosocial functioning, both immediately after treatment and at 3-year follow-up. The longer-term treatment effect declined somewhat, to an equal extent in both groups. Compliance of the child with the therapeutic regime and the skill of the therapist were the most important predictors of treatment outcome. The study suggested that, even if community treatment is an effective alternative to admission, it could only be used for a small proportion of all possible admissions, a finding also reported by others (Woolston, Berkowitz, Schaefer, & Adnopoz, 1998).

**Case Management**

Case management encompasses a number of approaches including assertive outreach, assertive community treatment, wraparound and intensive community treatments. It can be defined as “a commonly used strategy for increasing access to and coordination of services within the care system” (Farmer, Dorsey, & Mustillo, 2004). Case management in a child and adolescent mental health setting assigns the coordination and responsibility of care for an individual young person with a serious mental illness to a single person (or team). Case managers may be responsible for a variety of tasks, ranging from linking young people and families to services to providing intensive clinical or rehabilitative services. Other core functions include outreach to engage clients in services, assessing individual needs, arranging support services (such as education, careers advice, family benefits), monitoring medication and advocating for young people’s rights. Case management is not a time-limited service, but is intended to be ongoing, providing clients with whatever they need whenever they need it, for as long as necessary. This is a controversial point, as some authors feel that the “never discharge” philosophy encourages pathologizing of normal behaviors and re-invention of some of the worst practices of the old asylums, a de facto “institutionalization” in the community (Smith, 1999). Case management has been adopted in the UK, Germany and Sweden, but not in all European countries (Burns, Fioritti, Holloway et al., 2001a).

The two models of case management described most often are assertive community treatment (ACT) and intensive case management. A third model, clinical case management, refers to a program where the case manager assigned to a client also functions as their primary therapist, generally considered to be less effective (Burns, Farmer, Angold et al., 1996).

The **assertive outreach/community treatment model** for adults originated in an in-patient research unit at Mendota State Hospital, Madison, Wisconsin in the late 1960s (Stein & Test, 1980) in an attempt to create a “hospital without walls.” In the UK, it is now part of the national mental health policy for adults (Department of Health, 2003) with over 200 teams, but in Europe it has not developed to the same extent (Bonsack, Adam, Haefliger, Besson, & Conus, 2005). The key features of ACT are multidisciplinary teams, 24 h a day, 365 days a year care; low client : staff ratios; an emphasis on assertive outreach; provision of in vivo services (in the client’s own setting); an emphasis on assisting the client in managing their illness; assistance with activities of daily living (ADL) skills; emphasis on relationship building; and crisis intervention. The interventions are strengths-based and focused on promoting symptom stability, increasing the individual’s ability to cope and relate to others. Adult patients are rarely discharged (Smith, 1999) and this may lead to everyday difficulties being reframed as symptoms or dissuade commissioners and providers from developing ACT services (Bonsack, Adam, Haefliger et al., 2005).

In the UK, assertive outreach is a requirement for adults of working age only (Office of the Deputy Prime Minister, 2004) although as Early Intervention in Psychosis teams become more common and report on their outcomes this situation will change. Much of the evidence for the effectiveness of assertive outreach is from studies with overlapping age groups of young people and working age adults. Broadly, assertive outreach in young and working age adults is effective (Marshall & Lockwood, 2004; Minghella, Ford, Freeman et al., 1999) despite concerns that fidelity to the model is not always adhered to. Good quality assertive outreach studies have shown that assertive outreach is effective with young adults with early psychosis, the treatment effect size is similar to that of in-patient care, in-patient admission can often be avoided without increasing risk of critical incidents, and it can be highly cost-effective (Craig, Garety, Power et al., 2004). Whether it is more effective than “standard” community care is debatable, with mixed findings perhaps related to many community mental health teams being able to provide the “assertive” component for young adults when required. Two randomized studies of only young people report that compared with those who received standard community care, young people who received assertive outreach were more likely to access and continue using services, had better family relationships and fewer psychiatric symptoms (Evans, Boothroyd, Armstrong et al., 2003; Godley, Godley, Dennis, Funk, & Passetti, 2002). Service user views of young people and their families suggest that assertive community treatment is useful and valued (White, Godley, & Passetti, 2004), although this should be taken with caution as it was based on young people with substance abuse problems and may not be generalizable.

**Intensive case management** typically targets young people with the greatest service needs. It shares many key features with ACT, but relies more on an individual than team
approach. In addition, intensive case managers are more likely to “broker” treatment and rehabilitation services rather than provide them directly. Finally, intensive case management focuses more on family strengths and empowering families. Case managers act as advocates and brokers between services, and coordinate, plan and implement services.

Clinical case management is one of the intensive case management models but has the weakest effect of the models. An aggregation of studies comparing ACT with clinical case management found that while the generic approach resulted in increased hospital admissions, it significantly decreased the length of stay. This suggests that the overall impact of clinical case management is positive but might result in “revolving door” admissions. However, randomized trials have shown full-time case manager models to be perceived as more satisfactory and allow young people to access community rather than residential-based services, compared with treatment models where the primary worker or therapist also acts as case manager (Burns, Farmer, Angold et al., 1996).

Wraparound helps families develop a plan to address the child’s individual needs at home and school (Burns, Schoenwald, Burchard, Faw, & Santos, 2000). Research on the effectiveness of this model is still at an early stage. Wraparound addresses a child’s individual needs and builds on the child’s and family’s strengths, so the exact services vary. The services are provided through teams that link children, families and foster parents and their support networks with child welfare, health, mental health, education and the criminal justice services to develop and implement comprehensive support plans. Findings suggest that this broker/advocacy model results in behavioral improvements and fewer days in hospital. A randomized controlled trial of treatment foster care versus case management (with wraparound components) found that outcomes were better for young people in case management interventions than for treatment foster care and at one-third of the cost (Evans, Armstrong, Kuppinger, Huz, & Johnson, 1998). More radically, families or volunteers sometimes act as case managers in wraparound care, although this is probably more as a result of lack of support and funding than a philosophical step forward.

Multisystemic Therapy
Multisystemic therapy (MST) was developed as an intensive approach to juvenile offenders presenting with serious antisocial behaviors and who were at risk of being placed out-of-home (see chapter 68). It is an intensive family and community-based treatment program (Henggeler, Rodick, Borduin et al., 1986) designed to make positive changes in the various social systems (home, school, community, peers) that contribute to the serious antisocial behaviors of children and adolescents. It is based on the work of systems theorists such as Haley and Minuchin. Time-limited (4–6 months), it adheres strictly to a treatment manual with nine treatment principles, and relies for success on adherence to the treatment model and ongoing training of staff to this end (Henggeler, Schoenwald, Borduin, Rowland, & Cunningham, 1998). The main purpose of assessment is to understand the fit between the identified problems and their broader systemic context (Henggeler, Schoenwald, Borduin et al., 1998). Interventions are designed to promote treatment generalization and long-term maintenance of therapeutic change by empowering caregivers to address family members’ needs across multiple systemic contexts. Outcome studies show that staff adherence to the treatment model correlates to strong case outcomes (Henggeler, Rowland, Halliday-Boykins et al., 2003).

MST has a relatively strong evidence base (Farmer, Dorsey & Mustillo, 2004). Consistently positive outcomes are reported for young offenders compared with standard out-patient treatment (reduced offending, fewer out-of-home placements, less substance-related offending). Randomized controlled trials and pooling of previously conducted studies demonstrated significant symptom improvement in psychiatrically ill young people receiving MST compared with standard care (Curtis, Ronan & Bourdin, 2004; Henggeler, Rowland, Halliday-Boykins et al., 2003; Schoenwald, Ward, Henggeler, & Rowland, 2000). However, at 12-month follow-up, the two treatment approaches yielded similar results. Schoenwald, Ward, Henggeler et al. (1996) randomized MST against service as usual for adolescent substance abusers. The MST treatment resulted in a 46% decrease in the need for residential care at 1-year follow-up and succeeded in reducing dramatically the rate of imprisonment for substance abuse and abuse-related in-patient stays. The cost savings made through this almost compensated for the increased cost of the MST treatment.

A recent randomized trial (Henggeler, Rowland, Randall et al., 1999) compared MST with brief hospitalization for a diverse group of adolescent psychiatric emergencies in a relatively disadvantaged population. MST was given for 4 months whereas hospitalization was for 2 weeks only, followed by standard community aftercare. The MST condition involved a mean of 97.1 h of therapy contact time during the study and 24 h, 7 days a week availability of staff. Staff had a caseload of three cases each and there was high-frequency psychiatric supervision. By comparison, the hospitalization condition had a mean contact time of 8.5 h subsequent to the admission period. Nearly half of the young people in the MST condition in fact needed psychiatric admission in the initial period and MST only had the effect of reducing out-of-home placement by 50% through the whole study. Given these methodological qualifications, the MST had a significantly greater effect than hospitalization on disruptive behavior and targeted social outcomes such as enhanced family cohesion, structure and school attendance. Family and youth satisfaction was also higher. The hospital condition showed a significantly greater impact on youth self-esteem – a result that may reflect the individually orientated treatment model in the hospital group. No follow-up data beyond 4 months are reported. The study concluded that even this highly intense form of ecologically focused care does not substitute for the need for in-patient provision – but it can reduce the need, and results in enhanced outcomes over treatment as usual. It was
unfortunate for the design of the study that there was such an imbalance between the treatment intensity in the two conditions. The study – important as it is – does not yet address the question of the relative value of the residential component per se.

**Treatment Foster Care**

Treatment foster care (TFC) is one of the least restrictive treatment-based residential options for young people with emotional or disruptive disorders (Farmer, Dorsey, & Mustillo, 2004). It comprises structured therapy within a foster family setting, delivered with a multiagency approach. Theoretically, TFC is largely based on social learning theory. TFC programs recruit, train and support foster families, who usually only look after one fostered child. The families are closely supervised and supported, and receive a monthly salary. TFC specialists work with the child and foster parent on identified goals 1–2 h per week. This work is supervised by a mental health practitioner, who also meets with the foster-care family frequently (every 1 to 2 weeks) to coordinate services and ensure the treatment plan is being followed. TFC programs also prepare the child for successful transition to return home. TFC differs from standard foster care in three ways:

1. **Substantial training and supervision of foster parents by experienced case managers;**
2. **Detailed functional assessment and close monitoring of behaviors, their antecedents and consequences; and**
3. **Emphasis on “therapy.”**

The evidence base comes mainly from two well-reported randomized controlled trials undertaken by those who deliver the Oregon model (Chamberlain, 2002). Outcomes (improved behavior, reduced offending behavior) for both psychiatrically ill and offending young people were significantly better for those who received TFC than group home or hospital care. Outcomes were dependent on four main factors: the amount and type of supervision received by the young person; consistency of parental discipline; presence of a close, confiding relationship with a trusted adult; and not being closely linked with delinquent or deviant peers (Chamberlain, 2002).

Although most of the evidence base for TFC comes from its original proponents in Oregon, it has translated across the Atlantic successfully, albeit in an altered format (Brady, Harwin, Pugh, Scott, & Sinclair, 2005). Outcomes reported for young people in this project include: a greater stability in placements; an increase from 14% (on admission) to 71% in young people attending school. 21% showed significant improvements in their behavior and a further 25% some behavioral improvement. There was also a significant decrease in young people being cautioned or convicted of offenses with less than 1% receiving a custodial sentence. 21% young people returned home to their birth family and 10% moved to independent living. However, the level of professional and financial risk involved in a TFC project could only be sustained if it is based on a partnership agreement with one or more local authorities and CAMHS teams. A modified form of TFC is currently being implemented in the UK for looked-after children at risk of multiple placement breakdowns and is being systematically evaluated. Projects are also under way in Sweden, Finland and Holland.

**Staffing**

These intensive outreach models need much skilled professional time. In Woolston’s (1998) model between three and five professional teams, consisting of two senior clinicians or counselors, provide the home-based assessment and therapeutic input. They are backed up by a multidisciplinary infrastructure described in the model as a program director and medical director, a child psychiatrist, a clinical program co-ordinator, two senior clinicians and an administrator. This staff level is quoted as sufficient for a caseload of 25 patients. The intensity of the involvement can vary according to need and expense but a 24 h, 7 day on-call crisis intervention service is provided throughout the duration of the input. In one study of MST (Schoenwald, Ward, Henggeler et al., 1996), the average duration of treatment was 130 days (standard deviation [SD] 32 days), during which there was an average of 40 direct contact hours between professionals and family (range 12–187 h, SD 28 h). Woolston emphasized that the intensive home-based services are considered as supplementary to an array of more traditional services including in-patient and day patient hospitalization and out-patient programs.

**Conclusions**

There is now research evidence supporting the use of alternatives to in-patient care for certain groups of young people with mental health problems. The evidence suggests that, within these groups, treatment effects of several outreach models of care can be of similar size to those obtained through residential treatment, and may be sustained as long after follow-up. MST, TFC and assertive outreach have the strongest evidence bases, wraparound care the weakest. However, it should be remembered that the evidence for TFC is largely based on the model as delivered in Oregon solely, clearly limiting generalizability of the findings. Assertive outreach work is largely based on older adolescents and young adults, and comparisons with “standard” treatment do not reflect a fair comparison with CAMHS “standard” treatments, which arguably are already more “assertive” and “outreach” than standard adult mental health services. The evidence surrounding MST is now extending beyond use with antisocial behavior but still needs further work to demonstrate effectiveness in other disorders.

Therefore, there is not always the evidence to decide which model is best for which group of young people, and funding and service provision issues may not allow development of the chosen model, requiring pragmatic choices to be made by commissioners and providers. Little, Kohm, and Thompson (2005) rightly called for less ideology and more science. Comparative studies are needed to allow an informed decision.
CHAPTER 69

about which type of care best fits the needs of which group of young people.

Future Directions

A number of contemporary themes and future directions may be summarized. The trend for shorter in-patient stays and the development of intensive care alternatives to residential treatment is likely to continue but there may well also emerge a reactive emphasis on the value of intensive residential treatment experience for selected conditions. The demand for adolescent units to respond to acute emergencies is likely to continue to grow as the severity of presenting psychopathology moves down the age range. In well-provided health services there may be increasing growth of specialist environments such as specialized eating disorder or forensic units. Referral to intensive care facilities is often thought to follow a bimodal pattern: high when there are relatively few out-patient services, lower as out-patient services are more developed, and higher again when out-patient provision becomes still better and more complex need is identified. This should not imply that the potential demand for intensive services is endless: epidemiological surveys of children with complex needs suggest that the pool of these problems in communities is finite and measurable (Kurtz, 1994).

At the complex end of the spectrum, young people are likely to be involved with multiple agencies (Kurtz, 1994). This implies another necessary development; a more sophisticated integration between mental health care, education and social services to form complementary and mutually supporting provision. Some children who now are admitted to in-patient psychiatric units may be better placed in residential social care institutions with psychiatric input or in specialist residential schools; some children in these other institutions may be better placed in primarily mental health facilities. Case management approaches have much to offer in coordinating these complex care pathways and need to be systematically tested.

The development of robust alternatives to in-patient care will make possible the ethical use of randomized controlled trials to compare residential, intensive day and outreach alternatives for particular groups or severity of problems. Along with this we can hope for an increasing delineation of methodologies to measure treatment process. The result of these two developments may be further clarification of the specific value of the different components of intensive treatment – for instance, the specific indications for admission. The current evidence suggests that the residential milieu has a particular ability to provide stabilization and rapid reduction of symptomatology and risk. In medium-term treatments it provides an environment in which treatment and rehabilitation can occur outside the demands of the home environment – this is the historical function of respite. Notwithstanding the efforts that have been made in recent years to engage effectively with families, the residential unit is inevitably largely focused on the individual and individual pathology. This can prove highly advantageous in situations where assessment or treatment of complex individual psychopathology is at a premium but needs to be complemented by an emphasis on the environmental context during pre-admission and follow-up. Reduction of in-patient stays beyond a certain minimum negates any value of the in-patient milieu as a treatment in its own right, but the very fact of removal from a noxious mental environment in the community of origin may still result in temporary benefit.

Intensive outreach programs have already generated impressive levels of rigorous treatment programming and evaluation. The face validity of this theory of intervention is strong and in keeping with recent research in the developmental psychopathology of a number of disorders. The emphasis on changing presumed maintaining factors in the young person’s environment may result in longer stabilization of treatment gains – although this has not yet been tested. On the other hand, it should be quite apparent that these outreach solutions are no easy option, either financially or in terms of professional expertise. The first randomized trial including costing shows that the extra cost of the service only approaches being met if non-health cost savings are taken into account and there is evidence that the efficacy of the intervention drops if the intensity of the intervention is not adhered to (Henggeler, Schoenwald, Pickrel et al., 1994). Nevertheless, early studies of intensive outreach models are impressive and are undergoing replication outside the developing centers. Most of the comparative studies suggest that intensive outreach does not replace the need for the in-patient option but can certainly reduce its usage. The emphasis in this treatment on the social context of psychopathology is a strength and complementary to in-patient care but runs the risk of overlooking intrinsic problems in the patient. There is no evidence to support the development of intensive services for young people with a specific disorder over the development of generic intensive services, although many of the studies of intensive work have focused on broad unitary disorder services, such as those working with young people with psychosis or substance misuse. The flexibility of intensive services to cross over traditional age ranges should be encouraged, running alongside the move in traditional out-patient CAMHS to extend the client age covered.

Day unit care may seem to be a compromise between these two extremes and may often usefully be so. For the most severe problems, however, it may fall between the two and offer insufficient containment for safety or intensive outreach for effectiveness. The great strength of the day unit resource is its flexibility to adapt to different disorders and circumstances. It is unrealistic to believe that the day unit provision can substitute for other intensive treatment modalities.

Thus, in an ideal future there would be a set of flexible and complementary platforms for the delivery of intensive care for acute and complex disorders. Service providers would identify themselves as “serious disorder” or “intensive care” services offering a variety of different modes of delivery. In practice, organization and financial constraints will inevitably lead health services to have to make preferred choices. There is now
a greater likelihood that in the future an increased evidence base may inform such decisions.

INTENSIVE TREATMENT

CHAPTER 69

Pediatric Consultation
Annah N. Abrams and Paula K. Rauch

The child mental health consultant\(^1\) assesses the psychiatric status of an ill child in a hospital environment. The child’s phase of development, temperament, type and stage of illness, family dynamics and level of pain and anxiety are among the multitude of contributing factors determining the complexity of clinical care and research in the pediatric consultation population. Every consultation encompasses aspects of biology, mediating influences of family and community, and the primacy of personal meaning in defining an experience as bearable or traumatizing (Eisenberg, 1995).

Mental health consultants assess the following:
1. Children with primary psychiatric illnesses leading to medical conditions;
2. Psychiatric manifestations of medical illnesses or treatments;
3. Adjustment to a chronic or life-threatening illness; and

The consultant’s scope includes working with anxious or difficult parents and liaison with the ward staff. The child mental health consultant’s role may include offering didactic lectures for medical staff or parents. The consultant should also be an advocate for children, working with hospital leadership to develop more psychologically attuned standard practices. It is hoped that research in best practices for the medically ill child will increasingly guide future practice, but the limits of current evidence-based practice leave us relying on clinical experience, practice parameters and smaller research studies which are commonly disease-specific (AACAP, in press; for a fuller clinical approach see Rauch & Jellinek, 2002).

History

Adult consultation psychiatry arose in general hospitals during the 1930s, with the recognition that a mind–body dichotomy was an inadequate approach to providing quality medical care. Best practice demanded attention be paid to the psychological issues that were acknowledged to impact on medical illness and treatment (Ortiz, 1997). As the integral role of psychological factors was established in adult medical care, similar attention was focused on the needs of children.

Although a role for psychiatry with the medically ill child dates back to the 1930s (Lask, 1994; Work, 1989), consultation psychiatry by no means exists in every pediatric medical and surgical setting today. Recent articles continue to tout the benefit of collaboration between child psychiatrists and pediatricians, pediatric surgeons and pediatric nursing staff (Fritz, 2003; Watson, 2006), and encourage the establishment of consultation services and recommend their increased utilization.

Consultation services require financial support. In the USA, the National Institute of Mental Health (NIMH) provided grant money in the 1970s to support interdisciplinary pediatric and psychiatric clinical collaborations, thus increasing the number of consultation services nationwide. This seed money supported unreimbursed activities such as comprehensive evaluation and interdisciplinary team meetings. As this support ended in the 1980s, most consultation services were forced to downsize and decrease the range of activities and services offered (Shaw, Wamboldt, Bursch et al., 1987). In the USA, managed care has carved out psychiatric services from medical services provided to patients. As a result, consultation liaison services face barriers to reimbursement for psychological care. A recent report found that 60% of programs received lower rates than previously for service provided and collection rates for services covered averaged only 30% (Shaw, Wamboldt, Bursch et al., 2006). Throughout Europe, consultation resources are limited, and they are virtually unavailable in many developing countries.

Clinically, the approach to consultations has seen attention shift away from looking at the mother–child dyad as the source of psychopathology and toward appreciating the impact of pediatric illness on the entire family (Labay & Walco, 2004; Svaarsdottir & Sigurdardottis, 2005). As the medical care of children, like that of adults, is moving toward shorter hospital stays and greater utilization of out-patient settings for treatment of chronic and life-threatening illness, mental health consultants will be called upon to shift their availability to encompass these out-patient settings. This chapter focuses on the medical in-patient setting, but it is important to recognize that child psychiatry consultation liaison covers a much broader terrain.

\(^{1}\) In this chapter, the term mental health consultant refers to a child psychiatrist or child psychologist who is a mental health professional providing psychological and/or psychiatric care to medically ill children in an in-patient hospital setting.

Psychological Distress in the Pediatric Population

Children with medical illnesses serious enough to warrant hospitalization are recognized as at increased risk for emotional disorders (AACAP, in press). Those conditions that result in long-term physical disabilities or impact on the central nervous system pose additional risk (Meyer, Blakeney, Russell et al., 2004; Poggi, Liscio, Adduci et al., 2005a; Poggi, Liscio, Galbiati et al., 2005b), as may certain symptoms and challenges associated with specific diseases (AACAP, in press).

Disease-specific rates of psychological symptomatology are found elsewhere in this textbook. Estimates of psychological distress in hospitalized children and adolescents vary and range from 20% to more than 35% (Loutherenoo, Sittipreechacharn, Thanarattanakorn, & Sanguansermsri, 2002; Stoppelbein, Greening, Jordon et al., 2005). These rates reflect the particular medically ill and socioeconomic populations found in any given pediatric hospital and so vary substantially.

Collaboration Between Pediatricians and Mental Health Consultants

Pediatricians, nurses and parents caring for a child with behavioral, adjustment or coping difficulties often see the benefit in their improved ability to manage a child’s illness when a child psychiatrist or psychologist is part of the medical team (Carter, Kronenberger, Baker et al., 2003). Dissatisfaction with mental health consultations has been linked to a perception that the child psychiatrist was not available quickly enough or did not communicate findings adequately, or that findings were not tailored to the needs and realities of the referring pediatrician (Burket & Hodglin, 1993). Older studies also suggested that lifelong consultation practices may begin with access during training (Bergman & Fritz, 1985). In a study from the same era, mental health consultants for their part expressed frustration that consultations were requested too late in the course of the hospital stay instead of seeking a psychiatric assessment as an integral part of the initial work-up (Fritz, Pumariega, & Fischhoff, 1987).

Barriers to Requesting Consultation

Barriers to child mental health consultation include discomfort with talking to the patient and family about psychiatric consultation, lack of availability of child mental health consultants or the lack of their availability in a timely manner. Funding for child mental health services as well as misperceptions about the role of child psychiatrists in the care of medically ill children are additional obstacles. Hospital financial priorities and national health care policy as well as educational initiatives between clinicians and within hospital units are necessary to address some of these issues.

Consultation Models

Consultation service models are determined by the size of the patient group served, the illness severity of treatment populations and the availability of child mental health consultants. When consultants are available only for a limited number of hours, they need to utilize some of their time to supervise nurse clinicians, social workers or others, who are available to do more direct clinical service, reserving the remaining consultation time for seeing the most challenging cases. In many pediatric settings, child psychologists are the primary child mental health consultants, with child psychiatrists limited to acting as psychiatric psychopharmacologists (Shaw, Wamboldt, Bursch et al., 2006). Mental health consultants, regardless of their training discipline, need understanding of the disease process, medical management of relevant illnesses and a skill set that includes behavioral interventions such as desensitization, hypnotherapy and behavior modification.

Consultations can be initiated on a case-by-case basis, by protocol or a combination. In the case-by-case model, the pediatrician requests a consultation after assessing an individual patient, whereas consultation by protocol systematizes psychiatric consultation for children with certain diagnoses or risk factors. Examples of protocol-driven consultation include routine consultation for patients who are candidates for transplant or have been admitted after suicide attempts. Protocols can be based on factors other than the diagnosis, such as hospitalization lasting more than 2 weeks or injury requiring intensive care unit (ICU) admission. In the setting of short hospital stays, protocols maximize early identification of need and minimize time before consultation is initiated. When possible, for continuity the same consultant should follow a child over multiple hospitalizations or from in-patient to an outpatient specialty clinic.

In an older study of several hundred consultations, one-third of the consultation requests were ascribed to staff-related conflict (Hengeveld & Rooyman, 1983). Arguably, no consultation for a hospitalized child can be carried out effectively without the integral “liaison” component of understanding the child’s condition in the context of the concerns arising from members of the treatment team (Hengeveld & Rooyman, 1983; Tarnow & Gutstein, 1982). Liaison requires understanding and respect for the roles of each member of the multidisciplinary treatment team as well as sensitivity to particular challenges inherent in each discipline’s treatment demands. Unfortunately, the important liaison role of mental health consultants has decreased in many institutions because of lack of funding (Shaw, Wamboldt, Bursch et al., 2006).

Psychiatric consultation requests routinely differ according to the particular hospital setting. Consultations for children on the wards often deal with behavioral and adjustment issues, in many cases present prior to hospitalization (Carter,
Psychiatric consultation for the pediatric ICU tends to be more acute and requires the consultant to make assessments and recommendations more rapidly (DeMaso & Meyer, 1996).

Work with medically ill children is rewarding, but it can also arouse powerful feelings of sadness, frustration and helplessness. Pediatric units may seek to address the emotional challenges experienced by the medical team. The goal is to provide staff support that will assist them in their ability to provide the best care for patients and may prevent long-term burnout (Levi, Thomas, Green et al., 2004; Maytum, Heiman, & Garwick, 2004). For example, an emergency department or ICU may institute a time to meet together as a team after a traumatic case or upsetting outcome. A pediatric ward may institute bereavement rounds following the death of a patient to address the emotional toll of caring for terminally ill children and to share remembrances of the child.

When a member of the multidisciplinary medical team faces a personal or professional challenge that interferes with the ability to provide quality care, the consultant may be asked, in a liaison role, to facilitate referral to psychiatric treatment for the team member. The consultant should not personally provide treatment for a team member, as this would be crossing an essential boundary in a long-term working relationship. If a team member is believed by others to be impaired but seems unaware of his or her problem, concerned colleagues may approach the mental health consultant for direction on how to help this individual. The consultant can encourage the concerned colleague to share observations with the appropriate supervisor and may meet separately with the supervisor or director to share relevant personal observations. Behaviors that put patients at risk are mandated to be reported to the appropriate overseeing body such as the chief of service, a regional board of medical or nursing registration or hospital-based board.

**Approach to Consultation Requests**

The first task for the consultant is to understand what concerns have led to the consultation request by speaking with the consulting pediatrician or staff member, listening to the expressed concerns and asking for elaboration about concerns that seem present but not disclosed. It is helpful to work together to establish realistic goals for the initial consultation, with a plan to set additional goals after the initial meetings with the child and parents. The consultant should seek supporting information available from other members of the treatment team and from the hospital chart. It is useful to gather observations from several individuals as the child may behave differently in different settings, or may have established warmer relationships with some team members than with others. After the initial assessment, and with permission from the parents or guardian, the consultant may seek input provided by sources outside of the medical arena such as an out-patient psychotherapist, school professionals or members of other involved social agencies such as the department of social services, or the court system.

While the consultant will gather data from many sources, a basic tenet of consultation work is being clear about with whom the consultant is consulting. Ultimately, the goal of consultation is to facilitate the child’s receipt of optimum care, but the consultant may be serving the primary pediatrician, a subspecialist or a subspecialty team. Usually, what serves the child best is helpful to many team members and to the family, but there may be conflicts. For example, the consultant to the pediatrician may recommend that an aggressive interventional gastroenterologist chosen by the parents may not be the best choice for a somatizing child with recurrent abdominal pain.

It is best if the pediatrician or subspecialist, with whom the family already has a relationship, informs the parents of the decision to obtain a psychiatric consultation and its purpose. Psychiatric consultation may be presented as part of the diagnostic protocol, a way to help the team understand how the child is feeling and to help the child cope with the difficult circumstance that led to hospitalization or as a response to the challenges that hospitalization has presented. The mental health consultant may be asked to help the referring pediatrician articulate the reason for the consultation in a positive manner. Some parents and children are uncomfortable with the idea of a psychiatric consultation, and yet appreciate the intervention upon finding the child mental health consultant respectful, knowledgeable and attuned to the needs of the child and family. Other parents will be resistant, reluctantly agree under some pressure from the referring pediatrician, and perhaps remain ambivalent about the benefit of the assessment or come to appreciate its value. For those families who refuse consultation, the consultant may meet with the team in a liaison capacity and assist the team without directly interviewing the child. If the psychiatric consultation is deemed urgent, the pediatrician should seek input from the hospital legal counsel about the appropriate way to proceed within the legal system in which he or she practices. The British Medical Association and the American Academy of Pediatrics address the issues of consent and the right to refuse treatment in persons under the age of 18 and provide very helpful guides for the clinician in practice (AAP, 1995; BMA, 2001).

Depending on the age and circumstances of the child’s condition, the consultant will decide whether to meet with the parents first, the child first or both together. Meeting with older children without a parent present at some point in the initial work-up allows them to voice private concerns that may be censored when a parent is present. Even young children may not want to say things in front of parents that they believe the parent will find upsetting. Children under 6 years may be more comfortable meeting the consultant with a parent. Because the goal is to facilitate the child being most forthcoming in talk and play, it is key to respond to the child’s preferences for the initial interview.

The parents of young children are likely to want time alone with the consultant to share observations and concerns that
are not appropriate to share in the child’s presence. Similarly, many parents of older children find it easier to be candid about their worries in the absence of the child. Older children may be uncomfortable knowing that their parents are talking to the consultant without knowing what is being said. Nonetheless, it remains key to the initial assessment to provide an interview setting that facilitates the child and parent being independently able to express feelings freely, and this goal can be articulated to the child and parent.

Assessing the Child

Premorbid Functioning of the Child and Family
When assessing a hospitalized child, the consultant is seeing only “a snapshot” out of the child’s life. Some families are confronting a new diagnosis or change in the prognosis, while others may have had time to develop an ongoing coping strategy in the face of a chronic illness or a lengthy treatment protocol. Assessment should recognize the potential for wide variation in coping at different points in the unfolding medical experience.

It may be helpful to utilize a biopsychosocial model to understand the child’s coping and family’s functioning prior to the hospitalization. Under the “bio” heading, the consultant will want to understand the particular challenges presented by the child’s medical condition and interplay of medications. Under the “psych” heading, the consultant will want to learn about depression and anxiety preceding the medical condition as well as psychological strengths and resiliency. In the “social” arena, the consultant wants to know about the child’s relationship with peers and his or her functioning at school.

Developmental Perspective
Development is an important lens through which a childhood medical illness can be seen. A full review of the interplay of development and medical illness is beyond the scope of this chapter, but a few key developmental points are highlighted to illustrate common issues.

Infants and toddlers cannot understand the gravity of a given diagnosis. They live in the moment, experiencing the medical condition and treatment according to the physical limitations and discomforts imposed. Infants rely on key caretakers to hold and soothe them and to make the hospital environment feel safe. It is important for the hospital staff to support infant-parent attachment, and not allow treatments and technologies to interfere with this key emotional milestone. The pediatric unit can provide a milieu that supports breastfeeding mothers, and allows rooming-in by parents.

Very young children (3–6 years) are egocentric (i.e., they understand all events as occurring in relation to them). They have associative logic, which means that for them any two unrelated things can be understood as if one is causing or explaining the other. The combination of egocentricity and associative logic leads to magical thinking. Magical thinking is the weaving together of fantasy and logic to explain how the young child caused something to happen. In the medical setting, it is frequently the child’s misconception that having a “bad illness” means he or she did something wrong and is being punished. It is helpful to get young children (and older children as well) to elaborate their understanding of the etiology of their medical conditions to uncover self-blaming misconceptions and correct them. When young children have a life-threatening illness, parents often wonder if the child is worrying about dying. At this age, children do not yet have the cognitive capacity to comprehend forever, and envision death as a reversible event. The young child is likely to demonstrate the most affect around separations, such as having anxiety about going to sleep at night in his or her own bed, or wanting a parent to promise to be there when they wake up from surgery.

At this age, children cannot localize a medical condition to a specific body part, so they feel particularly physically vulnerable when ill. Faced with needlesticks, intravenous medication and surgical procedures, they are often fearful. They rely on parents and medical staff to prepare them for procedures.

Older children (7–12 years) can understand simple functional explanations of medical conditions. Many will pride themselves on mastering the names of medicines, illness-related terminology and how to use hospital equipment. Children of this age look for simple cause and effect etiologies for illnesses. They can understand viral illnesses being caused by “germs,” but are perplexed when there is no clear causal explanation (e.g., why they have cancer without having smoked cigarettes). It is important to explain illness and treatment simply and clearly. In the context of understanding why a treatment plan is being initiated, the medical staff should seek the child’s assent to procedures and treatments. In this age group, “rules” and it is troubling to the child that so often medical illness does not follow the rules (e.g., the child avoids asthma triggers and has an asthmatic attack anyway). One of the challenges of working with the preteens is to capitalize on the children’s pride in trying hard and their wish for competency, while keeping them from getting too disappointed by setbacks that occur in spite of their own best efforts.

Adolescents have the capacity for abstract thinking, and thus are able to understand the chance bad luck of having an uncommon, life-threatening or chronic illness with the same cognitive complexity as adults. Education is a prerequisite for behavioral change, but on its own is not sufficient. Commonly, teenagers do not have the maturity to incorporate the consistently health-promoting behaviors they know they should engage in into appropriate changes in lifestyle. Turning cognitive understanding into behavioral change is the common battleground of adolescent and authority figure – parent or physician. Assent for medical treatments is sought from the younger child, while consent is sought from adolescents who have the cognitive ability to comprehend the purpose of treatment and the ramifications of refusing treatment (BMA, 2001). Although some physicians may view seeking consent from an adolescent for treatments and procedures as time-consuming and burdensome, knowing that parents must give legal consent to proceed, these discussions foster trust and build a valuable alliance between patient and caregiver.
Adolescence is a self-conscious time, with the emergence of sexual interests and heightened reliance on peer group norms for style and status. Medical illnesses or treatments that affect appearance are particularly difficult (e.g., becoming Cushingoid on steroids or bald with chemotherapy). The medical staff is challenged to find ways to respect the teenager's age-appropriate wish to be more independent in the face of illness that so often increases dependency.

As children with chronic illnesses live into adulthood, the transition to young adulthood and understanding of associated issues become relevant. Young adults negotiate intimate relationships, career decisions, independence from parents, and sometimes relocation or parenthood. One challenge that the treatment team and patient may face is whether to transition care from a pediatric into an adult setting, which often necessitates a new treatment team. Some patients may prefer to be on an adult ward or waiting room, but may find it very difficult to leave lifelong caretakers and the pediatric model of care.

### Specific Challenges Associated with a Given Medical Condition

Each medical condition carries its own specific challenges. When the consultant is familiar with common frustrations or limitations imposed by a particular illness, this can provide a kind of credibility in the process of acquiring a child’s and parent’s trust as they relate what is hardest for them. Routine consultation to the same pediatric unit leads to the consultant becoming familiar with technology, treatment protocols and terminology, all of which makes it easier for the child and family to tell their medical story and feel understood.

### Mental Status Examination

Hospitalized children have many reasons for an altered mental status including delirium, CNS changes secondary to medical conditions, effects of medications and trauma. A formal mental status examination should be part of the medical record including observations of appearance, gross and fine motor function, speech, mood, affect, thought, suicidal ideation, memory and cognition. By performing a mental status assessment, the consultant may uncover significant mental impairment that has gone undetected in spite of multiple specialists seeing the child.

Medically ill children may be developmentally delayed or emotionally immature. It is helpful for the consultant to integrate the information from the mental status examination and premorbid school and developmental information to assist the medical team in understanding the child’s ability to comprehend medical information.

### The Family

No child can be understood independently of his or her family. In the initial evaluation it is therefore essential to assess the family’s level of functioning and their ability to support the child in the hospital and through the anticipated treatment and outcome. During hospitalization, parents often have to cope with new and anxiety-provoking information. Information presented by multiple caregivers is common on a medical unit and may lead to inconsistencies: one person emphasizing a particular laboratory value but another devaluing its importance, one suggesting discharge is imminent but another indicating it may be many days away. Parents and older children may find these inconsistencies confusing and upsetting. Many parents identify the continuous feelings of uncertainty as the hardest aspect of adapting to the child’s illness. The focus of the uncertainty changes during the course of the hospitalization as the challenges of the treatment evolve from the time of diagnosis to the child’s changing appearance and ultimately to when will the illness recur or what follow-up is necessary (Diaz-Caneja, Gledhill, Weaver, Nadel, & Garralda, 2005). Some parents derive support from other parents on the pediatric unit whereas others report feeling further traumatized by witnessing other families in crisis. Parental anxiety and distress are associated with a child’s psychological adjustment and capacity to cope (Bonner, Hardy, Gill et al., 2006; Sawyer, Streiner, Antoniou, Toogood, & Rice, 1998; Wagner, Chaney, Hommel et al., 2003). The consultant can help the medical team be mindful of the importance of addressing the anxiety around uncertainty and facilitating consistent communication.

Asking parents to share the history of the current illness, from the first symptoms through to the present hospital stay, allows the consultant to learn about the parents’ experience of the medical care (i.e., to what extent have they felt responded to or ignored in the process of diagnosis and treatment). It is helpful to understand the parents’ views of past and present medical caregivers as well as their experience of their own role in the child’s medical condition. The stress of a child’s illness and treatment may uncover parental discord and perhaps coincide with divorce although it should not be assumed to be causal. In a recent study, the rates of divorce after a child has died from cancer were not found to be increased relative to the general population (Kreicbergs, Valdimarsdottir, Onelov et al., 2005).

An assessment of the family should include psychiatric history (including use of substances). It is helpful to ask questions about depression symptoms for each parent and the siblings. Some parents may increase their own risk-taking behavior including use of alcohol or driving with less care. Many parents benefit from being reminded of the importance of eating and sleeping so that they do not compromise their own health during what may be a long period in which the sick child will need their additional care.

The family’s experience is affected by past experiences with illness and loss. The consultant will want to know if any other family members have had the same or similar illnesses, what the experience was of their care and the outcome. Helping the parent differentiate the current medical situation from past experiences helps the parent be more attuned to the child’s actual needs.

Siblings are often the forgotten sufferers (Murray, 2002; Wilkins & Woodgate, 2005). The sick child is commonly the object of everyone’s attention and recipient of many gifts; while the siblings often live with disrupted schedules, few gifts and often absent, less emotionally available parents. The consultant...
and social worker can model important empathy for the plight of the siblings, and help parents with ways of addressing the needs of their well children.

Pediatric hospital staff members may have a harder time working with some parents than with their child. The consultant can help the team understand the family better and feel more empathy for difficult behaviors. Difficult parents often cannot bear the feelings of helplessness, and vent their anger and frustration on hospital staff by being critical and devaluing (Groves & Beresin, 1999).

**Presenting the Assessment to the Treatment Team**

After meeting with the child and family for the initial assessment, the consultant will share observations and recommendations with the referring pediatrician and available team members, and write a note in the hospital chart. The preliminary formulation and recommendations should avoid the use of psychiatric jargon. Clear practical recommendations to improve coping, address behavioral problems, treat primary psychiatric disorders and maintain safety are most helpful. Hospital records are permanent documents and should not be used for private or informal communications between clinicians. One should assume that patients and parents will read the record, as can hospital staff and insurers. No one should write pejorative comments about other clinicians, patients or families in the hospital record. The consultant should be thoughtful about including personal information about the patient or family members, avoiding what is not germane to the care of the patient, such as a past history of parental substance abuse or marital infidelity.

When presenting recommendations, safety must be addressed first and an understanding of the urgency and time frame in which the referring doctor needs assistance must be attended to by the consultant. Sharing an understanding of motivations that may underlie maladaptive behaviors can increase empathy for the child and family, but the consultant must work with the team to arrive at concrete suggestions that can be implemented by the team in order for the consultation to be experienced as valuable.

**Emergency Consultations**

The most common emergency consultations relate to the suicidal or self-abusive child. The consultant’s first recommendations focus on the child’s immediate safety, recognizing that hospital units are not designed with the safety of a self-injurious child in mind. There is potentially dangerous medical equipment throughout the unit. It is therefore necessary to assess carefully the child’s risk for self-harm in this setting. After having made an impulsive suicide attempt or gesture, some children are frightened, regret their actions, feel supported by their families and may be assessed as being at low risk for self-injury while hospitalized. Others regret that the suicide attempt was unsuccessful or are uncommunicative, leaving the consultant unsure of their mental state. When unsure, one must err on the side of safety, providing continuous observation of these children on the pediatric unit. Once safety has been assured, the consultant can assess the precipitants for the acts of self-harm and recommend appropriate treatment in the hospital and disposition (see chapter 40).

Behavior that disrupts essential medical treatment also requires immediate intervention. Such behavior may be driven by extreme anxiety, delirium, disinhibition following head injury or as a side-effect of medication use. Angry threatening behavior in a child with a clear sensorium, but who views the essential medical treatment as an unnecessary assault can also create an emergency situation. Assessment of the etiology of the difficult behavior will determine the appropriate intervention.

Parental behavior may be the reason for an urgent consultation with the mental health consultant or the team social worker. Parents may be refusing essential medical treatment for the child or acting bizarrely. The reason for the parental actions may be unclear or may be revealed to be beliefs at odds with standard medical practice, mistrust of the hospital staff, psychiatric illness in the parent or extreme anxiety. Hostile parents can interfere with critical care by frightening the medical staff. Interventions will be determined by an understanding of the etiology of the parents’ behavior and may include the appropriate use of hospital security personnel.

The consultant may be asked to interact directly with the parent to help the referring physician work with the family or to recommend further assessment, including social services or court interventions. Often, parents who are obstructing necessary care for their child are doing so because they are overwhelmed with helplessness and are trying to control what they see as uncontrollable. By helping the parent to feel that he or she is an essential member of the decision-making process and thus has some control in productive ways, many parents will step out of a combative stance and into a more collaborative one. There are specific legal interventions that are implemented when parents prevent a life-sustaining treatment, such as a blood transfusion for a child with life-threatening blood loss. These interventions are determined by the legal parameters of the place of practice.

**Primary Psychiatric Illnesses**

**Depression**

Depression is common in the hospitalized child. It may be a secondary response to the stress of acute or chronic illness, or it may be the primary presenting symptom of psychosomatic illness or behavioral problems including self-harm. Practice patterns vary from country to country (see chapter 37). One barrier to the appropriate treatment of depression in hospitalized children is the misconception that depressed mood and symptoms are an appropriate response to serious illness. Another barrier to treatment is the difficulty of making the diagnosis of depression in a medically ill child given the overlap of somatic symptoms and depressive symptoms (Shemesh, Yehuda, Rockmore et al., 2005a). Individual and family therapy, play therapy, behavioral therapy and medication are
useful modalities in the hospital setting. Our clinical experience supports the use of antidepressants for depression in the medically ill older child or adolescent. Selective serotonin reuptake inhibitors have become the antidepressant of choice as they are generally well tolerated, have limited interactions with other medications and present a lower risk of intentional or accidental overdose (see chapter 37).

Anxiety
Anxiety can be secondary to the stresses of the medical condition and treatment or be pre-existing. Children with pre-existing generalized anxiety or specific fear of doctors, needles or shots are likely to have more difficulty adjusting to medical assessment and treatment. In addition to the obvious discomfort severe anxiety causes the child and parents, anxiety can interfere with procedures and complicate history-taking and symptom assessment.

Age-appropriate explanation of medical interventions for older children, and medical play with explanation for younger children, can decrease anxiety. Children from around 6 years of age can learn a variety of coping techniques to help them with anxiety-provoking procedures. Many children will respond to distraction, breathing exercises, visualization or hypnotherapy (Butler, Symons, Henderson, Shortliffe, & Spiegel, 2005; Gershon, Zimand, Pickering, Rothbaum, & Hodges, 2004; Mundy, DuHamel, & Montgomery, 2003).

Clinicians must pay attention to minimizing pain for every child (Greco & Berde, 2005). Effective interventions including preparation, relaxation, distraction, use of anesthetic creams before procedures, and treating chronic and acute pain with analgesics, significantly reduce the amount of stress experienced by the child (Schiff, Holts, Peterson, & Rakusan, 2001; Young, 2005). For young children, all painful procedures should occur in a treatment room and not in the child’s bed nor in the playroom. Protecting the child’s bed and the playroom as safe havens helps the young child relax in these settings.

Even with quality pain management, relaxation techniques and preparation for procedures, some children will continue to be too anxious to comply with treatment and may experience sleepless nights, be nauseated or frantic during the hospital stay or in anticipation of visits to the hospital. Benzodiazepines may be helpful adjuncts for lessening debilitating anxiety. In young children, one must be aware of the potential for benzodiazepines to disinhibit children and thus worsen coping difficulties.

Anorexia Nervosa
Anorexia nervosa is characterized by significant weight loss or the absence of appropriate weight gain for age and height in the setting of distorted body image and fear of gaining weight (see chapter 41). Pediatric hospitalization usually occurs when there has been rapid or profound weight loss, cardiovascular abnormalities, electrolyte imbalance and hypothermia. The goal of pediatric hospitalization is medical stabilization with nutritional assessment and treatment, psychological assessment of the child and family, and recommendation for level of psychiatric intervention after medical stabilization (Andersen, Bowers, & Evans, 1997). If the anorexic patient has been in out-patient psychotherapy, it is important to seek input from the out-patient therapist. Medical hospitalization often represents failure of the out-patient treatment for the child or adolescent.

It is often helpful to institute a detailed anorexia protocol with very restricted activity, including bed rest, observation during and directly after meal times, bathroom privileges only after weight gain has begun, and limited phone contact and visitation with family. As the child demonstrates that he or she is able to meet nutritional goals, privileges are added. Once the child is medically stable recommendations about disposition can be initiated as outlined in chapter 41.

Pediatric and nursing staff may feel frustrated and angry at anorexic patients, whom they may see as making themselves ill. This is in stark contrast to other children on the pediatric unit who are viewed as struggling to overcome “real” illnesses. Regular team meetings provide an opportunity for staff members to voice the feelings engendered by the patient, ensure that the protocol is being instituted consistently, unify the team in providing quality and compassionate care and provide an opportunity to give consistent information to the patient and their family.

Psychosomatic Illness (see chapter 57)
Some children are admitted to pediatric units with intense persistent somatic complaints such as headaches, abdominal pains, bowel complaints, neurological symptoms or fatigue. The pediatrician may suspect that the intensity of the symptoms or the combination of complaints exceeds what can be explained by a medical condition and reflects underlying emotional factors and may thus seek a psychiatric consultation. The pediatrician’s assessment that psychological factors are influencing the somatic presentation is usually at odds with the child’s and parents’ understanding of the etiology of the condition. Often the child and parents are seen as overly invested in an exhaustive medical work-up to prove a purely medical etiology. In psychosomatic illness, the somatic complaints are an unconscious expression of emotional issues, thus the child and parents believe that the child is seriously ill and needs this work-up despite its risks.

Commonly, psychiatric consultation is resisted, because it is viewed as evidence that the medical team either does not believe the symptoms or medical condition to be “real” or is unwilling to investigate fully all the medical possibilities. It is common for the family to seek multiple medical opinions, and often to choose the most aggressive specialists (e.g., those who perform the most diagnostic testing or prescribe the most medications). Diagnostic tests may be repeated to satisfy parental demands for action or in an attempt to decrease persistent patient and parental anxiety about undetected serious illness. Parents may overvalue insignificant positive findings from the diagnostic work-ups to vindicate their belief that a yet undiscovered medical etiology exists.

Hospitalization can be viewed as evidence of more serious psychosomatic illness and may be an important opportunity
CHAPTER 70

for a coordinated care plan addressing psychological and medical issues together. The psychiatric consultant must be willing to listen to the somatic symptoms and associated medical hypotheses in order to establish an alliance with the patient and family. Presenting the consultant’s role as one of helping the child cope with chronic symptoms that are interfering with school, peer activities or family life is less threatening than suggesting that the consultant has been sought because the symptom intensity reflects psychological issues. The child and family must be reassured that the presence of the child mental health consultant will not be associated with reduced access to the medical team, but is truly an adjunct to ongoing medical care. The pediatrician has the important role of re-examining the child regularly, reassuring the patient and family that no worrying new findings exist and not acquiescing to unnecessary testing.

Non-compliance

Non-compliance with medical treatments is common, ranging from estimates of 50% to as high as 88%. Surprisingly, confidence in the efficacy and importance of the treatment does not always translate into improved compliance rates (Van Sciver, D’Angelo, Rappaport, & Woolf, 1995). However, physicians should recognize that education and an alliance with parents and children can improve patient compliance rates (Cork, Britton, Butler et al., 2003; Feinstein, Keich, Becker-Cohen et al., 2005). Furthermore, beliefs about why a medication is not adequately treating an illness also need to be addressed to improve compliance (Rubin, 2004). The impact of non-compliance ranges from essentially harmless to life-threatening. Medical non-compliance in a particular child is multi-determined, associated with medical education, active versus passive coping style, pride versus embarrassment with respect to self-care, impulsivity, family support, peer support and relationship with medical providers (Dinwiddie & Muller, 2002). It may also be a function of underlying psychiatric illness including depression, anxiety, oppositional defiant disorder and attention deficit disorder. When consultation is sought for non-compliance, usually it is because of risk to the child’s health, escalating conflict in the family or frustration with inappropriate use of medical resources.

The consultant’s task is to understand why the child is non-compliant and to work with the team to modify aspects of treatments that trouble the child where possible, while working to help the child and family adopt strategies that support clinically important treatments. Treatable psychiatric disorders need to be identified and addressed. Treatment-promoting supports – including disease-specific support groups, more frequent meetings with clinicians, and psychoeducation groups – can be helpful.

Child Abuse (see chapters 28 and 29)

In the consultation setting, it is appropriate to restate the importance of suspecting abuse. Without educated suspicion, abuse will often go undetected. Injuries to body surfaces that do not commonly bear the brunt of an accidental fall, multiple broken bones or bruises in various stages of healing, bruises that resemble finger marks, belts or cords are highly suspicious. Implausible or inconsistent stories from caretakers, and inappropriate delay in bringing a child for medical care should raise suspicion, as should caretakers who ascribe the injury to siblings or self-inflicted injuries.

Suspicion of abuse must be reported to the appropriate social agency. When abuse is suspected, the child should be fully examined for other physical signs. It is important to notify authorities of other children known to be in a potentially unsafe home. The pediatric unit may serve as a safe haven for a child while allegations are being investigated.

Coping with Chronic Illness

Chromically ill children should not be defined by their illnesses (i.e., there is no typical child with diabetes or classic child with asthma). On the contrary, chronically ill children have the same range of personalities and coping styles seen in healthy children, and are engaged in mastering the developmental milestones and challenges they share with their peers.

Estimates of psychological morbidity associated with chronic illnesses in childhood range 10–30% (Bauman, Drotar, Leventhal, Perrin, & Pless, 1997), which is only slightly higher than the general pediatric population (Barlow & Ellard, 2006). Greater morbidity is associated with multiple admissions to hospital (Geist, 1977). Other documented risk factors for adaptation to chronic illness include physical disability and brain dysfunction, pain frequency, younger age, poverty, single-parent family and increased psychological symptoms in the parents (Knapp & Harris, 1998).

Specific illnesses present unique challenges, such as the dietary restrictions in diabetes (Patton, Dolan, & Powers, 2006) or the decreased exercise endurance in advancing cystic fibrosis. However, many factors influence how problematic a disease-specific challenge is for an individual child. It is the consultant’s job to understand the unique meaning of the illness to the child and family, and to assist in the process of adaptation. Disease-specific research in common chronic illnesses can inform clinical approaches with these illnesses and can offer useful guidance for approaches to children with other medical conditions.

The consultant needs to elucidate the child’s subjective experience of the illness, such as what is the hardest aspect of the illness or treatment from the child’s perspective, how does it affect the child’s image of themself, and are there specific worries about the future? Enquiries about the impact on peer interactions, and favorite activities, areas of conflict between the child and parent or the child and physician in relation to the illness, and the child’s perception of the parents’ worries may be useful. Variations of these questions can be asked of the parents and siblings.

Chronic illness requires adjustment on the part of the child, the family, and sometimes the school, friends and organizers of activities. Efforts should be made to assist a child’s ability to continue with age-appropriate activities and special interests. Children with personal strengths – whether in academics,
Sports, music or interpersonal skills – may have an easier time accommodating to the limits imposed by the illness and treatment. Temperament can affect a child’s ability to adapt, with more flexible and outgoing children likely to bear the uncertainty and limitations imposed by illness more easily. Parental support, warmth and attitude toward the illness and the child’s adaptive style are key. Parental anxiety, anger, sadness, guilt or blame can impede adjustment (Vance & Eiser, 2004; Wagner, Chaney, Hommel et al., 2003).

**Asthma**

Asthma is the most common chronic illness of childhood, with a pediatric population prevalence of 5–10% and an increasing mortality rate from 1980 to 1998 that appears to have reached a plateau (Akinbami & Schoendorf, 2002). Racial and ethnic disparities account for much of the increase in morbidity (McDaniel, Paxson, & Waldfogel, 2006). Recent studies have sought to understand the factors that affect adherence and compliance, delineate common psychosocial stresses that may act as triggers for asthma attacks, and devise psychoeducational programs, combined medical and psychological treatment strategies, and teach stress management skills to improve compliance and decrease morbidity (Bender, 2006; Hockemeyer & Smyth, 2002; Self, Chrisman, Mason, & Rumbak, 2005; Teach, Crain, Quint, Hylan, & Joseph, 2006).

Hospitalization is an opportunity to emphasize education. Clear guidelines on when to call the pediatrician for appropriate timely guidance can be established along with seeking input from the family about barriers to these contacts. Triggers in the home can be addressed realistically and empathically in light of the exacerbation that led to admission. Common triggers, such as smoking and pets, require a major commitment from family members in order to change. School-related issues need to be explored from the perspective of the child (e.g., embarrassment associated with going to the school nurse) and the school (e.g., access to inhalers in the classroom). Strategies to improve parent and child anxiety and to address parent–child conflicts around compliance are valuable.

**Diabetes**

Adaptation to insulin-dependent (type 1) diabetes presents special challenges associated with the need for tight control of blood sugar, the primary role of food as a source of nourishment and soothing, the meaning to a parent of providing or limiting access to desirable foods, and the complexity of monitoring blood sugars and delivering insulin involving needlesticks and thus pain. The acute consequences of blood sugar abnormalities include symptomatic hypoglycemia, hyperglycemia and ketoacidosis and may lead to hospitalization. The long-term sequelae include effects on vision, renal function and neuropathy. Symptoms associated with hypoglycemia are often difficult for parents to differentiate from common irritability in young children or for older children to recognize as different from anxiety. This leads to either more frequent blood testing or a tendency to keep the blood sugars at a higher level than the physician would recommend. Some children have considerable anxiety about hypoglycemia, either in response to an actual episode or arising independently. It is key to treat anxiety disorders in order to improve compliance as well as recognize emerging eating disorders in the female teenage population as a factor in non-compliance (Hamilton & Daneman, 2002; Jacobson, 1996; Strauss, 1996).

Parents of children with diabetes may benefit from the support of the child mental health consultant as well as parent support groups to help achieve a healthy family attitude towards eating. Concrete ways to minimize the child’s experience of being deprived of popular food treats are useful, such as having sugar-free desserts at school and at home, altering insulin to accommodate special events, and supporting the child’s understanding of how insulin helps him or her grow bigger and stronger.

When patterns of conflict between parent and child around non-compliance arise (e.g., lying about foods eaten, hiding sweets and refusing blood monitoring), psychotherapeutic input should be initiated early. Family conflict is strongly related to adherence (Lewin, Heidgerken, Geffken et al., 2006). Children who enter adolescence with pre-existing parent–child conflict around health maintenance can be expected to have greater difficulty during their teenage years. Non-compliance in type 1 diabetes can be life-threatening, so the full range of psychotherapeutic, educational and family supports should be utilized. Blood testing (hemoglobin A1C) enables the pediatrician to assess the child’s compliance over an extended period and may be considered an appropriate factor for protocol-driven mental health consultation.

**Cancer**

Childhood cancer presents numerous challenges to adaptation and development, fortunately however most studies suggest that childhood cancer survivors adapt well following treatment (Kazak, 2005; Zebrack, Zevon, Turk et al., 2007). There are predictable high stress points in the course of an illness which often coincide with hospitalization including diagnosis, onset of treatment and treatment completion, as well as for some recurrence, renewed treatment and end-of-life care. Psychological support for the child and parents is particularly beneficial at these critical points. Siblings also benefit from support at the various transitions during the course of the illness (Wilkins & Woodgate, 2005).

Diagnosis of a life-threatening illness is understandably frightening to parents and older children, creating a family crisis. Some children and parents respond to diagnosis and aspects of treatment by exhibiting symptoms seen in post-traumatic stress syndrome (Stuber, Kazak, Meeske, & Baraket, 1998).

Frequently, children and families will face the child’s cancer diagnosis with past experiences of cancer in a family member, or close friend, coloring their understanding of what lies ahead for their child (Hoekstra-Weebers, Jaspers, Kamps, & Klip, 1999). It is helpful to invite the child to share his or her understanding of the diagnosis as an opportunity to differentiate the child’s situation from that of others, while potentially uncovering misconceptions about the illness.
CHAPTER 70

Challenges to psychological adaptation include persistent pain, whether as a result of the cancer or of the procedures (Ljungman, Gordh, Sorensen, & Kreuger, 1999), persistent debilitating side-effects of treatment such as nausea, alteration in body image, school disruptions, compromised peer relationships, interference with ability to engage in favorite activities and conflicts in the family. Adolescents may worry about future health status, sexual function and reproductive capacities, and future career choices (Kazak, 2005; Patenaude & Kupst, 2005). Awareness of these challenges may guide the consultant in addressing concerns and adapting treatments whenever possible.

During the course of cancer treatment, many children develop strong positive relationships with members of the medical team, experience a special closeness with supportive parents and maintain key pre-existing peer friendships while acquiring new friends in the hospital. Many children will report feeling a special sense of purpose for living as a result of the cancer diagnosis and most will be treated with special status as a result of the illness. Resiliency and positive life change are also part of the cancer experience (Woodgate, 1999).

Organ Transplantation

Liver, kidney and lung transplantation are well-established practices in the pediatric population and intestinal transplantation is beginning to be undertaken. Transplantation centers in the USA are required to include psychological assessment in order to receive accreditation. Data on criteria for approval of candidacy for transplant are vague. The serious disease process leading up to transplantation, risks of surgery, long-term medical management of organ rejection post-transplantation, threat to survival, and the vast array of medical personnel involved should place these children in the highest of high-risk populations. It is noteworthy therefore that the data on adjustment to liver and renal transplantation suggest that overall these children view themselves as healthy and competent (Karrfelt, Lindblad, Crafrood, & Berg, 2003; Mastroyanopoulou, Scere, Baker, & Mowat, 1998; Tonquist, Van Broeck, Finkenauer et al., 1999). Not surprisingly, some children and parents are vulnerable to anxiety and experience distress post-transplant (Mintzer, Stuber, Seacord et al., 2005; Shemesh, Annunziato, Shneider et al., 2005b). It is therefore important that transplant centers involve mental health consultants and provide emotional support (Ullrich, Meyke, Haase et al., 1997; Walker, Harris, Baker, Kelly, & Houghton, 1999).

Dying in Hospital

The death of a child is an enormous tragedy affecting every member of the child’s family. There is no way to protect a child or family from the unique pain of the loss of a child, but sensitive care at this difficult time may serve to lessen regrets and support bereavement. Careful attention to the child’s quality of life in the last days or hours is essential. Attending to pain, anxiety and privacy/dignity needs is key. Adapting the medical setting to allow parents to nurture the dying child within the limitations of the setting or facilitating a child’s return home to die can play a significant part in the family’s experience of the death and the subsequent bereavement (American Academy of Pediatrics, 2000).

The emotional impact on the medical team deserves careful attention in order to best preserve team members’ ability to continue to deliver quality care into the future. The grieving process of the staff warrants recognition. Some units have staff meetings including the child mental health consultant or other facilitator after every death or after those deaths that are most troubling to staff members, such as a patient with chronic disease, a trauma-related death or an unanticipated death.

Many of the hospital-based pediatric deaths occur in neonatal ICUs or during infancy. Key to supporting the family of a dying infant is respecting the infant’s full status as a loved child. This may include facilitating religious ceremonies such as a naming or christening, creating mementos such as photographs, footprints or a lock of hair, and creating the most loving situation possible for the moment of dying such as providing a private room and allowing a parent to hold the infant at the time life support is disconnected.

From age 3 years onwards, the child’s personal experience of impending death should be considered. The child should be offered developmentally appropriate opportunities to express thoughts and fears associated with dying either with words, drawings or through play. It is not uncommon for even 3- or 4-year-olds to verbalize explicit thoughts of joining dead grandparents and seeing angels, but it is also common for dying children to focus only on wanting parents with them at all times, and exhibiting a shift in behavior with more resistance to medical treatment, loss of interest in activities and food, but without any explicit verbalization of an awareness of dying.

Children of all ages, but especially younger children, are likely to take their cues about whether explicit discussion of death is permissible from parents and caregivers. When parents invite this dialog it is more like to occur. When parents signal that such discussion would be unbearable, the child is likely either not to speak about dying or to talk with a medical staff member when the parent is not present.

Child mental health consultants may help ready parents for discussions with their dying child. Asking the parents for observations about shifts in the child’s behavior may help the parents recognize that they would not be introducing a new frightening idea to the child in talking about death, but would rather be accompanying the child in the thoughts that he or she is already engaged in. Asking open-ended questions about worries, enquiring whether the child has questions that he or she is afraid to say aloud, or asking if he or she thinks about peers from the hospital who have died, may serve as invitations to begin the dialog. Reminding children that articulating worries does not make them happen may free some children who are worrying silently to speak. Many parents will feel more comfortable embarking on end-of-life conversations with a child if they are told that they can welcome the child’s questions warmly without having specific answers. “I am interested in your ideas.” “What got you wondering about that?” “Your good questions deserve good answers. I want to think
about that or talk to our minister or the doctor." These are examples of reasonable responses to a child’s existential or medical questions. In the role of child mental health consultant, one of the most useful comments in response to questions about death is to tell a child, “I don’t know what it is like to be dead, because I have never been dead. But I am always interested to hear children’s ideas about it.”

Children from age 7 onward may talk about the life experiences that they will not get to enjoy. These discussions challenge a parent’s or professional’s ability to bear the sadness of facing an untimely death as well as whether to talk directly with a child about their death (Kreicbergs, Valdimarsdottir, Onelov, Henter, & Steinek, 2004). The child may talk about not getting to attend the 5th grade, never being able to drive a car or not growing up to be a doctor or a teacher. It is often the specificity of the opportunities lost in the words of a child that is so evocative. There is a sense of privilege that one experiences in listening to children as they face the end of their lives that is as special as it is sad.

Often, children will talk about being tired of the fight against the disease and will look to parents for permission to give up. When the surviving family members can support each other in the painful process of letting go of the beloved child, believing that everything that could be done was done, and that further treatment would be unfair to the child, the final phase of dying seems more peaceful. In the setting of a long battle against an illness, it is easier to get to this difficult emotional state. In the setting of an acute event with little time for adjustment, or when parental discord interferes with the parents’ ability to grieve together, such peace is harder to achieve.

The consultant should encourage hospital staff to follow up with parents 6 months to a year after the death of a child. Parents are appreciative when staff attend memorial services and funerals, write sympathy cards and make telephone calls (Bedell, Cadenhead, & Graboys, 2001; Macdonald, Liven, Carnevale et al., 2005). Telephone calls provide an opportunity to assess the parents’ grieving and need for referral as well as help the staff member connect with the family.

**Conclusions**

Child mental health consultants must stay attuned to the changes in the field of pediatrics. Advances in pharmacology, genomics and technology offer new hope and new challenges to psychosocial adaptation. Patterns of access to consultation will need to reflect shorter hospital stays and utilization of outpatient venues. New technology, such as telemedicine, can offer novel access to consultative expertise. Research in compliancy outcomes, efficacy and quality of life become increasingly important as the financial pressures of modern medicine force the consultant to justify the value of their work.

However, many of the key features of quality consultation remain unchanged. The consultant will continue to bring to the multidisciplinary medical team the combined expertise of psychodynamic understanding, psychopharmacology, a developmental perspective on the meaning of illness, adaptation to trauma, knowledge of psychiatric conditions, behavioral interventions, and CNS influences in medical illness and as a result of medical treatment. The goal remains to answer the consultation request in a thoughtful timely fashion which respects the needs of the child, the family and the treatment team while facilitating quality of care and quality of life.

CHAPTER 70

Rubin, B. K. (2004). What does it mean when a patient says, “My asthma medication is not working?”. Chest, 126, 972–981.

Only a handful of countries have an articulated national policy in relation to services for children and young people with mental health problems. Of 191 countries sampled in 2003, 14 (7%) had produced policy in this area (World Health Organization [WHO], 2005). The vision for the future is that it will become possible to agree a clear and coherent approach to service provision, based on a growing evidence base, underpinned by a comprehensive assessment of need and in line with the core values and priorities of a given society.

This chapter offers an approach to thinking about the organization of services across a range of contexts. It will not attempt to put forward one ideal model to fit all, nor attempt a comprehensive review of existing models of provision, but will try to develop a systematic way of considering the different aspects of service organization, trying to take into consideration some of the different factors that may present particular challenges in different countries.

The topic is examined in terms of the following five key domains, which are taken to represent crucial building blocks for thinking about service organization:

1. Responding to need;
2. Understanding the evidence base;
3. Developing a workforce;
4. Ensuring accessibility; and
5. Assuring quality.

**Responding to Need**

The issues of what counts as a “mental health problem” and whose needs should be the legitimate focus of service provision are far from settled. Clearly, there should be provision for children with diagnosable mental health problems that are causing a significant degree of impairment where there are effective treatments, but beyond that there is much room for debate (for an important but controversial discussion of these issues in relation to services in England see Goodman, 1997).

An ever-expanding conceptualization of what constitutes children’s “mental health needs” has rendered the concept of children’s “mental health problems” increasingly open to interpretation. At least four groups of children with “mental health needs” are routinely referred to in the discussions about developing national policy:

1. Children and young people in difficult (and often terrible) circumstances;
2. Children at risk of developing diagnosable mental health problems;
3. Children with diagnosable mental health problems; and
4. Children with levels of impairment resulting from mental health issues that make it difficult for them to function within their community or culture.

These groups of children are sometimes discussed (Remschmidt, Belfer, & Goodyer, 2004) as if they exist in the relation to each other shown in Fig. 71.1. In fact, it may be more appropriate

---

1. For brevity from now on the terms “children” and “child” will be used to refer to “children and young people.”

---

![Fig. 71.1 Relationship of groups of children with mental health needs.](image-url)
to think of these four groups as highly overlapping but potentially distinct populations of children (Fig. 71.2). Lack of clarity when discussing the needs of the different groups can obscure the fact that different groups may be a priority for different communities and lead to misunderstandings between service developers when discussing their common commitment to services based on “needs assessment.”

**Children in Difficult Circumstances**

Definitions of “difficult circumstances” vary with national context. The estimated 14 million AIDS orphans (concentrated largely in Africa) would fall into this category, as would the 12 million children in the USA living below the poverty line, along with all those children who are in contexts of war, famine or abuse (WHO, 2005). Although child mental health services are unlikely to be the main provider for the majority, this group is likely to include those children with high and complex mental health needs who are the hardest to reach and who are an increasing policy priority in many countries (Belfer, 2004). However, it may also include children who do not have specific mental health needs (Robertson, Mandlhale, Seif El Din, & Seck, 2004). Determining the most pressing needs of these children and determining the most effective contribution of mental health provision within this group are likely to be key tasks in terms of service organization.

**Children “At Risk”**

Risk factors for developing diagnosable mental health problems include some aspect of difficult circumstances (e.g., violent environments, lack of warm family environments) but risk is also heightened by other individual and interpersonal factors such as brain injury, low birth weight, poor parental mental health, low IQ, irritable temperament, family dysfunction and the lack of a key supportive relationship with an adult (Goodman & Scott, 2005). For children identified as “at risk,” the focus for mental health provision is likely to be on how to enhance resilience. There may be key opportunities for intervention, such as when the child is born or at key transition points (e.g., starting school, changing school, leaving school). There is an argument for targeting particular groups such as children of parents with mental health problems (Falkov, Phillips, Brady, Stathis, & Finney, 2003). However, promotion of resilience may best be achieved by agencies other than child mental health specialists, such as welfare sectors creating greater neighborhood cohesion, perinatal services reducing risk of low birth weight and educational services implementing appropriate programs to promote emotional well-being and support children in times of stress.

**Children with Diagnosable Mental Health Problems**

Epidemiological data from Europe and the USA suggest that around 10–20% of children have diagnosable mental health problems (using ICD-10 or DSM-IV criteria; Goodman & Scott, 2005). There are indications of differences between countries, with slightly lower rates found in India and Norway, for example (Heiervang, Stormark, Lundervold et al., 2007; Malhotra, Kohli, & Arun, 2002), and slightly higher in Brazil, Bangladesh and Russia (Fleitlich-Bilyk & Goodman, 2004; Mullick & Goodman, 2005). There is a need both for more international epidemiological data and for greater international consensus on some broad definitions of difficulties which would allow a common language to develop that could underpin appropriate policy development (Belfer, 2004).

Some diagnosable mental health problems in children may get better without intervention (such as depression in mild forms), suggesting it may be counterproductive to rush to provide services for all diagnosable difficulties in all circumstances. For these reasons, amongst others (in particular the fact that not all current treatments are proven to do more good than harm; see p. 1160), it may be unwise to go down the route recently suggested by the American Psychiatric Association of screening all children in schools and treating all diagnosable difficulties (American Psychiatric Association [APA], 2002).

**Children with Impairment Caused by Mental Health Difficulties**

This category covers children with a wide range of difficulties ranging from enuresis to psychosis, including those with chronic and multiple difficulties and those with discrete and defined difficulties. It includes those with difficulties where there are known to be effective interventions and those presenting with problems where the best course of action is much less clear. It may also include some children who do not meet the diagnostic criteria but still have significant impairment. Angold, Messer, Strangl et al. (1998) found that 50% of children attending one US clinic did not meet diagnostic criteria, but half of these were significantly functionally impaired.

The impact of significant and impairing mental health difficulties, if not effectively treated, can be substantial. Worldwide,
suicide is the third leading cause of death amongst adolescents; major depressive disorder, often starting in adolescence, is associated with substantial psychosocial impairment; conduct disorders amongst children tend to persist into adult life and are reflected in later drug abuse, antisocial behavior and poor physical health (Broidy, Nagin, Tremblay et al., 2003). Attempts to calculate the cost to society of unresolved difficulties are still in their infancy (Romeo, Byford, & Knapp, 2006), but some figures are being estimated. The additional public expenditure on a child with conduct disorder over a 7-year period in the USA was estimated to exceed $70,000, largely in costs related to criminal behavior (Foster & Jones, 2005).

Access to Provision
Since Rutter’s seminal work in this area in the UK in the 1970s, suggesting only 1 in 10 children identified with problems warranting specialist intervention actually accessed services, further studies have suggested that it has remained the case that the majority of children and young people with significant mental health needs do not reach services (Ford, Hamilton, Goodman, & Meltzer, 2005; Green, McGinnity, Meltzer, Ford, & Goodman, 2005; Rutter, Tizard, & Whitmore, 1970).

In the developing world, access to specialist services is likely to be far more limited and for those children also in difficult circumstances access is likely to be even harder. Access is limited not just by levels of resources available, but also in many countries by alternative beliefs about the best way to understand and treat problems and the stigma associated with not providing effective specialist mental health inputs can be an unhelpful drain on resources (Shooter, 2005). One documented example is when well-meaning voluntary groups enter a country following a disaster to provide “interventions for post-traumatic stress disorder (PTSD)” that were not linked to other relief efforts and actually interfered with and undermined key initiatives (WHO, 2005). While the costs of not providing effective specialist mental health inputs can be high, it is important to remember there are also costs to providing unhelpful services.

Prioritizing Needs
Each community will have to determine its own way to resolve the tension between the needs of these different groups. In some countries this may make independent child mental health provision an unaffordable luxury when pitted against other basic needs (Robertson, Mandlhate, Seif El Din et al., 2004). Where some resources are available, then the country will need to balance the desire to put resources into mental health promotion and prevention of mental ill health (to meet the needs of the first two groups above) with the need to ensure that adequate resources are available to provide services for the most impaired and troubled children (the latter two groups above). While there is as yet no easy metric to determine what the ratio should be, the World Health Organization suggested that where resources are particularly limited, priority for funds for child mental health provision should be given to those children with existing difficulties that occur frequently (and/or have highest cost implications); cause a high degree of impairment and the greatest long-term care/cost consequences; have an evidence base for treatment; and (particularly in those countries with the most limited resources) where the difficulties can be dealt with in primary care or universal services such as schools or GPs (WHO, 2003). In such circumstances, the best that can be suggested for promotion is to encourage positive activity in terms of universal service provision that does not require additional resource allocation.

In countries with greater resources, there is more opportunity to support a range of provision. In such countries, child mental health professionals’ input can be conceptualized as being provided at universal, targeted and specialist levels. This involves supporting and working alongside universal provision to promote emotional well-being whether in schools or via primary care health workers. Targeted provision aims to promote emotional well-being in those deemed either at most risk (group 2 above) or in most need (group 1 above), with the groups being determined by policy imperatives. Here, specialist mental health professionals will work alongside workers from other sectors who take a lead in relation to the needs of these groups as a whole, such as social welfare workers and primary care staff. Specialist provision aims to support group 4 above, and can be provided at a local community level, although more rare and specialized resources may be provided at a regional or even a national level.

In planning response to “need,” however, it is important to consider the potential negative and even harmful impact of increased specialist mental health services. Mental health professionals are frequently in danger of assuming that more specialist mental health provision is unquestionably an unalloyed good. The need for more provision must be set in the context of other (sometimes competing) “needs,” such as the primary need of children to be nourished, sheltered and protected; their need not to be stigmatized or miss education; and their need not to receive inappropriate, ineffective or harmful treatment. At times, an inappropriate mental health focus can be an unhelpful drain on resources (Shooter, 2005). One documented example is when well-meaning voluntary groups enter a country following a disaster to provide “interventions for post-traumatic stress disorder (PTSD)” that were not linked to other relief efforts and actually interfered with and undermined key initiatives (WHO, 2005). While the costs of not providing effective specialist mental health inputs can be high, it is important to remember there are also costs to providing unhelpful services.

Understanding the Evidence Base
The arguments for trying to promote evidence-based service development are compelling. Natural biases in reasoning mean that people tend to make decisions based more on things that fit their assumptive world view than those that challenge it and are more influenced by the charisma of those promoting a particular approach than by evidence for its effectiveness (Garb, 1997; Kahnemann, Slovix, & Tvmersky, 1982). When the evidence base is not used as the basis for service development, it makes it more likely that seemingly plausible but ineffective and/or harmful interventions may be introduced or continued and that new interventions that have been shown to do more good than harm may never be introduced (Muir Gray, 2001).
As yet, few services have been developed on the basis of considered evidence. This may in part be because of a lack of effective dissemination of evidence and a lack of effective means of supporting implementation (Woolgar & Scott, 2005). However, a major limiting factor remains the sheer lack of relevant evidence, and the difficulties of agreeing the meaning of what is there, despite huge strides in recent years.

The shortcomings of the evidence base in relation to child mental health interventions generally will not be analyzed in detail here – an overview can be found elsewhere (Fonagy, Target, Cottrell, Jeanette, & Kurtz, 2002) – but five key areas of limitation of particular relevance when looking to the evidence base to underpin service development should be highlighted.

The first, most obvious, problem is the sheer paucity of high-quality research. Even in the most extensively researched area in relation to child mental health service provision (exploring which interventions work in controlled conditions) studies are limited. There is even more limited research activity in relation to key questions about service design itself. This partly reflects the difficulty of designing studies that are rigorous, feasible and meaningful in this area.

The second key limitation is that the vast majority of service-related research so far conducted has been produced in the West, and the majority of this in the USA. The question is how far these findings can be generalized to other contexts, particularly those with very different cultural backgrounds and traditions (Hackett & Hackett, 1999).

The third key limitation is the lack of agreement as to appropriate outcomes to use to evaluate services. There is an emerging appreciation of the need to look at outcomes from a range of perspectives and across a range of domains (Kazdin & Kendall, 1998; Wolpert, Bartholomew, Domb et al., 2005a). However, there is as yet no consensus as to how to weigh the different outcomes that might arise from these different perspectives or across different domains. Thus, there is no agreement as to which type of outcome should be regarded as most important (e.g., change in symptoms, social adaptation, experience of care, or some other dimension) nor whose view should be prioritized where views differ (e.g., child, parent, practitioner or others). The issue of how to make valid comparisons across studies where different outcomes have been used is yet to be resolved (Weisz, Chu, & Polo, 2004).

Fourthly, there is inevitably a complex interaction between the emerging evidence base and the political priorities and preoccupations within a given country, both in terms of which topics are funded to be explored and in terms of the credence given to any findings that emerge. The pressure to implement a favored policy before it has been formally evaluated can mean that attempts to establish meaningful evaluation may be compromised (Rutter, 2006).

Finally, the way research is funded and the resources available for this from different groups may also crucially shape the nature of the “evidence” available. The financial resources available to pharmaceutical companies, for example, mean that disproportionately large amounts of research are carried out on “drug trials” as opposed to comparing different forms of psychological intervention.

Bearing these limitations in mind, the evidence will be considered in terms of how far it can contribute to answering two key questions:

1. “What interventions should be prioritized?”
2. “What organizational structures should be prioritized?”

What Interventions Should be Prioritized?

Attempts are starting to be made to summarize the existing evidence base to make it more accessible to practitioners and service developers. Table 71.1 offers an attempt to summarize some of the key findings in relation to interventions for children with diagnosable difficulties drawn from Goodman & Scott (2005) and Wolpert, Fuggle, Cottrell et al. (2006).3

The implications for service design might at first sight appear to be straightforward: that the interventions in the left-hand column of Table 71.1 should definitely be offered, those in the middle column should be at least considered and those in the right-hand column should be discontinued. However, caution must be exercised. No matter how rigorous the process used, any attempt at summary of the evidence will inevitably involve delicate judgments in determining what conclusions it may be appropriate to draw from existing studies. As alluded to above, much current research is flawed and limited. Any summary will need revision in the light of new evidence as it emerges. Moreover, even for the most well-designed studies, the evidence for the applicability of research findings to other contexts remains mixed. Research that looks at the impact of services using routine clinical practice, even where that could be anticipated to be relatively independent of context (such as when medication is prescribed), generally find lower effectiveness than is indicated in the studies informing Table 71.1 (MTA Co-operative Group, 1999; Weisz, Donenberg, Han, & Weiss, 1995). This difference may be because of differences in the populations of children seen, types of interventions made and/or outcomes assessed (Kendall & Southam-Gerow, 1995). Outcome-focused intervention studies are generally conducted with controlled groups of children in academic settings, so the relevance of any findings for children from different cultural backgrounds with complex overlapping difficulties needs to be established (Murray, Fayyad, Jensen et al., 2006); moreover, the role of non-specific factors such as therapeutic engagement, expectations of change and therapist warmth may need to be taken into account (Jensen, Weersing, Hoagwood, & Goldman, 2005).

It is hoped that as the evidence base develops so too should the sophistication with which it might be interrogated. For every intervention listed as having “good evidence” to support it, the following questions should be asked (modified from Kazdin, 2004, p. 113):

1. What are the costs, risks and benefits of this intervention relative to no intervention?
2. What are the costs, risks and benefits of this intervention relative to other interventions?
What are the key components that appear to contribute to positive outcomes?

What parameters can be varied to improve outcomes (e.g., including addition of other interventions, non-specific clinical skills)?

To what extent are effects of interventions generalizable across: (i) problem areas; (ii) settings; (iii) populations of children; and (iv) other relevant domains?

We are a long way from being able to answer these questions in relation to the majority of interventions in child mental health.

It is likely that more sophisticated models are going to need to be developed to allow such analysis. Current metrics available to compare financial costs and benefits for example include quality adjusted life years (QALYs) and disability adjusted life years (DALYs). These are based on adult populations and are thought to dramatically under-represent burden related to conditions such as attention deficit/hyperactivity disorder (ADHD), conduct disorders and learning disorders (Remschmidt, Belfer, & Goodyer, 2004).

Weighing mental health promotion initiatives against interventions for those with existing impairments may require particularly careful analysis. The evidence base for prevention and promotion programs is discussed in depth elsewhere in this volume, but it would appear that while there is evidence that such programs may promote emotional well-being (Barnes, 1998), research to date has not proved that this will reduce levels of significant disturbance and thus impact on specialist services, nor that such programs are necessarily the most effective approach (Harrington & Clark, 1998; McLellan, MacMillan, & Jamieson, 2004).

Similarly, the evidence base for in-patient provision is unclear (Offord, 2005). Examples of well-researched alternatives to in-patient care are now emerging that suggest viable opportunities for effective treatment for even the most disturbed and disturbing groups without the need for hospitalization (Hewson, 2002). However, it should be noted that these are not necessarily any cheaper than in-patient provision (Baruch & Cannon, 2006).

One clear inference that can be drawn from current evidence is that it makes sense to start by decommissioning ineffective interventions. Unstructured work for conduct disordered young people is still prevalent despite evidence of its ineffectiveness and even potentially harmful effects. More effort should perhaps go into stopping unhelpful interventions than currently.

What Organizational Structures Should be Prioritized?

The Fort Bragg study (and the subsequent Stark County study) conducted by Bickman et al. in the USA (in 1995 and 1999, respectively) perhaps warrants particular attention as it generated such high levels of interest and controversy. This study evaluated a large-scale system change project designed to improve outcomes by providing an unrestricted set of coordinated inputs from a range of services. Results were compared with other sites using traditional services. Information was collected on service use, cost, satisfaction, clinical and functional data over the course of the 3-year study and at follow-up since.
The study found greater access and increased rates of satisfaction and less use of in-patient services, but no differences in behavioral-emotional functioning overall and the cost was much greater at Fort Bragg. The subsequent Stark County study also found that a multiagency system for care led to no significant difference in clinical outcomes when compared with routine services (Bickman, Summerfelt, Firth, & Douglas, 1997). Bickman, Lambert, Andrade et al. (2000) concluded: “The current national policy of large investments in systems of care infrastructure is unlikely to affect children in the manner intended ... we need to focus on the services or treatments themselves to improve outcomes” (Bickman, Lambert, Andrade, & Penaloza, 2000).

This conclusion has been hotly contested. Flaws in the study design, implementation and interpretation have been pointed out (Friedman & Burns, 1996; Mordock, 1997; Saxe & Cross, 1997). It was argued that services were overwhelmed in the early months and provided less effective interventions, that the researchers failed to take account of some of the positive outcomes on some of the measures used and so on. It has been suggested that there is evidence that “wraparound services” (whereby a range of services are provided in a coordinated fashion to children and families based on their needs and not those of the services) do produce better outcomes and that the poor results above may have been a result of lack of fidelity to this model (Bruns, Burchard, Suter, & Force, 2005).

There is some evidence that shared understandings at the highest level and pooled budgets seem to be crucial to positive multiagency collaboration (Robinson, Anning, Cottrell, Frost, & Green, 2004). “MHSPY” in the USA is an initiative that involves five public and two private agencies that have come together with blended funding to provide a coordinated approach to focus on a group of “at risk” and ill children and where outcomes look positive, although lacking a control group or clear cost-effectiveness data as yet (Grimes, 2004).

It can be hypothesized on the basis of the current evidence that integral to creating joined up services may be the ability for state departments, or their equivalent, to agree joined up policy (rather than diverting resources into costly service reorganization). Thus, clear and shared agreements about protocols around information sharing, prioritized outcomes and agreed child protection arrangements are crucial, although often sadly lacking. The indications are that a key aspect is continuity of intent, reflected in a “shared mission through both administrative and clinical aspects of the system” (Grimes, 2004, p. 38).

There is little evidence available currently to guide service developers as to the best way to structure services in relation to a number of other key issues, such as what age group of children should be seen by different services; is it best to structure services around particular problems or around different age groups? In the light of lack of evidence and the fact that whichever way services are organized boundary issues arise, whether across age groups or specialisms, it may make sense to see the onus as being on service providers and developers to ensure that they work meaningfully across divisions rather than trying to create an ideal service structure. It may be hypothesized that, here too, non-specific factors are likely to be relevant. Thus, strength of the commitment of service providers to a particular shape of service and the ability of key individuals to collaborate across whatever boundaries are inevitably created, may impact as much, if not more, than the specifics of different forms of service structure.

**Building a Workforce**

The international literature has traditionally discussed child mental health workforce issues largely in relation to numbers of child psychiatrists. This may reflect the fact that in many countries, such as those in Europe, systems of care often developed in close conjunction with adolescent and child psychiatry as a specialty and as part of the health sector. However, increasingly research and policy highlight the importance of the input of a range of possible groups in relation to child mental health provision (Hansen, Litizelman, Marsh, & Milspaw, 2004; Homonoff & Malitz, 1991).

Schools are recognized as perhaps the most influential place in relation to help seeking and efforts are being put into training education staff to recognize and work with mental health difficulties (Remschmidt, Belfer, & Goodyer, 2004). Some promotion programs in schools are showing positive results in terms of emotional well-being and academic performance, such as the international FRIENDS program and the Roots of Empathy in Canada (Weare & Markham, 2005; Wyn, Cahill, Holdsworth, Rowling, & Carson, 2000). However, care must be taken not to overload schools and there is likely to remain a need for more specialist and health-focused provision for some children.

Pediatricians often work with some of the most difficult and complex children with a range of behavioral and psychological needs, particularly in the younger age range. In some European countries, such as Austria, Finland and Germany, links between pediatrics and child mental health services are particularly strong (Rydelius, 2004). Other health workers, such as health visitors in the UK who work as part of the primary care system working with mothers and babies in the early months and years, and primary care workers in India, have been found to have a positive impact as part of mental health initiatives (Davis & Spurr, 1998; Nikapota, 2002). In the developing world, the ability to engage a workforce that also links with relevant belief systems of the community, such as traditional healers, ayurvedic treatment and yoga, may be crucial and the use of extended networks of informal and formal sources of support can be of great benefit (Robertson, Mandhlate, Seif El Din et al., 2004; Thara, Padmakari, & Srinivasan, 2004).

There have been a number of attempts to agree a common framework for assessing and understanding difficulties across different sectors. Some specialist assessment tools have been developed, such as the Child and Adolescent Psychiatry Assessment (CAPA; Angold & Costello, 2000) and the Development and Wellbeing Assessment (DAWBA), which can be filled in...
CHAPTER 71

over the Internet (Goodman, Ford, Simmons, Gatward, & Melzter, 2003). However, national consensus as to the key items of information to collect has been hampered by professional disagreement about the appropriate conceptual model and approach to adopt. It is hoped that a consensus view of typology emerges that will allow enough agreement in the future for a common assessment approach to be used across child mental health.

In terms of the key staff to provide specialist mental health provision, while there is much assertion and rhetoric there is in fact very little hard evidence as to what form an ideal workforce should take, although some attempts are now being developed to model extent of need for specialist staff based on calculations of the amount and types of input required for particular difficulties (Goodman, 1997; Kelvin, 2005).

Traditionally, training of specialists in relation to mental health, on top of any core professional training, has been undertaken according to theoretical models. Thus, people are trained in “family therapy,” “play therapy,” “psychodynamic psychotherapy,” “cognitive–behavioral therapy” and “group therapy” to name a few. This has meant that when people come to practice they often come with an allegiance to a particular theoretical model and belief system.

It is perhaps not too fanciful to speculate that what is called for is a different sort of specialist training, built not around allegiance to models of therapy but founded instead on a commitment to act on the best available research and evidence base, drawing on a range of models and approaches, as appropriate, and an ability to review options in the light of emerging evidence. This is perhaps starting to emerge in some countries as training for new members of the workforce – variously termed generic child and adolescent mental health workers – is starting to be developed. This initiative might usefully be advanced by specific training for support staff to become expert in particular evidence-based interventions such as specialized providers of parent training.

Even allowing for any shifts in training approach, the accepted wisdom is that multiprofessional teams and multi-agency working will remain the way forward (Department of Health, 2004; Stroul & Friedman, 1986). The idea is that complex problems need the combined expertise of specialists which can best be provided as part of a team and that by bringing different agencies together the necessity for individual children and families to negotiate their way through a variety of systems is reduced. However, these assumptions remain largely unproven. The amount of time necessary to promote effective team building and the degree of anxiety that can be created between team members in clarifying their different roles and responsibilities may use up precious resources and reduce capacity to carry out direct clinical work. More empirical research in this area is needed.

In most countries, specialist mental health professionals are perceived as a scarce resource. Figures are generally quoted for psychiatrists. Worldwide, the availability of psychiatrists varies from 1:5300 in Switzerland to 1:1 million in China and even greater ratios in parts of the developing world. Sometimes, lack of psychiatric provision is more a result of inadequate distribution of resources, with psychiatrists working mainly in academic institutions in large urban centers. This appears to be the case in parts of South America (Rohde, Celia, & Berganza, 2004). Figures for other professional groups are harder to come by but it is likely that similar issues pertain. Staff shortages, particularly in the developing world, are exacerbated by the brain drain – there are more Indian psychiatrists working in the USA than in India (WHO, 2005).

In those countries where key professionals are an expensive and limited resource, policy seeks to ensure more equitable distribution of specialists and/or adopt a cascade approach whereby most senior mental health professionals spend most time in consulting and training others, such as in Bosnia (Shooter, 2005). This can be achieved via a range of means such as telephone or video links (Pesämaa, Ebeling, Kuusimäki et al., 2004).

Where resources are in particularly short supply, opportunities can be explored for mental health provision to piggyback on other sectors with more provision, such as HIV programs in Africa (Robertson, Mandlhate, Seif El Din et al., 2004). Models of very rapid professional training for primary care staff and training of traditional healers or educational support personnel have been promoted as attempts to improve mental health provision where specialist input is lacking (Robertson, Mandlhate, Seif El Din et al., 2004). However, research highlighting the importance of fidelity to model in terms of efficacy of interventions indicates that there may be a necessary threshold of amount of training combined with ongoing organizational support for subsequent interventions to be effective (Scott, 2004).

Even in the industrialized West it may be relevant to look to develop new workforces to extend capacity, such as by the use of support staff, technicians and volunteers. Models of encouraging family members to train as key workers are now being piloted in a range of contexts worldwide (US Department of Health and Human Services, 1999).

Ensuring Accessibility

Promoting Accessibility via Service Location
Wherever child mental health provision is located (either geographically or in terms of overarching management systems) boundary issues arise. Thus, age cut-offs, balance between regional and local provision and whether child mental health provision is located mainly within children’s services generally or as primarily linked to adult mental health, vary across countries. In parts of Europe – such as Switzerland and Hungary – and in Egypt, child mental health services are primarily organized under the auspices of education. This has many advantages for younger children in terms of reducing stigma and increasing accessibility, but can increase difficulties of coordination for older adolescents and those with more severe mental illness. Countries have dealt with boundary issues in a variety of ways. In Australia and New Zealand, there is
a deliberate 2-year overlap between youth and adult mental health service provision to try to help encourage flexibility for young people in this transitional age group (18–20 years; Hazell, 2005). In Finland, in-patient units for under-11-year-olds are located wherever possible nearer pediatric resources and those for adolescents nearer adult mental health provision (Piha & Almqvist, 1999). There is increased attention internationally to the need for services to be meaningfully linked across a range of sectors including the criminal justice system, substance abuse services and religious networks (Belfer, 2004).

**Promoting Accessibility for the “Hard to Reach”**

There is an increasing preoccupation with how to ensure that the most marginalized groups or communities in a given society can access services. As discussed above, attempts to make provision more accessible as well as less stigmatizing to these groups can include use of education and primary care workers, community and religious leaders, and family networks.

The work of voluntary organizations can be a source of innovation and energy, and communities need to find ways for statutory services to learn from them. For example, the walk-in community center Empilwent, South Africa, pioneered a more accessible drop-in approach (WHO, 2005).

There is currently a call for services to become more culturally competent, and widespread consensus on this aim, but it is unclear as yet what a culturally competent service would be like. Although there is a welter of innovative attempts to make services more culturally sensitive and appropriate, the evidence of the long-term impact of these initiatives is as yet limited (Nikapota, 2002).

**Promoting Geographical Accessibility**

It could be argued that child mental health services have been slow on the whole to “get out of the clinic” and in particular to embrace the impact of new technologies that might increase access. However, some interesting innovations are developing. These range from mobile services, such as the peripatetic child mental health team which travels across Germany providing, amongst other things, follow-up on previously hospitalized young people (Remschmidt, Belfer, & Goodyer, 2004) to increased use of telephone, Internet and text contact generally.

Telephone helplines such as KidsHelp in Australia, Childline and YoungMinds Parent Information Service in the UK are run by charities independent of statutory provision but it may be that greater links can be made between such resources and more traditional services in the future. Telefono Azzuro, Italy, shows the way these can be combined with other provision (Caffo, Forresi, Belaise et al., 2004).

A range of websites have been developed by and for young people, some of which allow for discussions between young people, and others offer access to specialist advice and support (e.g., ru-ok.com). The use of emails and text messaging to communicate between professionals and young people is now increasing, as is the use of IT aids to assessment and treatment. The pace of innovation in this area is likely to accelerate sharply in the future.

**Assuring Quality**

Whatever organizational structures a society adopts and whatever workforce is in place to provide services, systems need to be put in place to ensure quality of provision, promote best practice and allow for change in practice in the light of increased knowledge and future policy imperatives.

A key dilemma for policy-makers is how to get the right balance between centralized and devolved decision-making in relation to service development. Too great an attempt to control all aspects of service organization from a national center is likely to lead to unwieldy bureaucratic decision-making, while too much devolution to local decision-making can lead to huge variations in type and quality of services. There is no clear solution to this tension. One approach is to try to ensure that, where decisions are devolved to agreed geographical units (accountable to local populations), those charged with decision-making have the necessary skills and resources to enable them to plan and develop services in line with best evidence, in line with national guidance, and are able to implement effective performance management arrangements.

One mechanism of quality assurance is to set standards to ensure that key activities are undertaken. Services may then be evaluated by inspectors to ensure compliance and a variety of incentives and penalties can be applied. However, real problems are presented by the danger of perverse incentives, as activity can easily become skewed. In an effort to meet waitlist targets, for example, other crucial activities may be neglected.

National (and international) guidelines can be used to shape practice. Different countries have developed systems to sift the evidence and pull together consensus statements to guide and inform practice (e.g., National Institute of Clinical Excellence in England, American Psychiatric Association Practice parameters in the USA). The danger remains of overprescription on a very narrow evidence base and the possibility that the implementation of poorly understood guidance may be every bit as distorting as inappropriate targets. Some countries have sought to overcome this by stressing that guidance is advisory only. For example, in New South Wales, Australia, model care packages for adolescents with severe problems are outlined. These include one 90-min family-orientated mental health assessment and six 45-min family-orientated community contacts. The aim is to inform service planning, not prescribe or proscribe clinical work (Hazell, 2005).

Some of the most successful initiatives involve collaborations between service providers to promote best practice and disseminate and share information. Organizations such as the International Association for Child and Adolescent Psychiatry and Allied Professionals (IACAPAP) have done much to promote sharing of the latest research, and more formal peer review groups have also been established whereby members agree standards and undertake peer monitoring and evaluation, such as the Quality Network for Inpatient Care in the UK (Royal College of Psychiatrists: College Research and Training Unit).

It is increasingly recognized that for tacit complex knowledge, as is likely to underpin best practice in child mental health,
CHAPTER 71

having face-to-face meetings and encouraging learning collaborations are likely to be more effective than circulating written information alone (Office for Public Management, 2000). A number of countries distribute awards for best practice in child mental health – although the impact of these on quality is as yet unknown.

In order to ensure that child mental health services develop into self-reflective and learning organizations, allowing for future development and innovation, providers must have feedback about their current outcomes. This requires functioning IT systems and a core dataset (Tingay & Stein, 2004; Wolpert, Thompson, & Tingay, 2005b), but even in the most developed countries, the promise of coherent IT systems remains more a hope than a reality. It is key that IT systems are developed that are capable of supporting decision-making by providing easy access to information for practitioners so that they can obtain feedback on their work and learn accordingly.

While in no country in the world are there data systematically gathered for the assessment of child and adolescent mental health service outcomes at a national level, some encouraging national and international collaborations are emerging. The CAMHS Outcome Research Consortium (CORC; chaired by the author) is a collaboration between over half of all services across the UK who are implementing an agreed model of routine outcome and have agreed ways to present the data in order to inform service providers and users and to help inform service developments (Wolpert, Bartholomew, Domb et al., 2005a). The approach has parallels with that being employed in the USA (Ohio; Brower, 2003). In all cases, a small suite of measures is completed by service users and providers at initial contact and at some time later.

There is an increasing policy emphasis on the need for service users to inform service development priorities and to be part of any evaluation of services. Some innovative models have been tried, such as in Ohio, which has created outcome systems from a service user perspective, and in parts of the UK where young people are trained as service evaluators (“Investing in Children”, Durham County Council, UK), although, once again, the impact of these on quality of services is yet to be researched. There are also increasing attempts to inform service users about different options so that they can make informed choices. For example, the current author and colleagues have recently produced a small booklet which sets out to summarize the evidence base for different interventions for children and young people – this is freely available from ebpu@annafreudcentre.org/ebpu (Wolpert, Goodman, Raby et al., 2007).

Conclusions

There is no one ideal model for organizing services, but some key themes can be highlighted. It is helpful to start with an analysis of the range of anticipated needs, and to seek clarity at a policy level as to the current priorities for a given community. Where resources are limited, specialist mental health provision should be targeted foremost on those with greatest levels of impairment for whom there are available effective interventions. Implementation of effective models of prevention and promotion should be supported in so far as resources allow, but in the light of the current limited evidence base and likely resource constraints, providing treatment for people with existing difficulties should be seen as the highest priority. It is anticipated that the evidence base will grow and that while it is likely to continue to generate as many questions as answers, the emerging findings may increasingly guide practice, particularly in relation to decommissioning ineffective or harmful strategies. Signs of a shift in the professional culture for child mental health specialists have been noted, as they start to adopt a more evidence-based and an outcomes-focused world view and move away from firm allegiance to theoretical belief-based models. The range of innovative models of services, making increasingly good use of the new technologies and supported by increasingly mature collaborations and networks, may aid further the development of reflective, high-quality and accessible provision. Tension is likely to remain, however, between allowing for child mental health specialists’ creativity and innovation on the one hand and the increasing emphasis on the importance of fidelity to model and shared arrangements around initial assessments and outcomes on the other. How this tension is played out over the coming years may well determine the future shape of services for some time to come.

Acknowledgments

References

Primary care is the first point of contact for families seeking professional attention for health problems. It aims to clarify demand, diagnose disorder, offer information, advice, treatment and rehabilitation and coordinate care with other disciplines and sectors over time (Boerma, 2006). The relevance of primary health care to mental health has been highlighted, with emphasis on the need to enhance its central role and to build capacity, to reduce the global burden of suffering and impairment from mental and behavioral disorder (WHO, 2001, 2005). It offers scope for prevention and early intervention. The role within child and adolescent mental health has been less well documented but evidence is slowly accumulating, much of it from developed countries.

The chapter begins by describing different models of pediatric primary care service delivery. The relevance for child and adolescent mental health is then discussed in relation to the core roles of primary care. The mental health research literature on different age ranges (preschoolers, school-aged children and adolescents) and important disorders (depression, somatization, attention deficit/hyperactivity disorder [ADHD], behavioral problems) is considered as it pertains to the core primary care roles. Finally, the need and means for expanding capacity with future directions are discussed.

Primary Health Care Services for Children and Adolescents

Primary health care services across different countries vary widely in terms of setting, staffing, funding source and levels relative to the size of the population. Those for children and adolescents are delivered by a range of physicians (general practitioners/family physicians, general and community pediatricians) and non-physicians (nurses, health visitors, public health workers). They are based in primary care clinics, health centers, child health clinics, school medical services, emergency departments and ambulatory hospital/out-patient departments. Funding may be private, on the basis of insurance, or part of centrally organized national or regional health services.

A European survey demonstrated that 35% (12 of 34) of countries who took part had a system of pediatric primary care provided by pediatricians, 18% (6 of 34) by general practitioner/family doctor systems but the majority (47% or 16 of 34) had mixed systems (Katz, Rubino, Collier, Rosen, & Ehrich, 2002). Level, type and quality of care varied widely, with only 40% of countries having community pediatricians (defined as those concerned with recognition, prevention and treatment of community health problems such as child protection, children in need, behavior problems, teenager approach, growth and development, school medicine). Postgraduate training in pediatric primary care was available for the majority but not for all pediatric or family medicine trainees and levels of training in child protection were much lower, particularly for family medicine trainees.

Within the USA, both pediatricians and family physicians provide pediatric primary care. However, increasingly over the last 20 years these services have been provided by pediatricians (Freed, Nahra, & Wheeler, 2004). Particularly in more affluent areas, services often integrate well care and acute care. In many other countries, preventative services are offered in different settings from those providing acute illness care (Cheng, 2004). In contrast, in Canada, pediatric primary care is provided largely by general practitioners and public health units. In many developing countries, public health workers provide the point of first contact with health services and pediatricians provide specialized Western-type medical care (Cheng, 2004). Thus, globally, the differences in level of provision, structure of services and competencies of personnel delivering the services are important and likely to impact on the potential to provide mental health services for children and adolescents within the primary care setting. In addition to the nature and distribution of primary care services, this potential will be determined by patterns of attendance (i.e., who uses the service, how frequently and the nature of their needs).

Primary Care as a First Point of Contact for Child and Adolescent Mental Health Problems

Frequency of Contact

Contact with primary health care is a common experience in childhood. Over the course of 1 year, most parents take their children to primary care services, and work with children has been estimated to occupy one-quarter of the doctor’s
time. There are age trends, with young preschool children being seen more often than older children. Within the UK, over 90% of preschool age children and about two-thirds of 5- to 14-year-olds will consult primary care at least once a year (OPCS, 1995). A study of a large London inner city practice demonstrated that over 50% of 13- to 17-year-olds who were registered had attended in 1 year (Kramer, Illife, Murray, & Waterman, 1997). Within the USA, it has been reported that more than 70% of adolescents see a physician at least once a year (Frankenfield, Keyl, Gielen et al., 2000). This suggests a significant potential for attention to mental health within this context.

Modes of Presentation

The majority of the consultations are for physical health problems. Surveys in various countries have documented that 2–5% of children and adolescents attending primary care or general pediatric clinics present primarily for psychological problems (e.g., anxiety, behavioral problems and overactivity; Garralda & Bailey, 1986; Jacobson, Goldberg, Burns et al., 1980; Kramer & Garralda, 1998; Starfield, Gross, Wood et al., 1980). Higher rates of 10% for emotional–behavioral presentations have been given in some reports. Educational and social problems also feature as reasons for consultation.

Frequency and Nature of Associated Psychiatric Disorder

There is evidence that psychiatric disorders are present in a considerably higher number of children attending primary care than may be expected from the overt presenting complaint. Research interviews with children and parents, following primary care contact, have found disorders in one-tenth to one-quarter of children across different countries (Costello, Costello, Edelbrock et al., 1988; Garralda & Bailey, 1986; Giel, de Arango, Climent et al., 1981; Gureje, Omigbodun, Gater et al., 1994), with higher rates in adolescents (40%; Kramer & Garralda, 1998) and in schoolchildren attending hospital pediatric out-patient departments (28%; Garralda & Bailey, 1989). Although the range of disorders is seen, in contrast with population surveys, emotional disorders predominate over conduct disorders (Garralda & Bailey, 1986; Kramer & Garralda, 1998), suggesting a specific role for primary care in identifying and managing anxiety and depressive disorders. In the UK, levels of depressive symptoms in adolescents attending primary care have been shown to be high in both urban and suburban areas (with significantly different levels of psychosocial disadvantage), reinforcing the relevance of primary care for adolescent depression across socioeconomic groups (Yates, Kramer, & Garralda, 2004). This study found that the presence of depressive symptoms in adolescents was associated with an increased risk of substance abuse and with parental psychiatric symptoms, while a study in the USA found links with school problems and substance abuse (Burns, Cottrell, Perkins et al., 2004). These associations suggest that identification of psychopathology within primary care will provide an opportunity to identify and address a wider range of psychosocial difficulties.

Implications of the High Levels of Hidden Psychiatric Disorder

Do psychiatric disorders contribute to physical consultations in children and young people? Psychiatric symptoms have been found to be linked to high use of primary care and of other medical services by children and young people (Lavigne, Arend, Rosenbaum et al., 1998; Meltzer, Gatward, Goodman, & Ford, 2000; Monck, Graham, Richman, & Dobbs, 1994; Offord, Boyle, Sztamari et al., 1987; Richman, Stevenson & Graham, 1982; Yates, Kramer, & Garralda, 2004). Adolescent primary care attenders with associated psychiatric disorder describe greater frequency and more intense physical symptoms causing impairment than those without associated disorder (Kramer & Garralda, 1998). Children with psychiatric disorders who are frequent primary care attenders do not present with a particular physical problem. Nevertheless, their mothers view them as more lethargic, in poorer general health and more handicapped by their symptoms than mothers of frequent attending children without psychiatric disorder (Garralda, Bowman, & Mandalia, 1999).

In younger children who are brought to the surgery, maternal anxiety about the child is likely to be a factor leading to presentation. In a study of frequent surgery attenders (Garraula, Bowman, & Mandalia, 1999), mothers of children who had psychiatric disorders reported generally more stress in work, finances and relationships. However, what differentiated them most strongly from other mothers was the stress they felt about their child; over half of the mothers of children with disorder (compared with 10% of those without) felt highly stressed about them. Because they also saw these children as in comparatively poor physical health, it would seem logical to seek relief from this by focusing on symptoms for which help is available at the surgery. Nevertheless, this relief may be expected to be only partial, as it does not address the reasons that were presumably stressing mothers most and leading to frequent consulting, namely the child’s psychological distress and its management. Primary care practitioners could be more helpful to the child and mother if attention was directed directly to these associated emotional difficulties.

Functional Somatic Symptoms and Psychosomatic Presentations

Addressing mental health issues is of special relevance in the primary care setting, first for children presenting with recurrent and impairing functional or unexplained medical symptoms; and, second, when clinicians suspect that problems in psychiatric adjustment affect the child’s ability to manage physical problems effectively.

Recurrent unexplained functional physical symptoms (e.g., abdominal pains, aches and pains, and fatigue) are commonly seen in primary care. They can be an expression of the somatization of distress and are often seen in conjunction with psychiatric disorders (see chapter 57). Campo, Jansen-McWilliams, Comer et al. (1999) reported frequent complaints of aches and pains with no organic diagnosis in 2% of 11- to 15-year-old pediatric primary care attenders, and occasional
complaints in 11%, with a ratio of two girls to one boy. In about half of the children – significantly more than in children attending with other complaints – doctors and parents identified psychosocial problems and impairment caused by the symptom, and about one-third were described as frequent health service users. In 8- to 15-year-olds with recurrent abdominal pain attending primary care, Campo, Bridge, Ehmann et al. (2004) identified a comorbid anxiety disorder in as many as 79% and a depressive disorder in 43%, as well as an excess of temperamental harm avoidance and functional impairment. The close links between emotional and functional physical symptoms in children is further supported by indications that parental anxiety in the first year of the child’s life, together with reports of irregular feeding and sleeping habits in the child, can predict recurrent abdominal pains later in childhood (see chapter 57; Ramchandani, Stein, Hotopf et al., 2006).

Psychosocial problems and psychiatric disorders can adversely affect the physical health of a broader group of children. When doctors are asked to note any physical presentation with associated or contributing psychological factors (e.g., asthma exacerbated by stress), such presentations are recorded for about one-fifth of schoolchildren attending primary care and for as many as half in out-patient pediatric clinics, indicating a high degree of sensitivity and vigilance by many clinicians to these issues (Bailey, Graham, & Boniface, 1978; Garralda & Bailey, 1987, 1990). Presenting symptoms in these cases tend to be those regarded traditionally as having psychosomatic components (e.g., aches and pains, incontinence, asthma and blackouts) but virtually all physical complaints are featured. These children have an excess of emotional and behavioral symptoms, including mood changes and relationship problems. However, most do not have a psychiatric disorder. Mothers’ stress over parenting, and concerns over schooling have particularly been noted in primary care settings, suggesting the relevance of high academic and behavioral expectations.

Addressing the psychosocial concerns of families with children with psychosomatic presentations may have substantial consequences for medical service use. These families have a high tendency to focus on health issues, as shown by the fact that they are high users of primary care. The children themselves are given more hospital appointments, more referrals to specialist clinics and more follow-up appointments at the surgery than children with purely physical presentations (Campo, Jansen-McWilliams, Comer et al., 1999; Garralda & Bailey, 1987).

Thus, at the first point of contact with primary care, professionals could maximize the impact of the contact if they are alert to looking for hidden or associated emotional and behavioral difficulties and recognize links with physical presentation.

**Clarifying Demand and Diagnosing Disorder**

Attention to mental health is only possible once need has been recognized and demand for intervention clarified. Rates of recognition within primary care have been shown to be poor (Brugman, Reineveld, Verhulst, & Verloove-Vanhorick, 2001; Chang, Warner, & Weissman, 1988; Costello & Eddelbrock, 1985; Garralda & Bailey, 1986; Glazebrook, Hollis, Heussler, Goodman, & Coates, 2003; Kramer & Garralda, 1998; Sayal & Taylor, 2004), with poor sensitivity and high specificity (Brugman, Reineveld, Verhulst et al., 2001). Most affected children fail to receive any mental health services (Burns, Costello, Angold et al., 1995; Rushton, Bruckman, & Kelleher, 2002; Verhulst & Van der Ende, 1997). Recognition has been linked to severity of disorders, age (best in 7- to 14-year-olds), male gender, the presence of social difficulties (being on welfare, broken homes), presenting symptoms (chronic conditions, digestive problems and ill-defined problems), type of consultation (to well child clinics rather than acute care visits), clinician relationship with the child and parental perception of difficulty (Goldberg, Regier, McInerny et al., 1979; Horwitz, Leaf, Leventhal, Forsyth, & Speechley, 1992; Kramer & Garralda, 1998). Sayal and Taylor (2004) demonstrated that parental expression of concern during consultation increased the sensitivity of doctor recognition of mental health problems. In very young children (11–39 months), Ellingson, Briggs-Gowan, Carter, and Horwitz (2004) demonstrated that parental discussion with the primary care provider was associated with parental worry and perceived low socioemotional competence in the child, and with disruption to family routines. Nevertheless, even though many parents believe it is appropriate to express concerns about child behavior to a primary care provider, few parents who have concerns do so (Dulcan, Costello, Costello et al., 1990; Ellingson, Briggs-Gowan, Carter et al., 2004; Horwitz, Leaf, & Leventhal, 1998; Sayal & Taylor, 2004). Thus, education, which enables parents to identify their children’s needs, express these within the consultation and understand the potential for intervention, is an important first step in promoting identification within the primary care setting.

The use of screening questionnaires has been considered as a potentially quick and easy method to improve primary care identification (see chapter 20) across the age range (Borowsky, Mozayeny, & Ireland, 2003; Briggs-Gowan, Carter, Irwin, Wachtel, & Cicchetti, 2004; Luby, Heffelfinger, Koenig-McNaught, Brown, & Spitznagel, 2004). Information was improved if collected from both parents and children (Wildman, 2000; Wren, Bridge, & Birmaher, 2004) and at all types of visit to the service (i.e., whether injury or illness related visits as opposed to routine screening visits alone; Borowsky, Mozayeny, & Ireland, 2003). However, questionnaires alone are likely to over-identify the number of children requiring further assessment and intervention, and burden the limited resources. The primary care professional will still need to use clarifying questions about the nature, severity and associated impairment of any symptoms before deciding on appropriate action. Questionnaires may be best used to provide a guide as to when psychological, behavioral and psychosocial routes of inquiry should be followed.

Training for primary care physicians in the use of psychiatric diagnostic classifications such as ICD-10 or DSM-IV...
has been seen as a potential means of improving diagnostic reliability, treatment planning and communication between clinicians. In order to promote and facilitate the use of these classifications in primary care, versions specifically relevant to this setting have been developed, ICD-10 Primary Health Care and DSM-IV Primary Care (American Psychiatric Association, 1995; WHO, 1996) including advice on the management of children and adolescents with disorder (Jenkins, 2004). However, in the USA, Gardner, Kelleher, Pajer, and Campo (2004) demonstrated that primary care clinicians used DSM criteria in only 23% of visits where psychosocial problems were recognized, mostly for ADHD symptoms; in this survey half reported no use of DSM criteria whatsoever. The majority of primary care clinicians in the UK regularly use Read Codes to record patient signs, symptoms and interventions (www.connectingforhealth.nhs.uk/terminology/readcodes/faqs/index_html#6) whereas within the rest of Europe and Australia, use of the International Classification of Primary Care (ICPC-2; WONCA, 1998) is widespread. Although categories within both these systems have been linked with ICD-10 categories, evidence of practitioner knowledge and use of the criteria for psychiatric disorder in children and adolescents is lacking. A cluster randomized study of 30 primary care practices, following dissemination of Diagnostic and Management Guidelines for Mental Disorders in Primary Care: ICD-10 (WHO, 1996) in adult patients, failed to demonstrate improved sensitivity or specificity of diagnosis in clinicians who received the guidelines (Croudace, Evans, Harrison et al., 2003). The potential of these guidelines for use with children and adolescents, and in developing countries with very scarce specialist resources, has not been documented.

Systematic mental health screening of all child and adolescent attenders (at well child and other visits) would reach a large proportion of the population and reveal many of the currently untreated cases. However, as well as training primary care providers to do this, additional resources for intervention will be required. Primary care providers are unlikely to identify needs unless they are able to intervene.

Offering Advice and Treatment

Thus, large numbers of children and adolescents presenting to primary care with physical complaints have concurrent emotional difficulties. Primary care is viewed by many service users as more accessible and less stigmatizing than mental health services. Even where child mental health services are well developed, only a small proportion of psychiatrically disordered young people currently access these services (Rushon, Bruckman, & Kelleher, 2002) and specialist child and adolescent mental health services are already often working to full capacity or overburdened with long waitlists for treatment (US Public Health Service, 2000). Thus, policy-makers in the UK (Health Advisory Service, 1995) and the USA (US Public Health Service, 2000) have highlighted the need for improved provision within the broad range of services already in contact with children and adolescents (e.g., preschool, childcare, education, health, welfare, juvenile justice). If services are to become more available within primary health care, it makes sense to conceptualize a stepped provision with improved primary care recognition, followed by advice and treatment within primary care of the less complex and severe difficulties. Limited consultation duration presents a potential barrier to such interventions. One US study of 2- to 18-year-olds found that pediatricians spent an average of 10.3 min in each well visit consultation (Reisinger & Bires, 1980). A study of adolescent consultation times in the UK (Jacobson, Wilkinson, & Owen, 1994) demonstrated that consultation duration of 11- to 19-year-olds was shorter than for any other age group. Also, little is known about which child and adolescent mental health interventions are appropriate and effective when offered within primary care.

Bower, Garralda, Kramer, Harrington, and Sibbald (2001) carried out a systematic review and identified three types of child mental health intervention offered within primary care: management by specialist mental health professionals based in primary care (often referred to as shifted out-patient clinics); treatments offered by the primary care team; and consultation liaison models. They documented that there were a limited number of studies, many of which were of poor quality, and concluded that a significant program of research was required if the potential for child and adolescent mental health services in primary care was to be realized in an effective and efficient way.

Shifted Out-patient Clinics

Most early work on children and adolescents with actual psychiatric disorders involved treatment by specialist staff within primary care (so-called shifted out-patient clinics). Interventions described were brief (6–12 sessions) and included a variety of techniques: cognitive–behavioral therapy, family therapy, non-directive counseling, dynamic therapy, psychiatric evaluation and guidance, parent education and counseling, group work and child education (Bower, Garralda, Kramer et al., 2001). Studies consisted largely of simple before–after designs without control groups and often lacked details on the process of treatment delivery. Two large-scale studies that used randomization failed to demonstrate a marked effect on child health outcomes (Cooper & Murray, 1997; Nicol, Stretch, & Fundudis, 1993). Conclusions about effectiveness are therefore tentative. Moreover, provision of comprehensive coverage of this nature by specialist staff would require marked expansion of specialist services, is unlikely to be cost-effective and may not be achievable.

Treatment by the Primary Care Team

There is little information on the management of child emotional and behavioral difficulties offered by the actual primary care team. Bower, Garralda, Kramer et al. (2001) reviewed six studies of treatment offered by the primary care team, offering a variety of interventions for different problems. Of
the four controlled studies, only the study by Cullen (1976) and Cullen and Cullen (1996), of preventative interviews with preschool children, demonstrated significant objectively improved outcomes.

Wren, Scholle, Heo, and Comer (2005) documented the practice of 395 primary care clinicians during consultation with 20,861 consecutive attenders aged 4–15 years in the USA, Puerto Rico and Canada. Children identified as having a mood or anxiety syndrome were no more likely to be counseled during the visit than those with other psychosocial problems, and – unless accompanied by a comorbid behavioral syndrome – they were offered fewer scheduled follow-up appointments. Rates of prescription of antidepressants or antianxiety agents were comparatively higher for the mood/anxiety groups but this was still uncommon (6.7%) and they were also more likely to be referred to mental health services. Thus, even when identified, active management by primary care was uncommon in this group. This may be because primary care clinicians feel more responsible for recognizing than for treating child and adolescent depression. In Olson, Kelleher, Kemper et al. (2001) survey, respondents reported providing a wide range of brief interventions to almost 80% of young people with depression and prescribing medication to approximately 20%, but they also reported referring a similar proportion to mental health professionals. Factors limiting diagnosis and management most frequently cited included time and training/knowledge and, less commonly, financial or patient issues. However, the response rate in this survey (55–63%) was modest, and it is unclear whether these findings are broadly representative.

**Consultation Liaison Models**

Consultation liaison, in which the specialist acts to support management by primary care rather than take responsibility for individual patients (Gask, Sibbald, & Creed, 1997), has traditionally been viewed as a means of increasing the capacity of primary care clinicians to offer mental health services, partly through improving their skills and knowledge. In their review, Bower, Garralda, Kramer et al. (2001) identified only one study of consultation liaison offered to primary care personnel by specialist child and adolescent mental health workers (Neira-Munoz & Ward, 1998). The intervention (which included reviewing referrals, running liaison clinics and seeing patients on their own) was associated with a reduction in the rate of referrals to specialist mental health services and an increase in appropriateness. The service was rated highly by primary care staff but only one-third of primary care doctors thought that the liaison clinics increased their knowledge and skills. Connor, McLaughlin, Jeffers-Terry et al. (2006) have described a similar model of collaboration, in the USA. A child psychiatrist or specialist nurse offers telephone consultation during office hours (139 primary care practitioners in 22 practices). A proportion of cases will then be managed within primary care while the rest are referred to the child psychiatrist for assessment within 4 weeks. During the first 18 months, the child psychiatrist offered direct evaluation of 329 (54%) patients. Time was also spent educating primary care practitioners in case conferences and informal consultations. Neither of these reports included data on patient outcomes and both models included specialist mental health clinicians working primarily on this “specialist” area, consultation liaison with primary care. A survey of all specialist child and adolescent mental health services in England demonstrated that collaborative work with primary care was significantly associated first with a developed “specialist” provision for this, and second with larger sized mental health services (Bradley, Kramer, Garralda et al., 2003). This suggests that it is difficult for individual mental health clinicians to facilitate collaboration on their own when they have a broad range of other commitments. Furthermore, if there is an increase in collaboration, future work will need to address more clearly medicolegal responsibilities in those cases where primary care practitioners provide treatments on the advice of specialist clinicians, especially prescription of psychotropic medications, where primary care practitioners may have limited training and experience.

**Use of Psychotropic Medication for Child and Adolescent Depression**

There is evidence that prescribing of pediatric psychotropic drugs has increased over recent years across many countries (UK, USA, Canada, France, Germany, Spain, Argentina, Brazil and Mexico; Wong, Murray, Camilleri-Novak, & Stephens, 2004). More specifically, in the UK there has been an increase in prescriptions of antidepressants by primary care clinicians, between 1992 and 2002, especially of selective serotonin reuptake inhibitors (SSRIs) and venlafaxine rather than tricyclic antidepressants (Murray, de Vries, & Wong, 2004, Murray, Wong, & Thompson, 2005). However, treatment is often not sustained, with more than half of subjects discontinuing treatment after 2 months. Similarly, in the USA only 47% of youth continued out-patient treatment with anti-depressants at 3 months and 26% at 6 months, suggesting both inadequate duration of treatment and follow-up (Richardson, DiGiuseppe, Christakis, McCauley, & Katon, 2004). In a survey in North Carolina, 91% of family physicians (n = 242) and 58% of pediatricians (n = 349) had prescribed SSRIs for pediatric patients, most commonly for depression (Rushton, Clark, & Freed, 2000). In this study, very few physicians (8%) reported adequate training in the treatment of adolescent depression.

In a large community survey, approximately 1% of children and adolescents received out-patient treatment for depression, a rate below epidemiological prevalence estimates (2–8%) (Olsson, Gameroff, Marcus, & Waslick, 2003). Anhedonia was more common in adolescents receiving medication prescribed by psychiatrists, pediatricians or other physicians, but treatment was otherwise unrelated to measures of clinical severity (Olsson, Gameroff, Marcus et al., 2003), despite the recommendation of the American Academy of Child and Adolescent Psychiatry that antidepressant use should be limited to those with severe or psychotherapy-resistant disorders.
CHAPTER 72

Following widely publicized safety concerns and recommendations about the use of SSRIs, and the recommended ban of those other than fluoxetine as a treatment in child and adolescent depression (CSM, 2005), fewer children and adolescents have been prescribed antidepressants in primary care (Murray, Wong, & Thompson, 2005). It is unclear whether this reduction in drug treatment has resulted in more psychotherapeutic treatments being offered as an alternative in the UK, but in the USA provision of psychotherapy/mental health counseling declined between 1995–1996 and 2001–2002 (Ma, Lee, & Stafford, 2005).

Thus, comprehensive treatment of depressive disorders within primary care will require improved education of primary care providers in the treatment of depression and will need to address a balance of psychotherapeutic and medical interventions in addition to approaches to improve compliance and follow-up.

Complex Interventions for Adolescent Depression in Primary Care

Systematic reviews of screening and intervention programs for adult depression in primary care have outlined a range of issues that are relevant to intervention with young people. Simple educational strategies for staff or passive dissemination of formal guidelines to improve recognition and management have had minimal effect, whereas multifaceted programs that integrate improvements in detection, treatment and follow-up are most effective (Gilbody, Whitty, Grimsha, & Thomas, 2003; Katon, Von, Lin et al., 1999; Pignone, Gaynes, Rushton et al., 2002; WHO, 2004). These include combinations of clinician and patient education, nurse case management, enhanced support from specialist services and monitoring of medication. Further research is needed to clarify which elements of these complex interventions are active ingredients, who benefits most from different elements of the interventions, and to what extent the programs can be translated between different settings in different countries.

In light of the adult findings, Asarnow, Jaycox, Duan et al. (2005b) carried out a landmark study of adolescents in six primary care centers in the USA. They included two public sector, two managed care and two academic health programs and enrolled 418 patients aged 13–21 years into a randomized controlled trial of a “quality improvement intervention” versus usual care. The quality improvement intervention included:

1. Expert leader teams at each site to implement and adapt the intervention;
2. Care managers to support primary care clinicians with evaluation, education, medication and psychosocial treatment, and with linkage with specialist mental health services;
3. Training care managers in manualized cognitive–behavioral therapy (CBT) for depression; and

Treatment options included CBT, medication, combined CBT with medication, care manager follow-up, or specialist referral.

Usual care was enhanced by providing primary care clinicians with training and educational materials on depression evaluation and treatment. Six months after assessment, quality improvement patients reported significantly fewer depressive symptoms, higher mental health-related quality of life and greater satisfaction with mental health care. They had also received significantly higher rates of mental health care and psychotherapy or counseling. Enhancement of usual care meant that the benefits detected are probably conservative. However, almost one-third of quality improvement patients continued to show severe depressive symptoms. Increased use of combined psychotherapy and medication might have led to improved outcomes in this group (March, Silva, Petrycki et al., 2004). Moreover, screening and recruitment resulted in the loss of many young people from the study, indicating that this approach may benefit only a selected group and longer-term benefits require further study. Nevertheless, this study demonstrated improved quality of care, increased access to evidence-based treatments and favorable outcomes through increased support to primary care clinicians in naturalistic settings.

In the UK, Gledhill, Kramer, Lilfe, and Garralda (2003) have developed “therapeutic identification” techniques that incorporate training for general practitioners in the identification of depression with opportunistic intervention based on cognitive and interpersonal principles. In one large practice this was shown to be feasible in a pilot study, to lead to improved doctor detection rates and adolescent clinical outcomes, but it needs to be further evaluated and shown to be cost and clinically effective before it can become recommended practice. Approaches such as this that enhance the mental health care provided within primary care in contrast with traditional “shifted” out-patient specialist clinics, may offer the potential for more comprehensive and effective provision, but practically implementation requires investment in primary care and realignment of professional roles.

Intervention for depressive disorders is the most obvious focus for intervention by primary care workers with adolescents, because of the large contribution to hidden morbidity and the long-term adverse outcome (Asarnow, Jaycox, Duan et al., 2005a). However, other important areas for future investigation include intervention for anxiety and somatization-related or somatoform disorders in children, and disruptive disorders (Lavigne, Binns, Christoffel et al., 1993).

The development in primary care of appropriate techniques for the identification and management of functional or somatization-related somatic symptoms is especially relevant. Identification of these children can be aided by establishing the unexplained nature and impairment caused by the physical symptoms and taking notice of risk factors such as family social or structural problems, parental somatization and school problems (Konijnenberg, de Graeff-Meeder, van der Hoeven et al., 2006). Discussion of psychosocial issues needs to take special account of sensitivities by many parents and children in addressing these issues, as some parents – especially those of the more severely affected children – may feel undermined and threatened when these are explored, which
leads to their stressing the physical aspects of the child’s presentation (Smart & Cottrell, 2005).

Coordinating Care

The primary care clinician has a central role in coordinating care. Coordination includes referral to specialist or other services, as well as long-term management of those with chronic or complex conditions with support from specialist services.

Referral to Specialist Services

The most frequent interface between primary care and child psychiatry or mental health services is through referral to specialist psychiatric services. This may follow less than 10–17% of psychiatric presentations to primary care practitioners (Brugman, Reijneveld, Verhulst et al., 2001; Garralda & Bailey, 1988; OPCS, 1995). The psychiatric referral of schoolchildren by primary care practitioners has been found to be linked to the severity of the child’s disorder, male gender, the presence of antisocial symptoms and/or relationship problems and to psychosocial disadvantage (i.e., family stress, unemployment; Garralda & Bailey, 1988). Higher severity and male gender have also been confirmed as factors in other studies (Laclave & Campbell, 1986; Lavigne, Arend, Rosenbaum et al., 1998). One Dutch study found no link between referral and sociodemographic factors (Brugman, Reijneveld, Verhulst et al., 2001). In this setting, with a highly developed preventive child health system (90% of children and adolescents receive 3–4 preventative assessments during childhood and adolescence), referral was related to information regarding the mental health of the child per se. This may indicate practice that is directly focused on specific mental health need rather than on associated psychosocial risks. In most settings, parental request remains a central determinant for referral, the role of general practitioners and pediatricians tending to remain more passive (Bailey & Garralda, 1989; Briggs-Gowen, Horwitz, Schwab-Stone, Leventhal, & Leaf, 2000; Sayal, Taylor, Beecham, & Byrne, 2002). Parents’ views on the passive role taken by practitioners remain unclear, although one study found most parents of referred children to be satisfied (Bailey & Garralda, 1989).

For clearly diagnosable psychiatric problems in children who are not already under the care of mental health services, the primary care clinician needs to make decisions about whether and how to refer. Although existing research indicates that psychiatric referrals by primary care doctors are generally appropriate, increasing awareness of child and adolescent psychiatric problems by parents and primary care teams is likely to result in more referrals than specialist services can possibly accommodate. Protocols refining the criteria for severity, psychosocial complexity and likely response to treatments will need to be developed and audited jointly by child and adolescent and primary care services. Consultation liaison activities by child and adolescent mental health services may be particularly helpful in developing this work.

Managing Chronic Conditions

For problems such as hyperkinetic disorder, it has been shown that once recognized by the general practitioner or family doctor a referral to specialist services usually follows (Sayal, Taylor, Beecham et al., 2002). Other primary providers (e.g., pediatricians) are likely to initiate some treatment but mental health specialists will need to become involved in resistant cases or those with comorbidity (e.g., severe conduct disorder, tic disorders). As a chronic disorder with high levels of comorbidity, a comprehensive model of care could include long-term monitoring within the primary care setting with intermittent involvement of specialist services as appropriate for medication review or adjutant behavior therapy. However, general practitioners have been shown to be skeptical about hyperkinetic disorder as a diagnostic entity (Klassen & Goodman, 2000). Adequate training and ongoing support are therefore necessary if such a model of joint working is to be developed. Traditional consultation–liaison work by specialist child and adolescent mental health staff provides a mechanism for this joint working but has been limited by a lack of capacity. More recent models of improved collaboration have been facilitated through the use of non-physician care managers/professionals with specialized clinical and behavioral skills, who prioritize frequent communication with primary care clinicians and also maintain strong links with specialist mental health services.

Prevention and Early Intervention

Primary care services provide the most widespread point of access to health services among both the better and the less developed health care systems. As such, they are crucially placed for a role in prevention and early intervention for mental health problems of children and adolescents.

Many broad public health programs relevant to primary care, impact on the primary prevention of mental distress and disorder in young people by targeting risk and resilience factors. Examples are family planning programs, prenatal care, promotion of adequate nutrition, child safety information and home visiting programs. These programs are implemented by a range of professionals including general/family practitioners, primary care pediatricians (e.g., in the USA), community pediatricians and health visitors (e.g., in the UK) or community nurses, all of whom are in an ideal position to disseminate information on child health, development, behavior and positive parenting (Bower, Macdonald, Sibbald et al., 2003).

An early study of preventative general practitioner consultations during a child’s first 4 years demonstrated favorable outcomes at 6 and 20 years later (Cullen, 1976; Cullen & Cullen, 1996). This study demonstrated that mental health promotion interventions can be carried out systematically by general practitioners or family doctors who, through regular supervision, may be able to influence parental actions and have some long-lasting effects on their children’s behavior. However, it is unlikely that many general practitioners or pediatricians would be able to invest the time required into such an intervention.
CHAPTER 72

It may be more practical and cost-effective to implement prenatal and infancy home visiting by trained nurses with mothers at high risk of difficulties (see chapter 61). Olds (2002) and Olds, Eckenrode, Henderson et al. 1997, Olds, Henderson, Cole et al. 1998, Olds, Kitzman, Cole et al. 2004), in a program whereby mothers were visited during pregnancy and up until the child’s second birthday, have demonstrated in three large randomized controlled trials benefits for young, low-income, unmarried mothers and children. Improved parental care of the child included fewer injuries and accidental substance ingestions, which may in some cases reflect child abuse and neglect, fewer emergency visits and less use of punishment in the first 4 years. Further beneficial changes with regard to maternal life-course include fewer subsequent pregnancies, greater workforce participation and reduced use of public assistance and food stamps. In the first trial, the program also produced longer-term effects on the number of arrests, convictions, emergent substance use and promiscuous sexual activity of 15-year-old children. However, not all home visiting programs have been shown to be effective. A number of attempts at training primary care community nurses or health visitors to promote parenting in order to reduce behavioral problems in young children have reported inconsistent or equivocal results, and this remains an area requiring further exploration (Bower, Garralda, Kramer et al., 2001). It is important to establish which elements of such interventions are the minimum required to achieve mental health gains for children (see chapter 61).

Secondary prevention, aimed at early detection and diagnosis, is integral to child surveillance programs, and can be implemented by professionals in a range of primary care settings across different countries. For example, community-based group parenting programs, addressing child behavioral difficulties, have been shown to improve parenting practices, parent–child interactions and child behavior through multiple, independently replicated, randomized controlled trials (Scott, Spender, Doolan et al., 2001; Webster Stratton, 1989, 2001). In developing countries, where most of the health care is delivered by the primary or the general health care team, detection of developmental delays and epilepsy is also relevant. However, research is required to ascertain whether systematic early detection by primary care personnel would lead to better outcomes in the medium to long term.

The role of primary care personnel in suicide prevention has been well described (Gould, Greenberg, Velting, & Shaffer, 2003; Mann, Apter, Bertolote et al., 2005). Many suicidal young people (aged 15–34 years) have contact with primary care in the month prior to suicide or self-harm (Luoma, Martin, & Pearson, 2002; Pfaff, Acres, & Wilson, 1999). However, a study of pediatricians and family physicians in the USA revealed that fewer than half reported that they routinely screened their adolescent patients for suicide risk (Frankenfield, Keyl, Gielen et al., 2000). Although the Gotland study (in Sweden) demonstrated a decline in adult suicide rate following general practitioner education to improve diagnosis and treatment of depression, this was not maintained at follow-up (Rutz, von Knorring, & Walinder, 1992). A 1-day training course for general practitioners in Australia enhanced detection rates of adolescent psychological distress and suicidal ideation, but failed to lead to changes in patient management (Pfaff, Acres, & McKelvey, 2001). As with treatment for depression, educational approaches alone may prove insufficient to change the management of suicidal young people in primary care, and systematic screening may need to be integrated into more complex multifaceted approaches.

Parental Substance Misuse and Psychiatric Disorder

Children of parents with substance misuse problems and other psychiatric disorders such as depression and anxiety are at increased risk of developmental, emotional and behavioral difficulties (see chapter 27; Nomura, Wickramaratne, Warner, Mufson, & Weissman, 2002; Weissman, Feder, Pilowsky et al., 2004; Whitaker, Orzl, & Kahn, 2006). Primary care clinicians may be treating these adults or be aware that they are receiving help from specialist services. They should be alert to the increased risks for these children and especially vigilant in relation to their general and mental health needs. Advice, support and guidance for mothers on child rearing may lead to more favorable outcomes for children. Increased support to improve access to specialist services may also be required.

Building Capacity in Primary Care

Integration of mental health provision for children and adolescents into primary care requires improved professional knowledge, skills and attitudes as well as changes to service delivery systems to support this.

Educational interventions should address health workers’ undergraduate and postgraduate education. A number of initiatives have addressed this (Bernard, Garralda, Hughes, & Tylee, 1999; Bower, Garralda, Kramer et al., 2001; de Jong, 1996; Dogra, Frake, Bretherton, Dwivedi, & Sharma, 2005; Hughes, Garralda, & Tylee, 1995; Sanci, Coffey, Patton, & Bowes, 2005). Evaluation tends to show benefits by increasing skills and confidence of primary health care staff, but few studies have been methodologically rigorous. Leaf, Owens, Leventhal et al. (2004) demonstrated that pediatricians with advanced training in psychosocial problems were more likely to identify children’s psychosocial problems and use multiple management strategies compared with pediatricians without specialized training. However, not all general practitioners, pediatricians and other primary care staff wish to obtain training and implement potentially effective management techniques. Primary care is being expected to fulfill an ever-increasing number of preventative and curative interventions and some degree of prioritization is required. While some practitioners welcome the conceptual clarity and management guidance offered by psychiatric terminology and thinking, others have concern about medicalizing distress, especially in children and adolescents (Iliffe, Gledhill, daCunha, Kramer,
& Garralda, 2004). Future work may helpfully clarify which primary care practitioners are especially well suited to the task of promoting and managing child and adolescent mental health. Furthermore, clarification is needed about which specific components of evidence-based knowledge and skills should be included.

Improved training may not be enough to bring about the required change. Alteration to service delivery systems (Pincus, Pechura, Elinson, & Pettit, 2001) and the development of innovative roles for new workers may be required. This has recently been attempted within the UK. Policy aimed at improving access to child and adolescent mental health services led to the development of primary mental health workers (PMHWs) to work with both primary and specialist child and adolescent mental health services performing the following functions:

1. Consolidating the skills of existing workers in primary services;
2. Helping workers in primary services develop new skills and confidence through training and education;
3. Supporting recognition of disorders and their referral to more specialist services if appropriate; and

Initially, posts were filled by a variety of professionals including a majority of nurses but also by social workers, psychologists and others with significant experience of working in child mental health services (Bradley, Kramer, Garralda et al., 2003). Their presence has been shown to bridge the wide gap between primary care and specialist mental health services (Macdonald, Bradley, Bower et al., 2004) and improve integration of primary and secondary services. However, subsequent expansion of the role, with a limited pool of experienced professionals available for recruitment, would have led to the recruitment of professionals with less experience, raising questions about their effectiveness. Shortages of appropriately skilled personnel are likely to be a limiting factor in any program aiming to expand provision in primary care, underlining the need for training. There has also been a rapid expansion of specialist liaison nurse posts with roles similar to those of the PMHW within other medical services (e.g., in palliative care, asthma, epilepsy, infection control, HIV/AIDS; Hobbs & Murray, 1999). Surveys reveal high levels of patient satisfaction but there have been few randomized controlled trials to look at clinical and cost-effectiveness. Where these have been undertaken, evidence of effectiveness is conflicting (Hobbs & Murray, 1999). Research is needed to evaluate the impact of PMHWs on patterns of service use and health outcomes.

Another program with similar features has been developed in the USA in a large rural pediatric practice (Campo, Shafer, Strohm et al., 2005). After identification of emotional or behavioral problems by primary care clinicians, young people are offered an assessment of their clinical need by an advanced practice nurse (APN). Based on the level of impairment, complexity of the mental health problem, treatment history and needs, young people are triaged to routine care by primary care clinicians with APN support, to on-site mental health service for intervention or psychiatric consultation by the APN, psychiatric social worker and/or part-time pediatric psychiatrist, or referred to specialist mental health or emergency mental health services. In the course of 1 year, 789 (2.5%) primary care visits were referred for triage. Of these 789 visits to the APN, 279 (35%) represented first-time or new mental health contacts. Of these 187 (67%) received routine care, 52 (19%) received on-site mental health services, 36 (13%) were referred to specialist mental health services and 4 (1%) were referred for emergency evaluation and admission. Although at 2.5% the overall proportion of children requiring triage was low, the vast majority of new mental health contacts were assessed to be treatable within primary care, with most receiving intervention from the primary care clinician with APN support.

Pillay and Lockhat (1997) described a community program in South Africa. As in many developing countries, South Africa has a large proportion of young people in its population, and mental health services are lacking in many areas. Two clinical psychologists who had been providing a clinical service within an urban teaching hospital to young people from a large geographical area (up to 300 km away), changed their model to include providing a monthly service, traveling to five centers in outlying areas, in line with a combined shifted out-patient/liaison-consultation model. They offered a day that combined training in the identification of problems and intervention techniques for frontline workers (e.g., primary care, school and psychiatric nurses, social workers and teachers), with their own clinical assessment of more complex cases. As with the other models described above across different national contexts, this again confirms that it is feasible to improve integration of services, but research is required to assess whether integration is clinically and cost-effective, and whether these models of service delivery lead to improved access to services, clinical outcomes and user satisfaction.

Large-scale improvement in access to interventions for child and adolescent mental health problems through integration with primary services will require commitment of resources to build capacity. A global lack of mental health policy pertaining to children and adolescents contributes to the barriers to service development, in spite of the significant progress made in policy development over the last 10 years (Shatkin & Belfer, 2004). This should include attention to research, professional training and public education, in conjunction with service developments based on locally determined, culturally sensitive needs assessment (Rahman, Mubbashar, Harrington, & Gater, 2000). Intersectoral collaboration across health, education and social care is important across settings, whether in poorly or well-developed systems, with priorities for development according to patterns and profiles of disorder in relation to available resources and the growing evidence base for interventions.

Future Directions

It may be expected that in future years there will be a continuing impetus to enhancing attention to the mental health
of children and adolescents in primary care by the following developments:

• A better appreciation by the public and by health service providers of child psychiatric disorders such as ADHD and depression, with parallel increasing expectations of assistance and knowledge about these from professionals in primary care;

• Clearer identification of primary care staff with a special interest in child and adolescent mental health;

• More active “therapeutic identification” of child and adolescent mental health problems by primary care professionals, with the development of setting-appropriate information and well-informed advice providing techniques for children and families and halting the increase in the primary prescription of psychotropic medication in primary care;

• More attention to the appropriate management of functional somatic symptoms in the primary care setting;

• Development of general practice therapist posts to implement setting-appropriate therapeutic techniques; and

• Further development of liaison posts with clearer areas of expertise and enhanced training to help bridge the gap between primary and specialist mental health services.

On the research field, it may be expected that there will be further:

• Systematic description of innovative mental health informed interventions in countries with developing health services;

• In countries with better developed services, a trend for more evaluation of new setting-appropriate techniques for specific disorders using simple before–after controlled designs, followed by larger evaluations of complex interventions with the progressive elucidation of the more active treatment ingredients;

• Evaluation of new liaison services through the development of adequate outcome measures; and

• Evaluation of training to increase primary care workers’ awareness, knowledge and skills in relation to child and adolescent mental health problems.

Genetic Counseling and the Role of the Genetic Counselor

Genetic counseling is the process of requesting and receiving information on genetic disorders, risk and possible interventions for oneself and one’s relatives. Genetic counseling focuses on providing clients with information that will allow them to make informed decisions with regard to family planning and health care (Kelly, 1986). People presenting for genetic counseling may not have a health problem at the time of presentation. Although the term “counseling” is used, it differs from mental health counseling in being brief (usually 1–3 visits) and focusing on the communication of fact, with limited exploration of individual factors that may alter decisions about management of the information given.

Nature of Genetic Counseling in Child Psychiatry

The majority of child psychiatric disorders are complex in their inheritance in that multiple genes and environmental factors both influence the occurrence of disorder (see chapter 23). Susceptibility genes are usually common variants rather than rare mutations and co-act with environmental risk factors, which may also be common variations in experience or exposure. Single gene mutations, chromosomal anomalies and submicroscopic abnormalities do occur, predominantly but not exclusively in global intellectual disability, and these are important to be aware of, as intellectual disability may first be identified in child mental health services (see chapter 24). Genetic counseling in complex disorders raises a number of issues that usually do not apply in these other contexts. The first is that of deciding whether or not the disorder is present. A hallmark of many common complex disorders is the absence of a clear threshold between normality and disorder, whether this distinction is made by number or type of symptoms, degree of impairment, response to treatment or any of the other methods used in diagnostic classification systems. Most studies of recurrence risk of disorder start with probands who unambiguously meet full diagnostic criteria. Where the affected family member demonstrates milder symptoms or an atypical presentation, the genetic counselor must decide whether this person is “affected” with the full condition. For many psychiatric disorders, genetic liability confers a spectrum of abnormalities. For example, in autism, co-twins of individuals with autism may have autistic-like social and cognitive impairments that do not reach the diagnostic threshold for childhood autism (Bailey, Le Couteur, Gottesman et al., 1995). However, it does not follow that all individuals showing the broader autistic phenotype have the full genetic liability for autism. Thus, it is not currently known how to estimate the risk of autism in family members of more mildly affected individuals.

Disorder boundaries are also unclear in relation to psychiatric comorbidity. The available evidence suggests that this may often be because of genetic influences that increase liability nonspecifically for several disorders (i.e., that are risk factors for both disorders; Kendler, Heath, Martin, & Eaves, 1987; Silberg, Rutter, Meyer et al., 1996). Such findings raise more questions than they answer for genetic counseling. For example, the finding of shared genetic risk factors between symptoms of attention deficit/hyperactivity disorder (ADHD) and conduct disorder highlights that some families with children with ADHD are also at risk of having children with conduct disorder, but at present there are no methods for identifying the different risks.

In some cases, such as ADHD, some of the susceptibility genes appear to have been identified, while in others, such as autism, none are yet confirmed. However, even where one or more susceptibility genes are identified, it is not currently possible to predict with any degree of certainty who will develop the disorder. To date, most genetic testing has occurred where the presence of a risk genotype is strongly associated with development of the disorder. The costs and benefits of testing for susceptibility genes that lead to relatively small alterations in risk have not yet been fully explored but it is almost certain that the negative effects will have a greater influence than is the case when testing for Mendelian disorders.

A further challenge with respect to complex disorders is how to incorporate environmental risk factors into counseling. The extent to which environmental risk is important will vary across disorders and may be underestimated in classic behavioral genetic studies, which assume that genetic and environmental factors act independently rather than in concert. Empirical recurrence rates are agnostic to the origin of familiality and are also helpful because they are easily understood concepts. However, empirical recurrence risks in psychiatry are disorder-based and do not take account of etiological and clinical heterogeneity and comorbidity so that they may...
be imprecise for any individual. Even where environmental risk factors have been identified, it is not always clear how to use them within genetic counseling, either because the risk factor is inherently undesirable (e.g., child maltreatment) or difficult to avoid (e.g., life events). In other cases, knowledge of specific risk may be helpful, as in the interplay between catechol-O-methyltransferase (COMT) genotype and cannabis use (Caspì, Moffitt, Cannon et al., 2005).

With the exception of disorders caused by single gene and chromosomal anomalies, the nature of genetic counseling for psychiatric disorders is probabilistic rather than based on predicting binary outcomes (affected or disorder-free). Whereas genetic counseling has always included situations in which there is uncertainty about affected status, these are decreasing for Mendelian disorders and chromosomal anomalies but not for complex disorders. Genetic counseling for complex disorders is likely to remain probabilistic even as susceptibility genes and environmental risk factors are identified. An ongoing challenge will be to communicate probabilistic risk and uncertainties in accurate and helpful ways.

**Social Aspects of Genetic Counseling**

The explosion in requests for genetic counseling has fueled interest in alternative modes of delivery. Controlled trials comparing the outcomes of different methods of delivering genetic counseling are just beginning and include group-based counseling prior to prenatal diagnostic screening (Hunter, Cappelli, Humphreys et al., 2005), the use of structured presentations (Baker, Uus, Bamford, & Marteau, 2004), interactive computer-based systems and CD-ROMs to deliver basic information (Green, Peterson, Baker et al., 2005) and telemedicine (Coelho, Arnold, Nayler, Tischkowitz, & MacKay, 2005). Early results suggest these strategies are largely equally effective. These evaluations highlight the diversity of outcome measures employed, and uncertainty about what outcome measures are most appropriate. Outcome measures have included client satisfaction, enhanced knowledge of genetics and individual risk, anxiety reduction, help with decision-making and, where applicable, undergoing medical investigations and interventions. Perhaps the most important outcome to measure is whether clients can make informed choices, “based upon relevant knowledge, consistent with the decision-maker’s values and behaviorally implemented” (Broadstock, Michie, & Marteau, 2000). In some situations, the results of genetic testing may appropriately increase anxiety, such as where it has led to identification of the cardiac disorder of long QT syndrome, with its increased risk of sudden death (van Langen, Hofman, Tan, & Wilde, 2004); here the outcome of choice may be compliance with recommended treatment.

Because genetic counseling has been considered optional, the health inequalities related to differential uptake have not previously been considered. However, racial, ethnic and cultural diversity in genetic counseling affects uptake and use of genetic counseling. There are also racial, ethnic and sociodemographic differences in personal knowledge about genetic risk, perceived genetic risk and knowledge about family history more generally (Dormandy, Michie, Hooper, & Marteau, 2005; Hall & Olopade, 2005), with women from ethnic minority and sociodemographically disadvantaged backgrounds being less likely to take up prenatal screening for Down syndrome or counseling for themselves in relation to breast cancer (Armstrong, Micco, Carney, Stopfer, & Purt, 2005). This difference is similar to that in the uptake of preventive health care more generally.

The results of genetic counseling can produce a conflict between the individual patient wishing to maintain confidentiality about results and the potential harm caused by not altering other family members to their risk. While guidelines vary in the emphasis given to maintaining patient confidentiality versus informing relatives, all emphasize the importance of exploring such issues prior to genetic testing and of working with patients to help them communicate with family members (American Society of Human Genetics, 1998; Council on Ethical and Judicial Affairs of the American Medical Association, 2004; Taub, Morin, Spillman et al., 2004). There is ongoing concern about the use that health insurance may make of the results of genetic testing.

**Tasks of the Genetic Counselor**

Professionals from different backgrounds are involved in genetic counseling: clinical geneticists (medical doctors with specialist training), non-medical geneticists, genetic counselors (who come from a range of backgrounds but undertake postgraduate training in genetic counseling) and medical and other health professionals with an interest in particular genetically influenced disorders. With respect to child psychiatric disorders, counseling may be undertaken in the mental health setting or by referral to clinical genetics with the option of holding joint clinics. Genetic counselors vary widely in their experience of counseling for genetically complex conditions and psychiatric disorders in particular. Professionals giving genetic counseling must have adequate knowledge and skills and this should dictate the choice of setting. Because genetic counseling deals with a wide range of situations, the tasks for the counselor vary.

**Diagnosis of Genetic Disorders**

Geneticists are called upon to help make a diagnosis of a genetic disorder, either prenatally or later. Within child psychiatry, this most often occurs in the context of intellectual disability or developmental delay where investigation for genetic causes forms part of an overall investigation for etiological causes, in which general population studies suggest approximately 40–50% will have an identifiable cause (Srour, Mazer, & Shevell, 2006). The extent to which genetic investigation should be undertaken depends in part on severity of intellectual disability, family history, physical examination and the pattern of symptoms. A history of multiple affected family members or consanguinity always warrants further investigation, as do findings on physical examination suggestive of a specific disorder or
multiple dysmorphic features. Severe intellectual disability (IQ < 50) is more likely to be associated with identifiable medical causes. There is no firm consensus on when and how to investigate genetic causes of intellectual disability but routine chromosomal analysis is generally supported with either structural abnormalities or aneuploidy occurring in approximately 13% with moderate to severe intellectual disability and approximately 4% with mild to moderate intellectual disability (van Karnebeek, Scheper, Abeling et al., 2005).

There is much interest in investigations to detect microscopic deletions or duplications, using either fluorescence in situ hybridization (FISH) for telomeric rearrangements or comparative genomic hybridization (CGH) array, which may be abnormal in 5–10% of individuals with intellectual disability (Sharkey, Maher, & FitzPatrick, 2005). Clinicians should remain cautious about their use and interpretation because of inadequate population-based studies to determine the base rate for such findings and uncertainties about the distinction between normal variation and abnormality. Factors supporting an etiological role for cytogenetic and submicroscopic genetic variations include previous reports of a similar clinical picture associated with the abnormality and either a failure to find the abnormality in the parents (de novo mutation) or the abnormality segregating with the clinical characteristics within the family. Clinical characteristics associated with submicroscopic abnormalities include: positive family history of intellectual disability, prenatal growth retardation, postnatal growth abnormalities (including tall and short stature and micro- and macrocephaly) and dysmorphic features (de Vries, White, Knight et al., 2001).

Other investigations of intellectual disability are more focused and usually taken on by clinical geneticists or pediatricians (Cleary & Green, 2005; McDonald, Rennie, Tolmie, Galloway, & McWilliam, 2006; Sharkey, Maher, & FitzPatrick, 2005). Many of the investigations that may be undertaken do not involve a genetic test per se but, if positive, will diagnose a genetic disorder. Many genetic laboratories require evidence that the nature and possible implications of genetic tests have been discussed with patients or parents, but such a requirement is unusual for non-genetic investigations and clinicians must decide whether the genetic implications should be discussed prior to testing.

With respect to other child psychiatric disorders, clinicians must be alert to the rare but important instances in which genetic disorders may have a role in exactly the same way that other rare medical causes of psychiatric disorders need to be evaluated. Velocardiofacial syndrome (VCFS) should be considered in early-onset psychosis and Williams syndrome in ADHD and subaverage intelligence (see chapter 24). In general, protocols for investigating genetic causes of child psychiatric disorders do not exist at present and clinicians need to make individual decisions based on the clinical picture, including the presence of other features associated with the genetic disorder. Clinicians should also balance the possible benefits of an etiological diagnosis that may affect reproductive decisions for other family members against the cost of routine testing and the possible anxiety engendered while test results are awaited. An etiological diagnosis may have specific treatment implications and more commonly is helpful in highlighting other features of the genetic disorder, as well as giving patients and families a causal explanation.

**Pre-conception Counseling for Couples At Risk**

Couples present for genetic counseling because they believe themselves to be at risk of having a child affected with an intellectual disability or psychiatric disorder. This common genetic counseling situation is covered on p. 1185. Ensuring correct diagnosis in the affected family member is essential and may be difficult if direct examination and availability of contemporaneous records are not possible. It is important to obtain a full family history for both members of the couple, even when the affected person is related only on one side. Genetic testing of the unaffected couple should be considered but undertaken only where there is a specific question.

**Prenatal Diagnosis**

The aim of prenatal diagnosis is to detect abnormalities (both genetic and otherwise) at an early stage of fetal development, usually to allow parental choice whether to continue with the pregnancy or, rarely, to allow prenatal intervention. Prenatal diagnosis is considered in disorders resulting in severe disability not open to other treatment options, where there is an accurate diagnostic test and in instances where there is a reasonable chance the pregnancy will be affected (Harper, 1998). The boundaries in relation to what is considered a severe disability are not clear-cut and there is diversity across individuals, cultures and societies. Divergence in opinion is exemplified by the sex chromosome anomalies in which affected individuals frequently have subaverage intelligence and varying degrees of behavioral disturbance (Abramsky, Hall, Levitan, & Marteau, 2001; Ratcliffe, 1999). There has been debate about whether prenatal diagnosis should only be undertaken if couples wish to terminate an affected pregnancy. In population prenatal screening for common genetic disorders, such as the triple test for Down syndrome, it is common for the testing to be undertaken without ascertaining the couple’s view about continuing an affected pregnancy. Prenatal diagnosis for severe late-onset disorders such as Huntington disease evokes controversy as many clinicians believe parents have the right to terminate an affected pregnancy but highlight that otherwise current guidance discourages testing of children for late-onset disorders until they are able to give consent (Duncan, Foddy, & Delatycki, 2006). Prenatal diagnosis is possible for chromosomal abnormalities, many Mendelian disorders and for those caused by identified microscopic deletions and/or duplications, but these are relevant only rarely in child psychiatric disorders. In child psychiatric disorders in which there is an excess of affected males but no specific prenatal diagnostic tests, the question of female sex selection arises. This is an imprecise method of altering the risk of an affected child as the majority of male offspring will be unaffected and female offspring may develop the disorder.
Pre-implantation Genetic Diagnosis

Pre-implantation genetic diagnosis (PGD) involves genetic analysis of the embryo in vitro and selection for implantation only of those appearing disease-free. PGD has been used to detect mutations responsible for Mendelian disorders in the embryos of at-risk couples (Sermon, Van Steirteghem, & Liebaers, 2004), and to screen for chromosomal abnormalities in the embryos of couples at greater risk or with a history of multiple miscarriages, infertility for unknown reason or male factor infertility, or in vitro fertilization (IVF) failures. In non-disclosure PGD, couples at risk themselves for a late-onset disorder, such as Huntington disease, can opt for the selection of disease-free embryos without knowing themselves whether they carry the mutation. Parents have also selected embryos on the basis of their HLA type, to provide stem-cell donation for a sick sibling (Devolder, 2005). In the latter instances, there has been considerable ethical debate about the circumstances in which such methods should be applied and the practice is determined in some but not all countries by regulatory authorities (Takeshita & Kubo, 2004). Because embryo selection is perceived as less drastic than termination of pregnancy, it may be used in the future to select in relation to susceptibility genes, which increase the risk of, but do not determine the presence of, complex disorders.

Presymptomatic Testing

Molecular genetic tests allow detection of mutations that will lead to a disorder in currently healthy persons. Such presymptomatic testing should be differentiation according to whether there are therapeutic implications of a positive test result. In some conditions, including the hereditary cancers, a positive presymptomatic result has direct implications for screening and surveillance while a negative test result obviates this need. For other conditions, such as Huntington disease, there are at present no treatment consequences of a positive result and the reasons for requesting testing are more complex. The uptake of presymptomatic testing has, not surprisingly, varied according to treatment implications of a positive result. Uptake for Huntington disease testing has been approximately 10–20% (Crauford, Dodge, Kerzin-Storrar, & Harris, 1989; Quaid & Morris, 1993), compared with approximately 50% for hereditary breast cancer, where the role of early treatment is uncertain, and 80% for familial adenomatous polyposis, for which early surgical intervention has a significant health impact (Harper, 1998).

With regard to presymptomatic testing of children, current guidance indicates that children should not be tested for disorders for which there are no therapeutic consequences, until they are of an age to give consent themselves, unless there is demonstrable medical or psychosocial benefit (Clarke et al., 1994). Non-geneticists are more likely to offer presymptomatic and carrier testing of children at parental request; one commonly stated reason for testing was to reduce parental anxiety (Clarke, 1994). Although the impact has not been examined in children, studies of adults tested for late-onset disorders failed to find long-term anxiety reduction (Braidstock et al., 2000). In relation to diseases such as cancers in which a positive test result may alter the screening practice, current guidelines propose that testing should be permitted at the earliest age of onset (Kodish, 1999). In some cases, this delays testing until an age at which children can participate in the consent process. This position stems from the bioethics paradigm adopted by most genetic counselors which places pre-eminence on the autonomy of the individual (child) over that of the wider social network (family), but such a view ignores the broader psychological and cultural diversity in which family needs could take precedence over individual autonomy (McConkie-Rosell & Spiridigliozzi, 2004).

Child psychiatrists and their colleagues may be called upon to advise on the child’s ability to give informed consent to genetic testing or upon family issues thrown up by the genetic disorder and testing. Evaluating the child’s ability to consent follows the same principles as those for any medical treatment but account should be taken of longer-term consequences of genetic testing such as discrimination, the impact on wider family relationships and that, unlike some treatments, once testing has been undertaken, the information cannot be withdrawn.

Presymptomatic assessment is beginning to include testing of susceptibility genes for complex disorders. The preliminary results suggest that inclusion of genetic data in risk results, in comparison to similar risks based only on empirical recurrence, reduces anxiety and risk perception in those receiving a low-risk result (LaRusse, Roberts, Marteau et al., 2005) and does not alter risk perception in those receiving a high-risk genotypic result (Marteau, Roberts, LaRusse, & Green, 2005). Such presymptomatic testing is theoretically feasible for susceptibility genes in some child psychiatric disorders but is not routinely offered at present.

Carrier Detection

A carrier is someone who carries a single copy of a genetic mutation and is healthy at the time of study. With the exception of carriers of late-onset dominant disorders, carrier status is therefore of importance primarily for reproductive planning. Carrier status is a concern for families with affected members where healthy individuals are uncertain whether they may pass on the disorder to their offspring. The issues in relation to testing of minors overlap with those raised by presymptomatic testing (McConkie-Rosell, Spiridigliozzi, Rounds et al., 1999). The benefits could include a reduction in parental concerns regarding the child’s status, a longer time for the child and family to accommodate to the knowledge, an understanding of the genetic risks prior to any unplanned pregnancy and to consider alternatives regarding reproductive planning (McConkie-Rosell, Finucane, Cronister et al., 2005). However, the drawbacks include the loss of the child’s autonomy, possible labeling and differential (real or perceived) treatment of siblings according to genetic status, potential effects on the child’s self-concept and adverse effects on their ability to form future relationships, and possible discrimination (e.g., from insurance companies). The extent to which self-concept and future relationships are adversely affected by genetic testing of minors is largely unknown. Although parents with one
affected child may press to have other children tested for carrier status, current recommendations state this should be resisted until the children are of an age to give informed consent themselves (Clarke, Fielding, Kerzin-Storrer et al., 1994). An effect of waiting until children are able to give informed consent is that uptake of testing may be lower. In cystic fibrosis, where genetic carrier testing has been available for some years, uptake amongst siblings of affected people has been poor. Several reasons have been cited, including poor communication with parents regarding genetic issues and feeling that affected siblings would have difficulty accepting their decision to be tested (Fanous & Johnson, 1995a). The finding that beliefs about carrier status were not influenced by educational or income level suggests that emotional factors may play an important part in attitudes about screening (Fanous & Johnson, 1995b).

Population Screening
Population screening involves identifying those with or at risk of having offspring with genetic disorders amongst the general population. Population screening aims to detect diseases for which early treatment improves prognosis and to identify untreatable severe disorders in fetuses to allow couples to make informed reproductive decisions. Population screening may occur at any stage from the prenatal period to later life and now includes testing for common genetic variants that may influence disease, both in a Mendelian pattern, such as hypercholesterolemia associated with low-density lipoprotein receptor abnormalities and as a susceptibility allele for a complex disorder, such as apolipoprotein E4 in late-onset Alzheimer’s disease. Cascade screening is an intermediate strategy involving systematic contact of more distant at-risk family members with the offer of testing.

Genetic population screening differs from other forms of population screening because it detects disease of genetic origin, for which there may be implications for other family members. Unlike individual genetic testing, in population screening clients may have little knowledge of the disorder, raising uncertainty about the degree of informed consent. At present, population screening with respect to child psychiatric disorders is limited to conditions causing significant intellectual disability such as phenylketonuria and Down syndrome. There is debate over the merits of population screening for fragile X syndrome. As one of the most commonly inherited forms of intellectual disability, detection of the carrier state in mothers has the potential to promote greater reproductive choice. Current recommendations are that prenatal carrier screening for fragile X should be undertaken only in those at known risk (Sherman, Fletcher, & Driscoll, 2003). However, popular opinion does not fully support this strategy; women attending a prenatal diagnostic clinic for other purposes were strongly in favor of global screening (Fanous, Spangner, & Musci, 2006) as were parents of children affected with the disorder (Skinner, Sparkman, & Bailey, 2003), raising the question of who should decide which tests are available.

Multiplex genetic tests assess a person’s genotype for a range of different genes, much in the way current laboratory tests examine a range of blood chemistries. Such tests may provide the simplest and least expensive way to assess risk for one condition, but they may also detect variations in other genes for which testing was not intended and no consent was obtained.

Pharmacogenomics
Pharmacogenomics is the study of the variability in genes relevant to disease susceptibility and drug response (see chapters 16 and 23). Genetic variations influence drug response in three ways:

1. Affecting the processing of drugs by the body (pharmacokinetics);
2. Modifying the proteins that are targeted by drugs (pharmacodynamics); and
3. Altering the risk of acquiring certain diseases.

In psychiatry, pharmacogenomics holds promises especially for more effective, individually tailored treatments with reduced adverse effects. However, a range of ethical concerns are raised, amongst them the concern that more personalized treatments may also increase health inequalities and jeopardize patient confidentiality and informed consent (Breckenridge, Lindpaintner, Lipton et al., 2004; Nuffield Council on Bioethics, 2003; van Delden, Bolt, Kalis, Derijks, & Leufkens, 2004).

Counseling Prior to Adoption
Requests for pre-adoption genetic counseling occur when the biological parents are believed to have a genetically influenced disorder, especially as mental illness in parents is a common reason for childhood adoption. In considering such requests, one needs first to determine whether the individual requesting the information has the legal status to do so. In considering the child’s rights, one needs to balance the abrogation of his or her right to decide whether or not to be the subject of genetic counseling against the possibility that, without genetic information, prospective parents may decline the adoption, which may not be in the child’s interests. Alternatively, the results of genetic information may reverse a positive decision from prospective parents. In addition, one needs to consider the rights of adoptive parents to accurate information about the child’s background and what problems they are likely to encounter in rearing the child. Although genetic counseling for potential adoptees is currently mainly requested in relation to severe mental illness in parents, the considerations in relation to which disorders should be the focus of genetic counseling (see p. 1185) apply here as they do to couples making enquiries on their own behalf. Genetic counseling may be hampered by vague information regarding biological parents, as giving accurate advice requires specific information about both parents. Where parental medical records are available, it is essential to ensure that these have been obtained through legal and ethical channels. When it is impossible to obtain adequate background history, the information imparted needs to reflect this uncertainty and should include the range of plausible levels of risk. Should genetic testing of a child be considered, an independent advocate for the child should be involved in the decision-making. It has been suggested that
adopted children might be informed about known genetic risks from their birth parents at age 18, when they are able to request knowledge of the identity of their birth parents; otherwise, adopted children are at a disadvantage with respect to knowledge of their potential genetic risks (Nuffield Council on Bioethics, 1998).

**Role of the Child Mental Health Specialist in Genetic Counseling**

The considerable variation in uptake of genetic screening and counseling according to racial/ethnic and sociodemographic groups (Hall & Olopade, 2005) suggests it may constitute an area of a health inequality. The diagnosis of a disorder associated with a strong genetic risk places a responsibility on the professional to apprise family members of this risk and to assist with the provision of appropriate genetic counseling and investigation if desired. This requires the professional to have a good general understanding of the nature and importance of genetic risk factors. Only those able to interpret the results of a genetic test should order the investigation (Taub, Morin, Spillman et al., 2004), so that referral to a geneticist or a joint consultation may be most appropriate.

**Practical Aspects of Genetic Counseling**

**Referral for Genetic Counseling**

Almost all child psychiatric disorders show some degree of genetic risk (Rutter, Silberg, O’Connor, & Simonoff, 1999), but this does not mean genetic counseling is necessarily appropriate. First, the quality and precision of the evidence in relation to genetic factors require consideration. The heritability of the disorder, the proportion of individual variation that is accounted for by genetic factors and the recurrence risk in relatives of those affected should be considered. Although the latter is the figure most directly relevant to families, it fails to distinguish genetic and environmental causes of familial aggregation. For many child psychiatric disorders, the current literature contains widely varying findings that make it impossible to give precise information to families. Another practical problem is that the empirical recurrence risk may be known for offspring and siblings, but not for other relationships.

A second consideration is the extent of impairment or disability caused by the problem. Traits such as emotionality and sociability are strongly genetic but infrequently impairing in their own right. Whereas professionals should not impose their view as to which traits or disorders warrant genetic counseling, issues of severity, impairment and treatability should be considered by families and professionals alike (Nuffield Council on Bioethics, 2002).

Autism is the child psychiatric disorder (other than intellectual disability) for which there is the strongest case for formal genetic counseling and it is therefore the template for what follows. Although formal genetic counseling may not be appropriate for all other child psychiatric disorders, it may be helpful for parents to know when genetic influences have a role in their child’s difficulties, particularly if they have inappropriately blamed themselves or other causes for the problem.

Twin studies of autism show a high heritability of the disorder (Bailey, Le Couteur, Gottesman et al., 1995) and family studies concur that the sibling recurrence risk is 5–6% for autism and pervasive developmental disorder (Rutter, Bailey, Simonoff, & Pickles, 1997). Although population rates of autism have increased (Baird, Simonoff, Pickles et al., 2006), there is at present no evidence to suggest a similar change in the sibling recurrence risk. Autism is life-long, essentially incurable, severely impairing and creates a heavy burden on families. In the majority of cases, inheritance will be complex and is likely to involve a number of susceptibility genes and as yet unspecified environmental or random factors (see chapter 46). Although families may need some time to adjust to the diagnosis, it is important that they have access to genetic counseling before planning further children. If genetic counseling is to be offered by the clinician looking after affected family members, such counseling is best undertaken in an appointment specifically designated for this purpose.

**Assessment**

Genetic counseling should commence by confirming the diagnosis in the proband. The challenge of this task varies enormously depending on the information available, but is a necessary first step to ensure that genetic counseling is given for the correct disorder. This may raise at an early stage family issues of communication regarding illness and may delay the more formal aspects of genetic counseling until the necessary information has been obtained. In rare cases it is impossible to obtain adequate diagnostic information. Approaches vary but the clinician should usually go ahead with genetic counseling having apprised the clients of the uncertainty regarding diagnosis.

Consideration is given to etiological factors that may alter recurrence risk. In autism, 5–10% of cases are caused by a recognized medical disorder and these should ideally be excluded in the proband as they will alter the recurrence risk. The most common medical disorders causing autism are tuberous sclerosis and fragile X (Rutter, Bailey, Simonoff et al., 1997) and, in such instances, the relevant disorder for genetic counseling is the underlying medical condition. Where cytogenetic or microscopic chromosomal abnormalities are present, there may be less certainty regarding their etiological role and a clinical genetics opinion should be sought, as well as testing other family members.

Rare environmental causes in the proband should also be excluded. Congenital rubella is the most common infectious cause of autism. There has been much debate as to whether association of obstetric complications with autism (usually with milder levels of adversity) indicates a causative role (Goodman, 1990); the further association of obstetric complications with congenital anomalies suggests that abnormal development in the fetus may be responsible for the obstetric complications (Bailey, Le Couteur, Gottesman et al., 1995; Bolton, Murphy,
Macdonald et al., 1997). However, it is likely that severe perinatal adversity, as well as other causes of brain injury, can cause autism. Where an “environmental” cause of brain injury is the likely cause of autism, the recurrence risk may be much lower and possibly the same as for the general population.

In gathering information, a systematic family history is essential. Multiple miscarriages and consanguinity should be excluded. In determining whether there are other family members affected, enquiry should include a broad range of psychiatric and neurological disorders. If a pattern suggestive of Mendelian inheritance emerges, it may be appropriate to review the original diagnosis and consider whether further investigation is required. In multifactorial disorders where heavier family loading is thought to indicate greater disease liability within the family and therefore predict a higher recurrence risk (Carter, 1976; Falconer, 1981), such information can be used to alter the recurrence risk information given to families. In practice, there are few empirical data from which to vary recurrence risk for any of the child psychiatric disorders.

It is important to enquire about both sides of the family even when the proband is related to only one member of the couple. In genetically complex disorders, individual susceptibility genes are likely to be common and the risk for a couple seeking counseling depends upon the genetic contribution of each side. Family history should also take account of maternal and paternal age, as there may be a risk of chromosomal disorders that have not been considered and should note other disorders that may place the couple at increased risk of having a child with a genetic disorder.

Communication

When families attend for genetic counseling, it is essential to clarify at the outset the questions they wish to address. It is helpful to find out who has sought the referral and, if not the family, how they view it. A small minority of families do not agree with the diagnosis; without addressing this first, genetic counseling is unlikely to be helpful. Clients may have additional questions about the risk for other family members; the usual policy is to give specific counseling only to the couple attending the clinic. A further question for families may be whether there was a causal role of environmental factors. Families may wish to know whether there are any measures they can take to reduce the chances of having an affected child.

In discussing risk, it is important to clarify the clinical spectrum of the disorder. With autism, this includes the broader phenotype of speech and language delay, literacy problems and social eccentricities. Although these are substantially more common, they are also much less impairing and this is important to emphasize to families (Rutter, Bailey, Simonoff et al., 1997). Couples may be preoccupied with the risk of the disorder for which they have sought counseling and it can be helpful to remind them of the general population risk of 1 in 50 infants having a significant mental or physical handicap (Harper, 1998). Couples also find it helpful to compare their personal risk with that of the general population. It is important to ascertain that clients understand the risk information given to them; observational studies have suggested genetic counselors frequently fail to confirm this (Michie, Lester, Pinto, & Marteau, 2005).

There is a general view that genetic counseling should be non-directive, making information available to families but not advising them on how to proceed. In actual fact, this may be difficult to achieve. Michie, Bron, Bobrow, and Marteau (1997) found that counselors made an average of 5.8 pieces of “advice” and the same number of “evaluative” comments per counseling session, throwing into question the perception of the counseling process as non-directive. This may not be undesirable; in another study, 80% of clients at risk for having an offspring with a severe disorder reported that they wished to receive an opinion from their genetic counselor on what course of action to take (Furu, Kaariainen, Sankila, & Norio, 1993). In another study, patients receiving non-directive counseling perceived their risk to be higher than those obtaining more directive counseling, possibly feeling in the former case that the neutral counselor was withholding information (Shiloh & Saxe, 1989). Families receiving the same recurrence risk for a child psychiatric disorder have widely varying opinions of whether the risk is high and may make different reproductive decisions.

A great deal of information is exchanged during genetic counseling and it is good practice to write directly to clients following the consultation to summarize the information they have been given. It may be appropriate to offer follow-up sessions to the clients, particularly if there is a large difference in how each member of the couple views the information they have been given.

Problems and Limitations in Counseling for Child Psychiatric Disorders

With increasing awareness of the role of genetic factors in common disorders, clients make more sophisticated requests of genetic counseling, many of which extend beyond present knowledge. A common difficulty arises when the proband does not fulfill the full diagnostic criteria upon which the relevant genetic studies were based. It is often unclear whether the findings can be generalized to diagnostic variant, subthreshold cases or individuals with other comorbidities. When there are no empirical recurrence risk data for the client’s relationship to the proband, it is necessary to rely on genetic principles showing that for multifactorial disorders, there is a rapid fall-off in recurrence as the genetic relationship becomes more distant, to estimate risk. Whereas it is recognized that genetic heterogeneity will occur even within a homogeneous clinical picture and that the same genetic susceptibility can lead to marked clinical variation (Le Couteur, Bailey, Goode et al., 1996), it is unlikely that this knowledge can be used to modify risk until the molecular genetic basis is better understood. This means the genetic information for individual families is likely to be very imprecise. Families seeking genetic counseling often want a way of knowing in advance whether a child will be affected. In multifactorial disorders, it remains to be seen how precise risk information will become.

This means the genetic information for individual families is likely to be very imprecise. Families seeking genetic counseling often want a way of knowing in advance whether a child will be affected. In multifactorial disorders, it remains to be seen how precise risk information will become.
Genetic Testing in Research Contexts

In the last two decades, genetic research has increased exponentially and many non-genetic studies have chosen to include a genetic component. The research may be exploratory and without clear implications for participants. Consent is therefore often non-specific, open-ended and not discussed in detail with participants. Frequently, researchers do not expect to obtain findings with clinical implications for the research participant. Research samples are frequently anonymized to ensure confidentiality but there is little information on whether participants fully understand the implications of this. As genetic research becomes increasingly relevant to clinical concerns, it is essential that the framework for consent and conduct is regularly reviewed.

Conclusions

The rapid pace of advances in psychiatric genetics requires genetic counseling to be flexible in relation to its scope, approach to investigation and conceptualization of disorders. Those delivering genetic counseling will need to communicate effectively with mental health professionals diagnosing and treating disorders to ensure that patients and their families have access to genetic investigation and counseling when it is appropriate. Research on genetic causes of psychiatric disorder must be matched by research on the ethical and social consequences of providing the different aspects of genetic testing and counseling with respect to disorders that show a complex pattern of inheritance.

CHAPTER 73

This chapter examines educational provision for those children who, at some stage in their school lives, experience difficulties that interfere with learning. These are children who, because of developmental delays or behavioral difficulties, lack the cognitive, linguistic, attentional or social skills needed to cope with ordinary schooling and who thus require special help in order to access the wider teaching curriculum. They include children with long-term and pervasive conditions such as intellectual impairments (intellectual disability), developmental language disorders or autism; more specific learning disabilities, such as dyslexia; sensory and physical impairments or chronic illnesses; and children with severe emotional and/or behavioral difficulties.

What are Special Educational Needs?

Many different definitions exist, but the Special Education Needs (SEN) Code of Practice (Special Educational Needs and Disability Act, 2001) defines children with special educational needs as those who, compared with their peer group, have:

1. A significantly greater difficulty in learning; or
2. A disability that prevents or hinders them from making use of educational facilities of a kind generally provided.

Further, “A child is defined as disabled if he is blind, deaf or dumb or suffers from a mental disorder of any kind or is substantially and permanently handicapped by illness, injury or congenital deformity or such other disability as may be prescribed.”

The same document defines special educational provision as that “which is additional to, or otherwise different from, the educational provision made generally for children of their age in (state) maintained schools.”

However, decisions about what constitutes a “significantly greater disability” vary across schools and education authorities and are influenced by the political and financial factors operating at any one time. Moreover, although the same Code of Practice notes that children with special educational needs “should have their needs met . . . and be offered full access to a broad, balanced and relevant education,” how to achieve this remains unspecified.

What are the Goals of Special Education?

Educational goals are affected by the nature and extent of an individual’s disabilities. Many children with sensory or physical impairments or chronic illnesses are of normal intellectual ability and, with appropriate support, should be able to progress within mainstream settings. Children with more pervasive developmental, learning or behavioral difficulties require more radical modifications to the educational environment and curriculum. For the majority of children with special needs, education should provide them with the skills required for social inclusion as adults so that they leave school with the skills needed to fit in with and be accepted by society, develop strategies to minimize their difficulties and achieve emotional stability and positive self-esteem. Although scholastic attainments and academic qualifications are important, these should be of an appropriate kind and level, and there must also be a focus on broader aspects of social, emotional and behavioral development. Moreover, some children, particularly those with severe to profound intellectual impairments, are unlikely ever to lead totally independent lives. For them, education should promote the development of effective means of communication, the acquisition of basic daily living and social skills and the minimization of behavioral problems.

Does Special Education Mean Inclusive Education?

During the 19th century, individuals concerned to improve education for children with special needs (Gordon, 1885; Lettsom, 1894) fought to establish specialist, disability-specific schools. However, by the latter half of the 20th century, there were increasing fears about the long-term effects of isolating these children from their typically developing peers. Pressure for integration was strengthened by significant changes in legislation. In the USA, the Education of All Handicapped Children Act, 1975 (Public Law 94-142; now the Individuals with Disabilities Education Act [IDEA], Public Law 101-476) required public schools to provide all students with special needs with access to a “free and appropriate education” in the “least restrictive environment.” The Americans with Disabilities Act, 1990 (ADA, Public Law 101-336) further outlawed discrimination against any child with special needs. UNESCO’s
Salamanca Statement (1994) called for all governments to “adopt as a matter of law or policy the principle of inclusive education.” In the UK, the highly influential Warnock Committee report (1978) led to the widespread view that all pupils with special needs had a “right” to mainstream education (Department for Education and Employment, 1998).

However, although inclusion has often been interpreted as requiring the elimination of all segregated schooling, Public Law 94-142 states that there may be grounds for “special classes, separate schooling, or removal . . . from the regular education environment . . . (if) education in regular classes . . . cannot be achieved satisfactorily.” The UK Special Educational Needs and Disability Act (2001) also notes that pupils may be educated in alternative provision if their presence in mainstream is incompatible with the provision of efficient education for other children. Moreover, Warnock herself (2005) criticized the manner in which her original report was misinterpreted as espousing mainstreaming for all children, regardless of disability level, the impact on other pupils or the availability of adequate resources.

**Empirical Evidence for Inclusion**

Empirical research on the relative effectiveness of special versus integrated education is extremely limited. Indeed, it has been suggested that such research is inappropriate because the issue is one of rights, not evidence (Gallagher, 2001). Well-conducted comparative studies are rare, randomized controlled trials virtually non-existent and research methods and analysis vary from study to study (Lindsay, 2007). A major problem is that inclusion is not a simple unambiguous concept: “special educational needs” encompass specific learning disabilities, severe and pervasive developmental disorders, and disruptive and challenging behaviors. Programs range from the highly specific to a general (often poorly defined) “whole school inclusion policy”; and monitoring treatment fidelity presents major practical difficulties (Lindsay, 2003). Heterogeneity of samples and inadequate information on children’s cognitive, linguistic, social and behavioral characteristics make it almost impossible to generalize from one study to another. Finding appropriate comparison groups also presents difficulties because children in specialist settings often tend to have more academic and behavioral problems than pupils of similar IQ in mainstream (Rafferty, Piscitelli, & Boettcher, 2003). Even terminology is a problem. Thus, “learning disability” refers to specific difficulties (e.g., reading, spelling, motor) in the USA but is used synonymously with mental retardation (now termed intellectual disability; see chapter 49) in the UK. In a review of 1373 published studies on inclusion from 2001–2005, Lindsay (2007) identified only nine that compared outcomes for children with special needs in specialized versus mainstream settings. There were no randomized controlled trials; the results of most studies were equivocal and the few that did find positive effects for mainstreaming all suffered from significant methodological limitations.

**Alternatives to Full Inclusion**

The UK Office for Standards in Education (Ofsted, 2004) recently noted that, despite the widespread policy of inclusion, the numbers of pupils being sent to referral units or special schools was rising as mainstream schools were finding it increasingly difficult to manage students with social and behavioral difficulties. Even when pupils with special educational needs were mainstreamed, much teaching was carried out by unqualified staff and the quality of education was poor, resulting in disruptive behavior, poor attendance and high staff turnover, especially in secondary school.

Because of the conflicts faced by teachers trying to cope with the demands of perhaps 30 other pupils, various alternatives to full-time integration have been explored. Although critics claim these lead to increased discrimination by excluding difficult pupils from the classroom, there is some evidence of their effectiveness.

**Resource rooms** are usually separate classrooms where children can be offered individual teaching for part of the school day. Some cater for children with specific difficulties, others for pupils with broader impairments, and a combination of resource room and regular classroom teaching has been found to improve educational progress (Marston, 1996). Placement on the same site as the mainstream school seems more likely to result in integration than placement in units that are geographically isolated (Burack, Root, & Zigler, 1997) and students with special educational needs themselves indicate a preference for receiving support in a separate environment while being able to mix with their peers at other times (Norwich & Kelly, 2004).

**Dual placements** – in which pupils are enrolled in both mainstream and a special placement – are currently recommended by the Department for Education and Skills (2001a) in the UK as an alternative means of supporting inclusion. Dual placements can help prepare pupils for mainstream education by providing them with skilled individualized support for areas of particular need while mainstream teachers profit from the input and advice of specialist staff. Although evaluation of the benefits of dual placements is still needed, this flexibility could potentially meet the requirements of many pupils, and provides a bridge between fully inclusive and full-time special education.

**Specialist Teaching Programs**

There are vast numbers of publications offering advice on “the making of the inclusive school,” and how to improve the curriculum, environment, support structures and general attitudes. Co-operative learning (groups of students working together to achieve mutual goals) has been recommended in a number of studies although this seems to have more impact on social engagement than academic skills (Murphy, Grey, & Honan, 2005). Self-evaluation and self-monitoring programs (Sainato, Goldstein, & Strain, 1992), the Adaptive Learning Environment Model (ALEM; Wang & Walberg, 1993), Mediated Learning (Mills, Dale, Cole, & Jenkins, 1995), Instrumental Enrichment (Feuerstein, Rand, Hoffman, & Miller, 1980) and Creative Action...
Planning techniques (Forest, Pearpoint, & O’Brien, 1996) all have their advocates, but either experimental evaluations are small in scale or their findings are equivocal (Dale, Jenkins, Mills, & Cole, 2005; Hornby, Atkinson, & Howard, 1997).

The following sections address issues related to special education for children with different types of difficulties. The earlier sections relate to children with relatively mild intellectual impairments, “specific” learning difficulties, or sensory or physical problems, for whom the crucial issue is how their needs can be better met in mainstream settings. The latter sections deal with those pupils for whom the merits of inclusive education are much less well established – children with severe emotional and behavioral problems and those with pervasive disabilities, such as developmental language problems, autism or severe intellectual disability.

**Education for Children with Mild to Moderate Intellectual Impairments**

The American Association on Mental Retardation (2002) defines intellectual disability as “characterized by significant limitations both in intellectual functioning (generally accepted as IQ below 70) and in adaptive behavior (and) refers to a particular state of functioning that begins in childhood, has many dimensions, and is affected positively by individualized supports.”

**Academic Attainments**

The majority of studies on inclusion have focused on children with mild intellectual disabilities (IQ 50–70, DSM-IV-TR; American Psychiatric Association, 2000). Once they leave school, most of these individuals will be expected to live independently and be able to socialize with and work alongside their “typically developing” peers. Thus, it is important that they are provided with the skills needed for optimum social inclusion from the earliest years. In principle at least, helping them to learn with and from their peers should enhance academic skills, social adjustment and self-esteem. There is also evidence that once children are placed in segregated provision their chances of reintegration or of achieving age-appropriate educational standards diminish with age (Farrell & Tsakalidou, 1999). European statistics over the last 2–3 decades show a significant decline in the number of special schools for children with mild to moderate intellectual impairments (Meijer, Soriano, & Watkins, 2003) and those that remain tend to cater for children with more severe social and behavioral problems.

What is known about the educational progress of these pupils in inclusive settings? Baker, Wang, and Walberg (1994) summarized the findings of three meta-analyses of inclusive education 1970–1992 involving over 70 studies. The results provide only limited support for inclusion, with effect sizes for academic outcomes being generally small (range 0.08–0.44; average 0.22), albeit positive. Findings are also influenced by pupil characteristics. Mills, Cole, Jenkins, and Dale (1998) reported no main effect of classroom type for children with mild to moderate intellectual impairment but there was an interaction effect, with higher-functioning children gaining more from special integrated classes and lower-functioning children performing better in segregated classes. The choice of outcome measures further affects conclusions. Rafferty, Piscitelli, & Boetcher, (2003) found that although pupils with mild intellectual disabilities appeared to do equally well in segregated or inclusive classes, the subgroup with the lowest IQ made greater language and social progress in inclusive classes but showed higher rates of behavior problems than children in segregated classes.

A further experimental confound relates to the quality of the educational settings studied. Much research into the benefits of inclusive placements has been conducted, especially in the USA, in highly resourced university-based research settings, in small classrooms (often fewer than 15 children), and with preschool or elementary school pupils. In contrast, the poor progress of many pupils in special schools may be a result, not of segregation per se, but of the poor quality of teaching provided (Giangreco, 1997; Manset & Semmel, 1997).

Finally, conclusions are often limited by a lack of crucial information about the participants. One frequently cited study in support of inclusive compared with “pull-out” programs (Rea, McLaughlin, & Walther-Thomas, 2002) included only children of average IQ and provided very limited information on the preplacement skills of the pupils involved.

**Social Integration and Self-Esteem**

Writers espousing the human rights and equality arguments in favor of inclusion (Lipsky & Gartner, 1999) insist that this is essential for positive social development. Early reviews (Carlberg & Kavale, 1980; Cole & Meyer, 1991; Lakhn & Norwich, 1990) also claimed that inclusion led to more positive social outcomes and higher self-esteem. However, effect sizes for social improvements among children with mild intellectual disabilities in inclusive classrooms are typically even smaller than the effect sizes for academic attainments (range 0.11–0.28; average 0.19; Baker, Wang, & Walberg, 1994). A review of 14 studies (Nakken & Pijl, 2002) found some reported better social interactions and friendships among mainstreamed pupils; in others inclusion seemed to make little difference, whereas some reported negative effects. Other reviews (Burack, Root, & Zigler, 1997; Hornby, Atkinson, & Howard, 1997) have failed to find evidence of enhanced social skills, self-esteem or peer acceptance within inclusive settings. Moreover, for some pupils with mild to moderate intellectual impairments, the school experience can be very negative, with integrated schooling actually leading to lower self-esteem and increased stigmatization, bullying and rejection by peers (Bear, Clever, & Proctor, 1991; Norwich & Kelly, 2004).

**Education for Children with “Specific” Learning Disabilities**

**Reading and spelling difficulties**

Around 5% of school-aged pupils have persistent and significant reading difficulties and the adverse effects on many aspects
of children’s development, including emotional and behavioral disturbance, are well documented (see chapter 48).

Almost any type of intervention initially seems to produce short-term gains, although these are rarely well maintained. Overall, a combination of the “Reading Recovery” approach (intensive, structured, individualized reading programs; Clay, 1985) together with training in phonological awareness and explicit work on letter-sound correspondence, has proved most consistently effective (Troia, 1999). Computerized programs, allowing self-assessment of reading ability and providing clear and immediate feedback using synthesized speech, are also reported as successful (Vollands, Topping, & Ryka, 1999; Wise, Ring, & Olson, 2000). However, the gains may be very specific to the skills taught and often fail to generalize to other literacy problems or to new situations. Thus, a computer-based Colorado remediation project (Wise, Ring, & Olson, 2000) indicated that outcome may still depend on the amount of direct monitoring by adults. This study also reported an interaction between treatment response and the nature and severity of children’s reading problems although, overall, meta-analyses have failed to demonstrate a clear relationship between basic aptitude and type of intervention (Norwich, 2003).

Given the complexity of the problems of many pupils with reading difficulties, factors other than the specific literacy intervention are likely to have an impact: teacher effectiveness, classroom organization, amount of time spent on reading and adequacy of resources (human, environmental and technical). Classroom assistants can have an important role, but only if they are fully trained to implement the program. Peer tutors may also prove an effective source of intervention (Topping, 2001). Specific homework tasks can be helpful and parental participation is also important (Topping, 2001), but only if parents are given appropriate guidance in what to do; simply encouraging them to listen to their child has little effect. A major problem is the poor maintenance of reading skills once intervention ceases and research is still needed to identify the factors required to ensure continuing long-term progress. Extra tuition for children with reading and/or spelling problems often continues to be provided outside the classroom or in privately funded centers, both of which limit opportunities for participating fully in school life.

Specific Language Impairments

Specific language impairments are among the most frequent of childhood developmental disorders, with epidemiological studies suggesting prevalence rates in 5-year-olds of around 6–7% (see chapter 47). Co-occurring scholastic problems, related to reading, spelling and mathematics, are common and there is a significant risk of later emotional, social, behavioral and psychiatric problems. Meta-analyses of speech and language therapy interventions indicate that, although these may be helpful for children with phonological and vocabulary difficulties, the evidence for their impact on expressive syntax disorders is variable, and there is little evidence of effectiveness for children with receptive disorders (Law, Garrett, & Nye, 2003).

In recent years, much of the focus of intervention programs for specific language impairments has been on the development of improved reciprocal communication strategies for parents and very young children (Pepper & Weitzman, 2004). The University of Kansas Language Acquisition Pre-school Program (Rice & Wilcox, 1991) indicated that this inclusive preschool model, involving parents and normal peers, significantly increases children’s chances of remaining with their peer group once they reach school age. School-based programs for older children (e.g., Speech Foundation of Ontario, Hayden & Pukonen, 1996; or the ECLIPSE project, Schwartz, Garfinkle, & McBride, 1998) stress the need for individual assessment and involve the creation of an environment that is designed to elicit and enhance communication, the structuring of interactions with and by peers, and the use of naturalistic teaching strategies, together with specific techniques such as modeling, turn taking, topic manipulation, conversational repair, scripts and time delay. The FastForword program (Tallal, Miller, Bedi et al., 1996) involves an intensive computer-based program designed to develop a range of language skills, although recent research has shown disappointing results (see chapter 47). Moreover, there are few interventions that can be readily used by class teachers, either in mainstream or specialist settings. The FastForword program, for example, requires a rigorous 100 min per day, 5 days per week for 4–8 weeks. Instead, for most children access to language therapy, of any kind, tends to be limited. Mainstream teachers frequently have little understanding of the wider needs and problems of these children (Lindsay, Dockrell, Mackie, & Letchford, 2005) and few receive any direct input from specialist therapists (Davison & Howlin, 1997).

Lindsay and Dockrell (2000) suggested that self-esteem may be higher in children with speech and language disorders educated in special rather than mainstream schools, but generally evidence for the benefits of different placements on academic, social or even language outcomes is lacking. Lindsay et al. (2005) found widely varying practices and very different degrees of inclusion and levels of classroom support in their study of specialist language provision for children in England and Wales. The criteria for admission to language units, integrated resources or special schools also differed so it was not possible to make direct comparisons between specialist or integrated provision – each seemed to have some advantages and drawbacks. Of particular concern is the lack of any specialist provision for most children, including those with severe language impairments, when they reach junior school (at around 8 years). Once speech improves (even though many other difficulties persist) children are often transferred to mainstream school, without any additional help (Davison & Howlin, 1997). Howlin, Mawhood, and Rutter (2000), in a follow-up study of 20 individuals with receptive language impairments, found that although half had required specialist (often residential) schooling during the primary years, by secondary age 50% were in mainstream schools with little or no additional support. The remainder were in a variety of non-language-specific placements, including schools for behavioral, learning
and emotional disorders. The children also experienced frequent changes of school, often resulting in educational failure, exclusion, bullying, social rejection and low self-esteem.

**Education for Children with Behavioral and Emotional Problems**

Definitions of “emotional and behavioral disorders” (EBD) vary widely and encompass a host of different problems: conduct disorders, antisocial behaviors, hyperactivity, attention deficits, learning disabilities, psychiatric or mood disorders, or any combination of these. The US National Association of School Psychologists (2005) defines EBD as conditions in which “behavioral or emotional responses of an individual in school are so different from his or her generally accepted, age appropriate, ethnic or cultural norms that they adversely affect performance in such areas as self care, social relationships, personal adjustment, academic progress, classroom behavior, or work adjustment.”

Low academic attainments, high rates of challenging behavior and increased dropout from school are typical and the controversy over segregated versus inclusive education for these pupils has been particularly marked because of the disruption they can cause in the classroom. However, the heterogeneity and complexity of problems involved make it impossible to identify any one specific form of effective educational intervention.

Ideally, any treatment program should be based on detailed assessments of the child’s behavioral difficulties, family circumstances, social competence, learning strategies and academic capabilities. Successful interventions involve cognitive-behavioral therapy, interpersonal problem-solving, social skills training, counseling and play – or other individual therapies together with remedial input to enhance general academic skills, memory, auditory and visual processing, and sequencing (Cooper & Ideus, 1996; Hechtman, Kouri, & Respitz, 1996). Other approaches include preschool preventative programs and educational enrichment strategies; there are also studies indicating the importance of combining child-focused interventions with parent training (Frankel, Myatt, Cantwell, & Feinberg, 1997). Randomized controlled trials, conducted in experimental settings, indicate moderate effect sizes on reducing disruptive and/or aggressive behaviors for programs involving social competence training and cognitive-behavioral strategies. Relatively few of these programs have been successfully incorporated into routine educational practice (Wilson, Lipsey, & Derzon, 2003). However, interventions such as the “Dinosaur program” (Webster-Stratton & Reid, 2004) and Promoting Alternative Thinking Strategies (PATHS; Karn, Greenberg, & Kusché, 2004) have been shown to be effective in special education and preschool settings and to have lasting benefits.

It is also important to be aware that judgments as to whether a child has behavioral or emotional problems may depend as much on the attitudes, policies and practices of the school, or the tolerance level of individual teachers, as on the child’s own characteristics. A child who shows very disruptive behavior in one setting may not do so elsewhere (Werthamer-Larsson, Kellam, & Wheeler, 1991) and the role of schools in maintaining or minimizing disruptive behaviors has been widely investigated (Reynolds, 1991; Rutter, 1983). In some cases, transfer to a different class, or a move to a school where teachers are more sensitive to the child’s needs may be sufficient to significantly reduce the level of problems.

**Management Techniques Within the Classroom**

Although school-based programs alone are likely to have only a partial impact on the child’s problems, strategies based on behavioral principles have been shown to be effective in many single-case and studies of small groups for improving disruptive, aggressive and on-task behaviors within the classroom (Gresham, Watson, & Skinner, 2001; Herbert, 1995). As with much behavioral intervention research, group sizes tend to be small and long-term follow-up or generalization measures are often lacking (Evans, Harden, Thomas, & Benefield, 2003). However, there is an increasing number of randomized controlled trials demonstrating the effectiveness of a range of classroom management techniques (e.g., Fast Track Program, Good Behavior Game and Webster-Stratton’s Teacher program; for review see Greenberg, Domitroivich, & Bumberger, 2000; see also chapter 62).

Behavioral approaches have considerable advantages in that they do not require removal of the child from the class and, in principle, the basic techniques can be adapted to the particular needs of any individual child or classroom. On the whole, a focus on positive on-task behaviors is more effective than concentrating on disruptive behaviors (Barkley, 1997; Scott, 1998; Warner Rogers, 1998). Extinction and time out techniques, although extremely effective in controlled settings (Barkley, 1997), can be difficult to apply consistently in the classroom. Other pupils or staff may respond to activities that the class teacher is trying to ignore, or the behavior may escalate to such a level that ignoring is no longer an option. Time out is all too often interpreted as “time out from the classroom” – not necessarily a deterrent for many children – and there is a danger of exclusion periods becoming increasingly lengthy.

Cognitive-behavioral strategies are also effective (see chapter 63; Sawyer, MacMullin, Graetz et al., 1997) but because of the variability of such programs it is generally not possible to identify which specific components are most crucial. Moreover, the more complex the program the more difficult it becomes to incorporate within the regular classroom. The use of other behavioral approaches, such as token economies, differential reinforcement or response-cost, has also been reported in many studies (Rutherford & Nelson, 1995). The most successful programs are based on a detailed functional analysis of the causes and nature of the problems involved but many of these more sophisticated studies have been conducted in specially designed or experimental classes (Gresham, Watson, & Skinner, 2001). The consistent use of such strategies is much more difficult for mainstream teachers coping with 30 or more pupils.
“Co-operative learning” programs, in which students with emotional and behavioral problems work together in groups with typically developing peers, have proved popular, particularly in the USA. A review of co-operative learning programs (Sutherland, Wehby, & Gunter, 2000) indicated some limited evidence for a positive effect on on-task behavior and social skills, but not disruptive behaviors. Nelson, Johnson, and Marchand-Martella (1996) also found that direct instruction was more effective in improving on-task engagement and behavior problems than co-operative learning. Other researchers caution that children with emotional and behavior problems may lack the social and communication understanding required to benefit from these programs (Sutherland, Wehby, & Gunter, 2000).

Sometimes, simple environmental modifications can have surprising effects. For example, the provision of specially designed study areas or changing sitting arrangements from groups to rows can significantly improve on-task behaviors (Hastings & Schwieso, 1995) and reduce classroom disruption (Ware, 1994). Morning teaching sessions tend to be more productive than teaching later in the day; visual aids and brightly colored materials increase attention, and the presentation of materials in small chunks, interspersed with brief breaks, is likely to improve concentration and co-operation (Warner-Rogers, 1998). Generally, however, in order to have a significant impact on severely disturbed or disruptive pupils, attention must also focus on factors outside the classroom, such as the wider school curriculum, organization and climate. Strategies for avoiding potentially high-risk situations (i.e., those when the setting, peer group or even a particular teacher is likely to exacerbate difficulties) also have an important role. Negotiating potentially difficult situations with children themselves, so that they feel part of the consultation and planning process, can increase appropriate behaviors, while remedial intervention for academic difficulties may prevent the escalation of secondary behavior problems. Finally, the involvement of parents is also crucial for the generalization and maintenance of behavior change (Desforges & Abouchaar, 2003).

Children Who are Excluded from Mainstream School

The push towards inclusion has coincided, in the UK at least, with government requirements for a rise in school standards, generally measured by formal examination results. However, the presence of one or more disruptive pupils in the classroom can affect the academic progress of other children and official exclusions from school on behavioral grounds have risen over recent years (from 3833 in 1991 to 9880 in 2003–2004; Department for Education and Skills, 2005). The rates of unofficial exclusions are unknown. Children registered as having special educational needs are nine times more likely to be excluded than other pupils, and exclusions from special schools are also rising (about 300 per year in the UK). Boys are almost five times more likely to be excluded than girls, with rates being highest among Afro-Caribbean boys and children in foster care. Most exclusions (around 60%) are for physical assault or persistent disruptive behavior; around 15% are for verbal abuse or threatening behavior; the remainder involve racist abuse, drugs and alcohol, theft, damage to property and bullying (Department for Education and Skills, 2005). Nevertheless, individual schools and local authorities differ widely in their reasons for and rates of exclusion, and headteachers’ attitudes, school status, policies and practices may have a greater impact than a pupil’s behavior (Hornby, Atkinson, & Howard, 1997).

Overall, the outlook for children excluded from mainstream school is bleak. Around 25% receive home tuition, usually for only a few hours a week; many others attend pupil referral units (over 14,500 children in 2002–2003; UK Department for Education and Skills, 2006). These placements are generally part-time and, as they are not required to offer the full national curriculum, pupils often fall even further behind academically. Moreover, other mainstream schools are often reluctant to accept a child who has been previously excluded. Once they reach their mid-teens, little effort is made to reintroduce these pupils back into school and as many also come from unsupportive and/or disrupted homes they risk drifting into a life of continuing social exclusion.

Although the cost of exclusion to pupils, their families and to society has been widely publicized, the issue of how to deal with it remains largely unsolved. There is general agreement that effective intervention requires better training and resources for teachers, together with the expertise and input of a network of interagency support (Department for Education and Skills, 2006). In practice, provision of such services is limited and many schools only seek specialist support when the classroom situation has totally broken down, rather than at an earlier stage when there is some chance of remediation.

Although some specialist day and boarding schools for children with emotional and behavioral problems survive (some offering intensive therapeutic as well as educational provision), critics claim that these placements are very expensive, isolate children from their home and community and are particularly unsuitable for children from ethnic minorities (Abbott, Morris, & Ward, 2001). However, although data on long-term academic or social benefits are lacking, they may be a helpful resource for some children and their parents (Crawford & Simonoff, 2003) and residential provision can offer a vital “break” for children whose difficulties are largely a result of a severely disturbed or deprived family environment.

Education for Children With Physical and Sensory Handicaps

Physical Disabilities

The desirability of integrating children with physical handicaps into normal classrooms has been recognized for well over a century (see Cole, 1989) but developments in medical technology now mean that increasing numbers of children are surviving with long-term and often highly complex needs. For example, children with cerebral palsy may also have incontinence or epilepsy; they may be unable to communicate effectively; sensory,
Hearing Impairments (see chapter 59)
In developed countries, approximately 1 child in 1000 has a profound hearing loss and 3–5 per 1000 have mild to moderate hearing loss that can affect language acquisition. Deafness can have a profound effect on parent–child relationships and around 25% of children with severe hearing loss show additional emotional, intellectual, physical or sensory problems (Roberts & Hindley, 1999).

The issue of appropriate education for deaf children is complicated by opposing arguments within the deaf community. The poor signing skills of many hearing parents and teachers, and the fact that deaf children of deaf parents often make better academic and social progress than those of hearing parents, have led to claims that education should be provided in specialist settings (residential if necessary). Cochlear implants are criticized as depriving children of their “right” to belong to the deaf community, and fluency in signing, with its own grammar and idiom, is considered a primary educational goal (Balkaney, Hodges, & Goodman, 1996). However, studies of children with successful implants suggest that they are more likely to move into mainstream settings, are better able to communicate with hearing peers and continue to make good progress into secondary school and beyond (Beadle, McKinley, Nikolopoulos et al., 2005; Geers & Brenner, 2003). There are no well-controlled comparative studies of different models of communication teaching (signing, lip reading + speech, cued speech, in which hand signs are used to assist lip reading, or speech alone). Because a focus on signing alone can result in isolating children from their families and neighborhood (Groenveld, 1998), “total communication” (the combination of a formal signing system with written and spoken language) has become widely adopted, both in special schools and some mainstream placements (Hindley & van Gent, 2002). The success of such programs is at least partly dependent on the adequacy of parents’ signing skills: 20% of deaf children have no family members who sign and 40% have only one signing family member (Gravel & O’Gara, 2003; Preisler, Tvingstedt & Ahlstrom, 2002).

Early intervention programs involving a combined oral–visual approach are suggested as being crucial for avoiding the “cultural divide” that may otherwise develop between hearing parents and their deaf children (Hindley & van Gent, 2002). Massaro and Light (2004) reported on the use of “Baldi,” a computerized talking head, which can teach children to control tongue, mouth and face movements and airflow, thereby improving both speech production and perception. Sample sizes have been small, and the effects are limited once training ceases, but this approach could potentially assist many children.

Hearing impaired children have many additional problems, and poor cognitive and educational attainments, and increasing isolation from their hearing peers with age, are of major concern (Antia, Stinson, & Gaustad, 2002; Martin & Bat-Chava, 2003). Although, academically, deaf children in regular schools seem to do better than those in specialist placements (Powers, Thoutenhoofd, & Gregory, 1999), it is also evident that their difficulties may be significantly underestimated by mainstream teachers. Thus, the choice of an appropriate placement depends not only on the extent of hearing loss, but on factors such as IQ, the presence of other impairments and, most importantly, on the quality of instruction offered (Roberts & Hindley, 1999; Watson, Gregory, & Powers, 1999).

Visual Problems (see chapter 59)
Around 14,000 children in the UK are estimated as having significant visual impairment, although only one-third of these are registered as blind or partially sighted (Keil & Clunies-Ross, 2003). Children with visual difficulties are also likely to have a range of additional problems including cerebral palsy, epilepsy, linguistic and hearing impairments, autism, intellectual disability, and emotional and psychiatric disturbance (Groenveld, 1998; Webster & Roe, 1998). The proportion
CHAPTER 74

Educated in specialist provision has declined steadily in the UK – from 22% in 1998 to 5% in 2003 (Keil & Clunies-Ross, 2003) – and those special schools that still exist tend to cater for pupils with more complex physical or cognitive needs. For the remainder, education within mainstream settings is necessary to meet their educational and social needs and enhance future job prospects (Arter, Mason, McCall, McLinden, & Stone, 1999; Davis & Hopwood, 2002; Wagner & Blackorby, 1996). However, successful inclusion requires considerable modification to teaching materials and curriculum. Input from specialist staff is needed, with teachers, teaching assistants and specialist advisers working closely together. The teaching environment must be carefully structured in order to facilitate interactions with peers, and the successful integration of a severely visually impaired child requires careful preparation of all staff, sighted pupils and their parents.

Education for Children With Severe and Pervasive Intellectual Disabilities
(see chapter 49)

Many different teaching strategies have been reported as effective in enhancing inclusion for this group of children. These include peer-tutoring, co-operative learning, parallel instruction, behavioral and token programs, discrete trial learning, modeling, shaping, prompting and reinforcement techniques, naturalistic teaching, embedded instruction and many more (McDonnell, 1998). Much research in this area involves single-case or small case-series but there are some successful reports of implementing behavioral approaches within a “whole school” framework. Harris, Cook, and Upton (1996) utilized a combination of behavioral strategies, together with communication and social skills programs, to enhance overall functioning and reduce challenging behavior in pupils with severe intellectual disabilities in a mainstream school. Nevertheless, teachers found the program difficult to cope with, and many felt they lacked adequate support. Generalization to other settings or staff members was also limited.

The most successful inclusion programs have generally been conducted with very young children in settings that are unrepresentative of most mainstream schools (university-based experimental units; highly skilled educators; very small classes). For preschool children with severe intellectual disability, inclusive education may produce greater gains in language and social skills (Hundert, Mahoney, Mundy, & Vernon, 1998). However, other studies have found no social or cognitive advantages of inclusive preschools, and behavior problems may actually be more frequent in these settings (Rafferty, Piscitelli, & Boettcher, 2003). For older pupils with severe intellectual impairments there is no good evidence that inclusion enhances cognitive or social development (Kavale & Mostert, 2003; Lindsay, 2003). Acceptance by peers and teachers tends to decrease with age and few studies have reported on successful integration within secondary school (Beveridge, 1996; Booth, 1996). Moreover, unless there is adequate support, children with severe disabilities may receive significantly less individualized instruction in mainstream than in segregated classes.

Advocates of inclusive education for children with severe intellectual disabilities claim that it has a positive impact on both their social development and that of their typically developing peers. However, there is little evidence that simple exposure to non-handicapped peers improves either language or social skills (Lewis, 1995). Moreover, although guided contact with their disabled peers can have a positive impact on other pupils’ attitudes (Farrell, 1996), joint spontaneous interactions remain limited and close, reciprocal friendships are very unlikely to develop, particularly at secondary school (Burack, Root, & Zigler, 1997).

Many studies in this area are compromised because of the tendency to treat children with severe intellectual disabilities as a homogenous group. It is thus difficult to reach conclusions on what types of inclusive setting work best for which children, at which stage of their lives and in which development domains. For example, in comparison with children of similar cognitive levels, pupils with Down syndrome seem to do better academically in mainstream, but social interactions are enhanced in specialist settings (Buckley, 2006). Kavale and Mostert (2003) suggest that “Empirical evidence, not existential exaggeration, should be the cornerstone of deciding where students with special needs should be served.” They note that so-called “fully inclusive” classrooms may actually increase segregation and isolation. High self-esteem in pupils depends principally on the ability to achieve academically and socially in comparison with peers (Heward, 2003). If this is not attainable, children with special needs may have lower self-esteem and feel more stigmatized in “inclusive” than in specialist provision. The primary goal must be to improve existing provision and the quality of teaching to ensure maximum opportunities for inclusion for those children who will benefit, while providing high-quality segregated or partially integrated provision for those who may not. Resource bases within mainstream settings may provide the most flexible option for many students, allowing full-time inclusion (with support as necessary) for some, while providing others with the daily opportunity to mix with mainstream peers.

“Syndrome Specific” Approaches to Education for Children With Severe Intellectual Impairments
(see chapter 24)

There are now over 750 known genetic causes of intellectual disability (Dykens, 2000) and research into cognitive and behavioral phenotypes has greatly increased understanding of syndrome-specific deficits. Fragile X, for example, is associated with deficits in visuospatial abilities, abstract reasoning, motor coordination, memory and sequential processing. Vocabulary skills, simultaneous processing and ability to learn verbally based factual material are relatively unimpaired. Perceptual organization, visuospatial memory and fine motor skills are strengths in children with Cornelia De Lange syndrome (Kline, Stanley, Belevich-Brodsky, Barr, & Jackson, 2005). Expressive language skills are particularly poor in children with cri-du-chat syndrome. These cases illustrate how syndrome-specific deficits meet the criteria of Syndrome Specific Approaches. Many children with severe intellectual disabilities also have additional disabilities, such as hearing loss or autism spectrum disorder, presenting challenges far beyond the scope of Syndrome Specific Approaches.
syndrome (Cornish & Munir, 1998). Short-term auditory memory deficits are typical of children with Down syndrome (Jarrold, Baddeley, & Phillips, 2002). Smith–Magenis syndrome is characterized by difficulties with arithmetic, sequential processing and short-term memory; long-term memory for facts and information is relatively good (Udwin, Webber, & Horn, 2001). Individuals with Prader–Willi syndrome typically show deficits in arithmetic, writing, short-term memory and auditory attention but have strengths in visual organization and perception, long-term memory, reading and vocabulary (Cassidy & Morris, 2002). Understanding the underlying phenotype can help teachers adapt teaching strategies to suit specific profiles of skills and difficulties (Hodapp & Fidler, 1999). However, this requires acceptance by educational providers that a child’s diagnostic “label” is of value in highlighting potential strengths and weaknesses and recognition of the need for detailed individual assessment, including the use of formal psychometric measures. (For examples of teaching guides to specific syndromes see Lorenz, 1998 for Down syndrome; Lewis & Wilson, 1998 for Rett’s syndrome; Saunders, 2001 for fragile X; Waters, 1999 for Prader–Willi.)

**Children With Autism Spectrum Disorders** (see chapter 46)

Recent research indicates that not only is the prevalence of autism spectrum disorders (ASD) far higher than originally estimated, possibly as high as 1% of the population (Baird, Simonoff, Pickles et al., 2006), but also that around 40–50% of all those affected are of normal IQ (Edelson, 2006). These figures have enormous service implications and specialist educational approaches for children with ASD have been studied in particular detail. Programs may be center-based (e.g., Waldon; LEAP; Douglass); home-based (e.g., Applied Behavioral Analysis; Pivotal Response Training) or school-based (e.g., TEACCH; Denver Model; Harris, Handleman, & Jennet, 2005). Although evaluative data are limited, highly structured, visually based approaches to teaching appear to be particularly helpful. The internationally used TEACCH program, for example (Marcus, Schopler, & Lord, 2001), emphasizes the need for structure, appropriate environmental organization and the use of visual cues to circumvent communication difficulties in autism. The program stresses the importance of individually based teaching, and incorporates developmental, behavioral and cognitive approaches. A recent small-scale study of TEACCH (Panera, Ferrante, & Zingale, 2002) reported significant gains in educational and adaptive behaviors compared with progress in an integrated classroom.

Many other educational programs for children with ASD have been reported. Most are US-based, and include peer-tutoring programs to enhance social interactions and play; co-operative learning groups; the Bright Start Program, which concentrates on the development of cognitive and metacognitive abilities; and the STAR curriculum (for reviews see Arick, Krug, Fullerton et al., 2005; Lord & McGee, 2001). The effectiveness of various developmental and behaviorally based programs has also been demonstrated (Harris, Handleman, & Jennet, 2005). In UK settings, Jordan and Jones (1999) describe a variety of innovative techniques that can be used in the classroom and Cumine, Leach, and Stevenson (1998, 1999) provide practical suggestions for teaching children with autism and Asperger syndrome within mainstream settings.

One program widely used throughout the USA, Europe and Australasia is the Picture Exchange Communication System (PECS; Bondy & Frost, 1996). PECS aims to increase communication skills by means of pictures or objects and claims to improve both verbal and non-verbal skills (for review see Howlin, 2006). A large randomized controlled trial (Howlin, Gordon, Pasco, Wade, & Charman, 2007) found that children exposed to formal PECS training showed significant increases in their use of PECS symbols and in spontaneous initiations, but little change in other forms of communication. Outcome also varied according to the characteristics of the children involved.

The approach that has given rise to most controversy in recent years, mainly because of claims of “recovery from autism,” is the Early Intensive Behavioral Intervention program (EIBI) of Lovaas and colleagues (Lovaas, 1993, 1996; McEachin, Smith, & Lovaas, 1993). EIBI involves 40 h per week or more of behaviorally based teaching, starting at the age of 2–3 years and lasting for at least 2 years. Initial evaluations reported IQ gains of up to 30 points with 40% of participants becoming “indistinguishable from their normal peers.” However, reanalysis of the early data, and reviews of more recent EIBI programs, indicate that although this approach is certainly effective, the overall results are neither as marked nor as universal as initially claimed (Shea, 2004).

For children with ASD of average IQ, full access to the normal school curriculum is crucial for their future academic and employment prospects. In contrast, fully inclusive schooling is unlikely to succeed for children with the most severe cognitive, behavioral and communication difficulties. Although some studies have found that cognitive and linguistic development in this more severely impaired group can be enhanced by inclusion, the educational settings involved tended to be experimental in nature and/or involved very young children (Harris, Handleman, Gordon et al., 1991). Other research indicates that while mainstreaming does not necessarily improve cognitive or language skills, it may help to improve social and play behavior, at least in preschoolers (Handleman, Harris, & Martins, 2005).

A number of specialized programs in the USA (e.g., Denver model, Douglass Developmental Disabilities Center, LEAP, May Center for Early Childhood Education, TEACCH and Waldon; for reviews see Arick, Krug, Fullerton et al., 2005; Handleman, Harris, & Martins, 2005; Harris, Handleman, & Jennet, 2005) now involve staged integration into inclusive schooling, together with training and support for mainstream class teachers. Harris, Handleman, & Jennet (2005) concluded that, as there is no good evidence in favor of any one specific model, the choice of program needs to be based on the needs of the individual child and his or her family. An educational program suitable for a child with Asperger syndrome, for example, is unlikely to suit a non-verbal pupil with autism and severe cognitive delays. Furthermore, children’s needs change over
time, and placements should be reviewed at regular intervals. Many very young children with ASD require specialist, one-to-one teaching, but once basic communication and social skills have been acquired a gradual program of integration can begin. For some children this will mean continuing support in mainstream, for others specialized help in some settings/classes but not in others, and for others full inclusion. However, unless the very specific needs and difficulties of pupils with ASD in mainstream are recognized, these children can become extremely isolated, suffering bullying and rejection from both children and teachers (Sainsbury, 2000).

General Approaches to Improving the Classroom Environment

Without appropriate resources, simply placing children with special educational needs (SEN) in mainstream settings will almost certainly result in educational deprivation and social alienation (Hornby, Atkinson, & Howard, 1997). Successful inclusion requires mainstream teachers to be appropriately trained and supported (Burack, Root, & Zigler, 1997); the curriculum and teaching programs should be appropriately individualized and structured; and teaching goals must be clear to both teachers and pupils (Farrell, 1997). Time spent on learning activities, the use of directive teaching methods, together with reinforcement, feedback and monitoring techniques, are all associated with improved classroom behavior. Several reviews (Farrell, 1997; Hunt & Goetz, 1997; King-Sears, 1997; Manset & Semmel, 1997; Wehmeyer, Lance, & Bashinski, 2002) concur in suggesting a number of specific strategies related to “best academic practice”:

- **Co-operative learning** – teaching activities structured to ensure that typically developing children and students with AEN work and learn together;
- **Differentiated instruction and one-to-one provision** as necessary, according to individual needs and abilities;
- **Explicit instruction** – including step-by-step teaching, feedback and reinforcement;
- **Generalization training** – to ensure that skills taught in one-to-one or small group sessions are maintained across the wider school;
- **Strategy instruction** – teaching pupils with SEN to acquire self-directed learning strategies;
- **Curriculum-based assessments** – to ensure that students with SEN continue to make progress in areas covered by the teaching curriculum; and
- **Training for teachers** in SEN awareness and in the use of techniques to modify problem behaviors and enhance learning.

Other factors related to “best practice” include a high staff: student ratio; help for pupils with special educational needs to acquire self-determination and self-advocacy skills; the development of social networks to facilitate peer support and friendships; collaboration between school staff, and between teachers, parents, other therapeutic agencies and the wider community.

The issue of class size has provoked considerable debate (Zarghami & Schnellert, 2004) but evidence that this directly affects outcome, either for regular or special needs pupils, is limited. Blatchford, Edmonds, and Martin (2003) found no impact of class size on the educational attainments of regular primary school children, but class size did affect teaching style and modes of learning, with children in smaller groups taking a more interactive role. A review by Wilson (2002) concluded that although, overall, class size had little direct influence on progress or behavior, smaller classes benefited younger pupils and those from disadvantaged or minority groups; they also reduced teacher stress. Moreover, in almost all successful studies in inclusive settings, class size has been far smaller than in most state schools (the average class size in the EU is 20; many experimental classes comprise only 8–10 children). It is suggested that, to maintain an effective teacher: pupil ratio within inclusive classrooms, each child with special needs should be counted as the equivalent of six typically developing pupils (Pirrie, Head, & Bryna, 2006). Structured small group teaching also appears to enhance academic and social skills (Ainscow, 1995) and may also profit typically developing peers.

Improving Training and Support for Teachers

While mainstream classrooms and curricula can be adapted to meet the requirements of children with SEN, this is not an easy task for most teachers who are already working under considerable pressure. Although specialist training is crucial, full-time courses have been increasingly replaced by cheaper part-time modular courses and even the best-trained teachers are unlikely to be effective without adequate support. Collaborative teamwork, a shared framework for teaching, clear role relationships among professionals, procedures for evaluating teaching effectiveness, adequate training, administrative support and effective use of support staff are among the factors identified as important in maintaining positive teaching practices in inclusive settings (Giangreco, 1997; Salend & Duhaney, 1999; Villa, Thousand, Meyers, & Nevin, 1996).

Teachers’ attitudes are also crucial. In a review of 28 studies, Scruggs and Mastropieri (1996) found that although two-thirds of teachers supported the general concept of inclusion, only one-third considered they had sufficient time, experience, training or resources to implement this successfully and 30% felt inclusion could have a negative impact on typically developing peers. Negative attitudes to inclusion are greater among teachers of older pupils or pupils with severe intellectual, physical or behavioral problems. Negative attitudes are also associated with poor collaboration between staff, inadequate support, larger class sizes and lack of confidence in their own teaching competence (Salend & Duhaney, 1999; Soodak, Podell, & Lehman, 1998).

Conflicts may also arise because the teaching strategies that are most effective for children with severe intellectual disabilities (i.e., highly structured and individualized) may be very different
to those utilized in typical mainstream classrooms (i.e., experiential, group learning). Similarly, whereas the communication skills of children with severe language and/or cognitive impairments are enhanced by teaching styles that encourage initiations and spontaneous language, in mainstream classes the interactive styles of both teachers and other pupils are mainly directive (Bayliss, 1995). Moreover, because the educational goals for this group of pupils often involve developing very basic self-help and independence skills, it is difficult to accommodate these within the more academic National Curriculum, especially in secondary schools.

**Role of Para-professionals**

Almost by definition, children with special needs require some one-to-one teaching, especially when learning new skills. The role of para-professional support staff is crucial here but they are frequently assigned to students with the most challenging behavioral and learning needs. They are expected to: work collaboratively with other staff and pupils; foster the child’s academic and social progress; plan and carry out individually tailored educational programs; teach basic life skills; take care of feeding and toileting; and deal with very difficult behaviors. Rarely are they adequately trained or supported to meet these demands and all too often their role focuses on the minimization of behavioral difficulties. Moreover, assigning the least powerful staff within the school hierarchy to the least powerful students may simply perpetuate the “underclass” status of both groups (Giangreco, Edelman, Broer, & Doyle, 2001). Working individually with a pupil with special needs in the corner of the classroom (or in the library or medical room) may actually increase rather than decrease segregation and without close liaison between teaching and support staff children can become over-dependent on the teaching assistant, which in turn becomes a further barrier to inclusion (Marks, Schrader, & Levine, 1999). Although it is clear that para-professionals can be trained successfully to carry out and monitor a range of different behavioral, educational and social interventions and that they gain personal satisfaction from so doing, if training and support are inadequate, both they and their pupils will be disadvantaged (Giangreco, Doyle, Halvorson, & Broer, 2004).

**Consultation Services**

Consultation by outside agencies may be required for a number of different reasons: to improve teachers’ general skills in dealing with children who have special needs; to train them in the use of specific intervention techniques; or to assess or treat children directly, thereby reducing the need for referrals to external psychiatric or psychology agencies. Consultation services may be requested at times of crisis although increasingly they are part of a planned contractual service to schools. The relationship between the consultant and consultee is a complex one and requires careful clarification of the expectations and roles of all concerned. Effective consultation can have a positive effect on teachers, individual children and the classroom as a whole, resulting in a reduction in behavioral problems and in referrals to outside agencies (Dyson, 1990; Fuchs, Fuchs, & Bahr, 1990; Jordan, 1994). However, inadequate preparation may simply undermine teacher status and independence (Dockrell & Lindsay, 2001; Law, Dockrell, Williams, & Seeff, 2002). The quality of research on school-based consultancy for children with mental health problems is generally poor, but there is some evidence for the value of consultancy services in providing cognitive–behavioral therapy, social skills training and general support for teachers (Hoagwood & Erwin, 1997). Nevertheless, pupils themselves often indicate that they would prefer to receive additional help from their own teacher rather than from a specialist, because this makes them feel less conspicuous (Jenkins & Heinen, 1989). There is also a need to extend specialist support into the home setting if any advantages are to generalize. A report for the UK National Foundation for Educational Research (Fletcher-Campbell & Cullen, 2000) noted the very variable effects of introducing external support agencies into schools and cautions that, when collaboration between mainstream and specialist staff was weak, “it was the pupil who was disadvantaged.” The benefits derived from consultancy services may also be short-lived. For example, in a randomized controlled trial, using specialist consultants to introduce the use of specific communication strategies into classrooms for non-speaking, low IQ children with autism, the positive treatment effects were not maintained once consultations ceased (Howlin, Gordon, Pasco, 2007). The provision of specialist support teachers (not untrained classroom assistants) working alongside the class teacher may be more beneficial in the longer term, but again, support teaching often fails because of inadequate liaison and planning (Thomas, 1992).

**Parental Roles and Views**

Ensuring generalization of treatment effects is a crucial issue for any intervention. Many of the more successful special educational or inclusion programs have actively involved parents (Desforges & Abouchaar, 2003; Frankel, Myatt, Cantwell et al., 1997; McEachin, Smith, & Lovaas, 1993) and family-centered models for curriculum development have become increasingly popular (Skrtic, Sailor, & Gee, 1996). Without parent involvement, and often parent training, the benefits of intervention are unlikely to generalize to non-school settings, and inconsistent or ineffective parental strategies may weaken the impact of successful school programs. However, the involvement of parents, and indeed the wider community, in SEN programs cannot be expected to occur without adequate planning, resources and full understanding of the background of pupils with special needs.

There is little evidence to suggest that parents are either overwhelmingly for or against inclusive education and around 65–80% of parents of SEN children in either mainstream or segregated settings express satisfaction with the placement. Many parents of children in inclusive placements believe that this facilitates both social and academic progress but others express concerns about the lack of individualized instruction,
CHAPTER 74

inadequate support (for both pupils and teachers) and the risk of teasing or rejection by other children. Parental views are also likely to be affected by the age of their child, the nature of his or her disability and their own educational background (Duhaney & Salend, 2000).

Impact on Other Pupils

Overall, the available evidence does not support concerns that the progress of typically developing pupils is negatively affected by the presence of children with special needs. A review of 26 (mostly US-based) studies (Dyson, Farrell, Polat, Hutcheson, & Gallannaugh, 2004) found that 23% reported a positive academic and/or social impact on “typical” pupils; 15% suggested a negative impact; 53% a neutral impact; and 10% a mixed impact. Studies involving the inclusion of children with physical, sensory or communication difficulties were generally positive but there were more negative effects when pupils had behavioral or emotional problems. However, the authors noted that few data were available on secondary schools and they stressed the need to study the relationship between inclusion and the achievements of classmates over time. Data from British schools indicated a small but negative relationship between the level of inclusivity in schools and pupil attainment, but the schools with higher levels of inclusion tended to be those serving more disadvantaged, lower-achieving populations (Dyson, Farrell, Polat et al., 2004).

Improving Acceptance by Peers

Without specific intervention, integration is unlikely to improve acceptance by peers. Social interactions may occur more frequently in integrated settings but children with developmental delays still remain relatively isolated, spontaneous joint play is infrequent, close friendships are rare and bullying is a significant problem (Burack, Root, & Zigler, 1997; Norwich & Kelly, 2004; Siperstein & Leffert, 1997). Programs that have focused on training typically developing peers to initiate interactions or implement co-operative learning strategies have been successful in increasing the frequency and quality of social responses and in enhancing academic skills (Hornby, Atkinson, & Howard, 1997). Peer tutoring appears to be more effective than attempts to change attitudes by indirect methods, such as teaching tapes, stories or simulations, and also improves peers’ academic attainments, social maturity and empathy (Hornby, Atkinson, & Howard, 1997; Topping, 2001). “Circles of friends” or carefully structured pairings of typical pupils and children with special needs are also claimed to promote social inclusion, but evaluations are few and generalization is often limited (Newton, Taylor, & Wilson, 1996).

Early Prevention Programs

For children at risk of learning or behavioral problems because of social disadvantage, the best known, and best funded, community-based interventions are the Head Start and Early Headstart Programs. The short-term effects on children’s cognitive, social and physical development are well established and early interventions of this kind can produce improvements in mother–child interaction and a reduction in problem behaviors (Bailey, Aytch, Odom, Symons, & Wolfe, 1999; Barnett, 2004; Reid, Webster-Stratton, & Hammond, 2004). There is less agreement about the longer-term benefits. In a detailed review, Barnett and Hustedt (2005) noted the lack of adequately controlled, long-term follow-up studies and despite positive effects on academic achievements and social adjustment, effect sizes are smaller than for some other model programs, such as the Abecedarian Project (Campbell, Ramey, Pungello, Sparling, & Miller-Johnson, 2002) or the Chicago Child Parent Centers (Reynolds, Temple, Robertson, & Mann, 2002). Other criticisms include the very variable timespan and quality of these programs, the relatively small number of children involved (under 1.7% of the total infant population), the racial imbalance (poor Blacks are significantly more likely to be enrolled than poor Whites) and the often poor standards of teaching (fewer than 30% of teachers have a Bachelor’s degree and salaries are far lower than in public school kindergartens). Sure Start is the UK version of Head Start, but variations in the quality and funding of programs in different areas, and arguments concerning the most appropriate means of delivery, mean that the findings remain inconclusive. The program seems to benefit those parents who are less socially disadvantaged or have greater personal resources, but there may be adverse effects for the most disadvantaged families (Belsky, Melhuish, Barnes, Leyland, & Romanuik, 2006; Rutter, 2006). Moreover, recent government-directed changes in the focus of (and funding for) Head Start, Early Head Start and Sure Start mean that many questions remain about the effectiveness of their various components, the real long-term benefits and the types and ages of children for whom they prove most effective.

Post School

The difficulties and social exclusion experienced by many children with special educational needs frequently extend into adult life. Dropout rates from school are often double those of other students, and fewer than half obtain any formal qualifications or go on to further education. Outcome is particularly poor for pupils with intellectual disability, learning disability or emotional disturbance. Unemployment is as high as 60–70%, even for individuals with mild intellectual disability or sensory problems, and earnings, job status and stability are low (Lipsky & Gartner, 1996; Wagner & Blackorby, 1996). Long-term dependence on parental support is also typical (Howlin, 2004; Lipsky & Gartner, 1996). Although there has been an increase in post-school vocational training programs over recent years, few such courses are of an appropriate academic or vocational level. Many students may find it difficult to gain access to courses that adequately meet their needs.
Clinical Recommendations

Education has a major influence on the life of any child but for pupils with disabilities the quality of schooling they receive is likely to have an even greater and longer lasting impact. Clinicians can play an important part in providing schools with guidance on how to help these children because failure to meet their educational needs will undermine the effects of any other forms of treatment. Attention to the following guidelines may be helpful.

- Placement in appropriate education from the earliest years is crucial. Early failure in mainstream settings can result in the need for much more expensive intervention subsequently, while early success in a specialist setting can provide children with greater chances of later inclusion. A “let’s try it and see” approach to mainstream is unlikely to be helpful.
- Children with special educational needs are a broad and heterogenous group and require a range of different educational provision. This should include highly specialist placements for those with the most severe and handicapping conditions. For some older children, particularly those who will require residential care as adults, residential schooling may also be needed.
- Families need to be offered detailed information on the full range of educational and other provision available locally. Lack of information and the feeling that they have no choice in educational decisions are significant factors in leading parents to seek out alternative, expensive and often unproven therapies.
- Appropriate placement will depend on a thorough assessment of children’s and families’ needs, and of children’s profiles of skills and difficulties. Standardized assessments of cognitive, linguistic and other abilities are not a waste of time, and can prove highly valid and reliable indicators of children’s potential, as well as highlighting areas of deficit and skill.
- Understanding the nature of the underlying condition and any associated behavioral, social, emotional or cognitive impairments is crucial for optimal educational provision. The view that “We don’t label children here” is of no help to the child, parents or teachers, and recognition of the characteristics associated with particular disorders can be of great help in informing educational practice.
- The number of children requiring specialist educational help and advice greatly outweighs the number of professionals who are able to offer this – educational psychologists, speech and language therapists and occupational therapists are particularly thin on the ground. Thus, professionals in child and adult mental health services (CAMHS) teams need to work together to develop a group expertise that can assist different children with different problems in a variety of different ways.
- Most of the conditions described in this chapter are both pervasive and persistent. Parents care more for professional consistency than professional background, and need to have long-term access to staff who can continue to offer individualized help or advice over the years.
- Similarly, these conditions do not disappear when children reach puberty or school leaving age – indeed, new problems may emerge at these times. Ongoing support for young people and their families at these transitional stages is vital, as are careful planning and close inter-professional liaison.
- Finally, when clinicians are involved in advising schools as to how pupils with special needs should, or should not, be managed, it is important that they are aware of the realities of the local situation – unrealistic and impractical recommendations will not enhance working relationships or benefit the children or families involved.

Conclusions

Warnock (2005, p. 38) suggested that the correct view of special education is one that: “Maximizes the entitlement of all pupils to a broad, relevant and stimulating curriculum. All schools whether special or mainstream should reflect a culture in which the institution adapts to the needs of its pupils. The most appropriate setting is . . one in which children can be most fully included in the life of their school community and which gives them a sense of both belonging and achieving.”

Warnock stressed that the pursuit of equality should be directed at ensuring that children with special needs have equal opportunities as adults – this does not mean that they should all be educated under one roof. Instead, the concept of “special school” should be replaced by “specialist school” along the lines of those now being designed for children with particular gifts in music, art or technology.

The goal should be to ensure that all children with special needs are provided with an education that enables them to make optimum academic, social and emotional progress and offers them the best chance of inclusion as adults. This will require a flexible continuum of provision, including special schools, resource units and special classes which, as far as possible, allow ready access to mainstream school and the normal curriculum. The perspective of the family, the teachers and other pupils should also be acknowledged and positive involvement with non-disabled peers fostered as early as possible.
