There has been very little research examining how to mitigate the potential impact of a serious parental physical disorder on children’s development. However, a number of studies have focused on the nature of the communication between parents and children in the context of maternal breast cancer and provide pointers to intervention (Barnes, Kroll, Burke et al., 2000; Forrest, Plumb, Ziebland et al., 2006). These studies indicate that many children will have picked up that something is seriously wrong from changes in their parent’s mood or behavior well before they are told of the diagnosis. From as young as 7 years children may associate the diagnosis of cancer with the threat of dying, and therefore not talking about this connection does not protect children. Children’s reactions to bad news may belie their feelings. Thus, withdrawal, lack of upset, or else angry challenging behavior does not necessarily indicate indifference, a lack of distress or lack of sympathy or empathy. Parents and clinicians often underestimate children’s needs for information and try and protect them, and children may not ask about emotionally charged subjects. However, the more children are prepared and informed (as appropriate for their age and development), the more it seems likely children are prepared and informed (as appropriate for their age and development), the more it seems likely that they will be able to cope. Individual differences, as well as age, developmental stage and previous experience need to be taken into account. Parents diagnosed with cancer or other serious illnesses should be offered help to think about whether, what and how to tell their children about their illness, and about what the children can understand, especially as the parents may well be struggling themselves to come to terms with their illness. In the first instance, this is probably best done by clinicians involved with the illness, but guidance or even direct involvement of mental health professionals may be of particular benefit. Mental health professionals can have a key role in the training of other clinicians undertaking this work.

Among the many children who live with a parent who has some chronic physical or psychiatric illness, a small proportion (perhaps 4%) will have acted regularly as a carer for a parent or other relative during their childhood. The extent to which a carer role is undertaken will depend on many factors, including the severity and chronicity of the parent’s illness, the input of the second parent, other family and social supports, the age of the child and siblings, and pre-existing family relationships (including that between parent and child). A number of recent reports (Aldridge & Becker, 2003) rightly stress that each family and presentation is different, and that the carer role is not always detrimental to the child’s well-being. Nonetheless, there are important possible difficulties and risks for a child required to take on a caring role which must be considered by clinicians. These include potentially missing out on some normal activities such as school and meeting with friends, lacking or inconsistently experiencing parental support and discipline, as well as experiencing anxiety about their parent’s health and fearing possible separations for episodes of hospital admission. In relation to maternal depression, it has been hypothesized that caring for the mother may be particularly burdensome for the child (Radke-Yarrow, Zahn-Waxler, Richardson et al., 1994), and may form part of the process whereby the offspring of depressed parents come to be at increased risk for depression themselves (Zahn-Waxler, Cole, & Barrett, 1991; Zahn-Waxler, Kochanska, Krupnick et al., 1990). While these will not all be issues for many children, they are important to consider, as professionals may be able to assist children and parents in accessing supportive services as well as those services to help effectively treat the parental illness.

**Future Considerations**

It seems very likely that there will be a number of exciting developments in both clinical and research domains within the next few years of direct relevance to our understanding of parental psychiatric disorder, and its effects on children. Research is likely to lead to clearer elucidation of the early developmental risks for children, including parental psycho-pathology, and to an increased understanding of the mechanisms by which risk is transmitted from parents to their children. There are three main areas of research that we highlight as being particularly promising.

First is the study of the early developmental origins of mental disorder, and of parental psychiatric illness as a key measurable risk in this endeavor. There are two specific time periods whose study seems most likely to lead to advances that will affect our understanding and practice. These are the antenatal (prenatal) period and the early postnatal period. The rapid advances in knowledge regarding the early developmental origins of health, in both animal research and in the study of other human diseases such as diabetes (Gluckman, Hanson, Spencer et al., 2005), are likely to extend increasingly into the study of early effects on behavioral and emotional development. We have already alluded to some of the research on maternal postnatal depression that has given some insight into the effects of disturbances in early care on child development, and other work has demonstrated an independent association between maternal stress or anxiety in pregnancy with children’s subsequent behavioral development, and also with the longer-term setting of their HPA axis. These strands of work are likely to advance with scientific developments in psycho-
endocrinology and also scanning technologies, with implications for early preventative work.

Second is the area of epigenetic effects. These are likely to lead to an increased understanding of the complex mechanisms by which parental psychopathology affects children. Relatively recent work (Weaver, Cervoni, Champagne et al., 2004) has begun to point to the ways in which early environmental exposures might impact upon the genetic expression in the HPA axis. This is likely to have particular significance for our scientific understanding of the intergenerational transmission of mood and anxiety disorders.

The third area where we anticipate significant advance is in our understanding of those factors that predict resilience and more positive outcome in the face of adversity. Once risk factors such as parental depression are identified, an important, and often neglected, next step is the study of those children who do well despite exposure to the risk factor. Through these means we can anticipate further improvements in our understanding of the way in which risks exert their effects. This has particular significance for clinical practice, and it is to this arena that we now turn our attention.

There are two particular areas of clinical advance for the coming years that we wish to highlight: the further development of early-years interventions, and the internationalizing of these clinical interventions. Recent years have seen a significant focus on early child development. This has included the development and implementation of a number of early-years interventions. Coupled with some of the research advances we anticipate above, these should become more sophisticated both in terms of the intervention components, and in their targeting. There are already developments in the targeting of specific interventions for key clinical groups in research studies (e.g., the use of video feedback for parents; Velderman, Bakermans-Kranenburg, Juffer et al., 2006) and specifically mothers with eating disorders (Stein et al., 2006). The next stage is the translation of these findings to clinical populations in a strategic and efficient manner.

The second clinical area is the importance of this work in the international context, especially in relation to developing countries. Very little research has been conducted in this context, and this omission needs to be rectified. It is becoming increasingly clear that the bulk of the burden of impact of parental psychiatric disorder falls not in the developed world, but on the developing world. Depression is already one of the major issues in developing countries, including India and Pakistan (Patel, DeSouza, & Rodrigues, 2003; Patel, Rahman, Jacob et al., 2004; Tomlinson, Cooper, & Murray, 2005). The identification of high levels of depression in association with HIV, in particular, argues for urgent research into the impact of depression on children’s development in this area. We hope to see increasing development of interventions that are adapted to the setting in which people find themselves, where individual-specific components are developed with the context in mind, so that this vulnerable group of children and their families can be helped across far more of the world than at present.

Child Maltreatment and Mental Health

The abuse and neglect of children and young people are issues of grave social concern, internationally (World Health Organization [WHO], 2002). They involve fundamental human rights for children and adults; children having the right to be free from abuse and neglect; and parents the right to family life. Child maltreatment is the antithesis of adequate caregiving and parenting (Wolfe, 1991). Not surprisingly, maltreatment of children is associated with significantly increased risk for psychopathology throughout life. Hence, child maltreatment is of major importance to those working in child and adolescent mental health services, research, social welfare, policy-making and legal systems.

Maltreatment incorporates a variety of acts, and deprivation of care, by those who look after children. It involves parents, carers and those who care for children within settings such as schools, hospitals and residential units. The concept has expanded over the past 40 years from physical assault to incorporate neglect, sexual and emotional abuse of all severities. The exponential rise in referrals in North America, the UK and Australasia has led to efforts to reformulate the notion of child abuse and neglect, to distinguish situations where the child's primary need is for added services and support in order to facilitate the child's development, from those who need protection from overt harm. In England and Wales this has been achieved through amending the guidance linked to the Children Act, 1989, so that two streams, support and protection, are distinguished in policy and practice guidelines (Department of Health, the Department of Education & Employment and the Home Office [DOH, DOEE & HO], 2000).

Child maltreatment is not a psychiatric diagnosis; rather a description of a phenomenon affecting children and young people. It may or may not lead to discernable harm, physically or psychologically. There are no specific syndromes of physical or sexual abuse, instead child maltreatment is a major environmental risk factor for non-optimal development, both physically and psychologically. The influence of maltreatment on development and psychopathology, and implications for child mental health practitioners, are now examined further.

International Perspective

WHO (2002) defines child abuse and neglect, or child maltreatment, as all forms of physical and/or emotional ill-treatment, sexual abuse, neglect or negligent treatment, or commercial or other exploitation resulting in actual or potential harm to the child’s health, survival, development or dignity in the context of a relationship of responsibility, trust or power.

Definitions in North America, the UK and Australasia all center on the notion of harm caused to children as a consequence of care provided to them. Definitions vary at the operational level, including the degree to which intention and detectable harm are included.

Reporting practices differ between countries. Some countries have followed the American policy of mandatory, legally required, reporting of potential cases, while in others a voluntary system is in place. The UK has no legal requirement to report suspected cases, but professional regulation and government guidance emphasize requirement to report, resulting in the UK being closer to mandatory than voluntary reporting. In some western European countries, such as Belgium and the Netherlands, the approach is more voluntary, with greater emphasis on social support and intervention.

The focus of each country’s concern will vary according to the most numerically pressing problem that it faces. For some countries the emphasis is on child labor or prostitution, while in others the focus is on intrafamilial abuse. Nonetheless, all countries need to attend to the full range of maltreatment of children within their boundaries. Additionally, each country should consider how it may make a contribution on a worldwide basis (e.g., the UK’s initiative to curb child “sex tourism”).

A Major Public Health Issue

WHO’s (1999) initiative on violence and human health stressed that children are vulnerable to violence from war and natural disaster, and maltreatment in the context of a relationship of responsibility, and sometimes both. The response plan recommended includes national action plans for violence prevention; data collection; research on causes, consequences and prevention of maltreatment; strengthening victim responses; and better collation and information exchange (Mian, 2004).

CHAPTER 28

Public health principles shift the emphasis from a reaction to violence to a focus on underlying social, behavioral and environmental factors (Mercy, Rosenberg, Powell et al., 1993). To this may be added genetic factors (Rutter, 2005; Rutter, Moffitt, & Caspi, 2006a). The health burden of child maltreatment on human health has also been evaluated (Andrews, Corry, Slade et al., 2004). These initiatives have placed violence and child maltreatment in the forefront of international public health concern, forcing the agenda toward prevention, with integration of different disciplines, organizations and communities (Mercy, Rosenberg, Powell et al., 1993).

Types of Maltreatment

WHO (2002) distinguishes five subtypes: physical, sexual, and emotional abuse, neglect, and exploitation. The focus of this chapter is neglect, physical and emotional abuse. Exploitation refers to children used in work or other activities for the benefit of others (e.g., child labor, prostitution and child soldiers; WHO, 2002). In England and Wales the Government’s definitions (HM Government, 2006) are similar to WHO’s, but differ through being more operationally defined, and to varying degrees incorporating harm caused to the child. As this distinction is similar to that in other countries, England and Wales definitions are utilized in the sections below.

Physical abuse involves “hitting, shaking, throwing, poisoning, burning or scalding, drowning, suffocating, or otherwise causing physical harm to a child. Physical harm may also be caused when a parent or carer fabricates symptoms of, or deliberately induces, illness in a child” (HM Government, 2006). The “battered child syndrome” refers to younger children presenting with multiple bruises, skeletal and head injuries, frequently accompanied by visceral trauma or neglect and fearfulness, whose parents deny responsibility (Kempe, Silverman, Steele et al., 1962). It represents the severe end of the continuum of physical abuse.

Physical abuse is normally diagnosed by pediatricians, on the basis of the discrepancy between physical findings and history, in the absence of a non-abusive explanation. Occasionally, the child makes a direct account, or there is a witness, or confession by a carer. There may have been previous similar, less severe episodes. Explanations, imputed or proffered, include developmental challenges, persistent crying, toileting, feeding problems or issues of discipline and independence in later childhood. Delay in presentation and parental absence of concern or unreasonable behavior described by Kempe, Silverman, Steele et al. (1962) are not reliably present.

Fabricated or induced illness (FII) is where a parent or carer feigns an impression or induces a state of ill health in a child whom they are looking after. The child is harmed either through the fabrication of symptoms, signs, reports or specimens, through directly inducing ill health (HM Government, 2006; Jones & Bools, 1999) or through combinations thereof. A wide variety of presentations have been described (Rosenberg, 1987), but common forms include fabricated epilepsy, non-accidental poisoning or life-threatening events in infancy (either fabricated or directly induced).

FII is best considered a form of child maltreatment than a type of parental psychopathology, notwithstanding the observation that personality disorder is common amongst perpetrators. DSM-IV tends to emphasize the latter rather than the former. This is unfortunate, because much controversy has emanated from assumptions being made about parental motivation when children have been harmed in this way.

The phenomenon involves the coalescence of three elements: health professionals being misled; a child harmed (directly or through unnecessary investigation or treatment); and parental need for involving health-care systems is met through apparent, or actual, ill health in the child (Jones & Bools, 1999).

The concept has had utility in pediatrics, enabling the possibility of harm to be considered in the differential diagnosis of unusual presentations; much as in the 1960s the use of the emotive term Battered Child Syndrome drew professional attention to previously unrecognized harm caused by carers. The concept should remain confined to health consultations, and not expanded to disparate situations where parents deceive professionals (Jones, 1996a).

Covert video surveillance has been successfully employed to identify serious cases (Southall, Plunkett, Banks et al., 1997). However, the practice remains highly controversial. The practice brings a child’s right to be protected from harm and parental right to privacy into conflict. Clearly, covert surveillance is highly intrusive and therefore the threshold for its use must be very high. Normally it is only employed when all alternative sources of assessment have been exhausted but where high levels of suspicion remain. Even then, in England and Wales, the practice only occurs with the involvement of police and high-level prior strategic planning, when all aspects, including ethical dimensions, are thoroughly explored.

It may be more acceptable ethically, and fruitful diagnostically, to require a period of enforced separation of child and parent in order to see whether symptoms recede in the absence of the suspected fabricator. Nonetheless, many would agree that an unpleasant degree of professional secrecy is acceptable in order to prevent a child continuing to be seriously harmed, provided no other, less intrusive, means can be employed. It is therefore important that the possibility of its use is retained, albeit uncommonly used.

Sexual abuse is considered in chapter 29. It involves “forcing or enticing a child or young person to take part in sexual activities, including prostitution, whether or not the child is aware of what is happening” (HM Government, 2006). Neglect is defined as “the persistent failure to meet a child’s basic physical and/or psychological needs, likely to result in the serious impairment of the child’s health or development.” (HM Government, 2006). Neglect comprises four principal domains: physical, supervision, cognitive and emotional neglect (Straus & Kantor, 2005). Prenatal neglect and abuse may occur through maternal substance abuse. Physical neglect includes failing to provide adequate food, clothing, shelter, or exclusion
or abandonment. Supervision also includes the use of unsafe caretakers and failure to utilize health care. Emotional neglect involves inattention to the child’s emotional cues and insufficient parental love and affection. Some authors have termed this “psychological unavailability,” describing parents/carers who ignore their children’s cues and signals, despite clear indication of the child’s needs for warmth and comfort (Erikson & Egeland, 1996). Cognitive neglect ranges from inadequate parental speech and responsiveness, leading to speech and language delay (Thorpe, Rutter, & Greenwood, 2003), through to denying access to education.

Neglect must be linked to the developmental needs of the child and distinguished from the effects of poverty. Recognition is assisted by utilizing multiple sources of information, including the children themselves, caregivers, examination of longitudinal case records, observation and standardized measures. Recognition is often delayed because of its chronic insidious nature, absence of crises requiring immediate social services or health responses, problems with definition and high thresholds for social services intervention (Gibbons, Conroy, & Bell, 1995; Smith & Fong, 2004). Despite these difficulties, neglect is the most common form of child maltreatment.

Emotional abuse is “the persistent emotional maltreatment of a child such as to cause severe and persistent adverse effects on the child’s emotional development.” The definition proceeds to incorporate the following: conveying to children they are worthless, unloved, inadequate or only valued to meet expectations, including overprotection, limitation of exploration and learning, or preventing normal social interaction; witnessing the ill-treatment of another; serious bullying and terrifying, exploitation or corruption (HM Government, 2006).

It is evident from the above that in England and Wales there is considerable overlap between definitions of neglect and emotional abuse, particularly with respect to the omission of affection, care and parental psychological availability. This confusion is reflected internationally. Schneider, Ross, Graham et al. (2005) found only four cases of “pure” emotional maltreatment in a sample of 250 where this was recorded, despite emotional maltreatment being recorded in half of the children suffering other forms. They found that neglect of psychological safety and security (including exposure to domestic violence, threats of injury, suicide and abandonment), or acceptance and self-esteem (included verbal and non-verbal negativity, or active rejection) were the most common categories of emotional maltreatment, with neglect of age-appropriate autonomy or restriction being uncommon. Glaser (2002) also found that children living with a parent with physical or mental illness, disability or marked impairment or those who were exposed to interparental violence were also increasingly identified as suffering emotional abuse. Clearly, other psychological dimensions to parenting are omitted from the above approaches, including guidance, limit-setting, promoting socialization and supporting children’s relationships (Jones, 2001; Sroufe, 2005). Emotional abuse would probably be better termed “psychological maltreatment” in order to encompass all impairments to psychological aspects of parenting (Jones, 2001).

While there is little disagreement that protection is necessary for serious neglect of physical and/or emotional needs that threaten a child’s safety or health, for many, extra services for the child are required rather than safeguarding (see p. 429; Emery & Laumann-Billings, 2002).

Child abuse and neglect are not clinical conditions but terms arising from social consensus concerning the care of children. While there is little debate about overt physical abuse and sexual abuse between and within cultures, it is nevertheless important to retain cultural sensitivity in relation to practices that do not necessarily cause major harm to children and young people. For example, Korbin (1997) has drawn attention to the fact that leaving an infant all day in the care of a 7- or 8-year-old sibling is relatively usual in parts of the Far East, but considered neglectful in contemporary North American society. Conversely, parents in some parts of South-East Asia consider the western European practice of young children sleeping separately from their parents as neglectful (Korbin, 1997). Difficulties arise where there is disagreement about harm caused (e.g., female circumcision) or where strongly held belief systems lead to child welfare considerations being held secondary to religious certainties (e.g., animist beliefs and practices, which were one thread in the events that led to Victoria Climbie’s death; Department of Health, 2003). Anthropologists traditionally eschew taking a moral stance on such issues, yet an international public health perspective requires just such a moral position and legal stance, as has been adopted with female genital mutilation (UNICEF, 2006, p. 64). In an individual case, the laws of the respective country dictate responses to controversial practices affecting children’s health and development (see chapters 8 & 15).

Family Violence

The importance of family violence is underlined by strong associations between child maltreatment and intimate partner violence (IPV), and possibly also elder violence, within the same household (Slep & O’Leary, 2005). The traditional stereotype of one aggressor to both partner and children has been overturned, through community-based studies, by a picture of violence within a family characterized by verbal and physical violence occurring in multiple directions (Krueger, Moffitt, Caspi et al., 1998). Slep and O’Leary (2005) found that 60% of families exhibiting significant violence were characterized by violence occurring between the parents in both directions and between each parent and each child. Furthermore, the predominant pattern of aggression changed over time in one longitudinal study (Sternberg, Lamb, Guterman et al., 2006). Studies using multiple informants reveal higher rates of IPV (Slep & O’Leary, 2005; Sternberg, Lamb, Guterman et al., 2006). IPV shows a weak to moderate effect on emotional and behavior disturbance in children in meta-analyses (Kitzmann, Gaylord, Holt et al., 2003; Wolfe, Crooks, Lee et al., 2003).
CHAPTER 28

Effects include emotional and disruptive symptoms, particularly anxiety, depression, post-traumatic stress and aggressiveness. Physical health outcomes of childhood exposure to IPV are likely to be seen in terms of risk-taking behaviors, including substance use, early and multiple sexual partners (Bair-Merritt, Blackstone, & Feudtner, 2006).

However, these effects lose significance once persisting child abuse and other adverse events are accounted for (Fergusson, Boden, & Horwood, 2006; Wolfe, Crooks, Lee et al., 2003). Sturge-Apple, Davies, & Cummings (2006) found that the effect of interparental hostility was indirect, and mediated via parental emotional unavailability.

Nonetheless, despite an absence of convincing evidence of long-term effects of IPV, unless accompanied by child abuse and other adversity, effects are evident in the short term. Children under the age of 2 years are most at risk of physical injury, through being caught in the cross-fire of partner violence (Casanueva, Foshee, & Barth, 2005). Additionally, initial as yet unreplicated findings suggest that infants of 1 year may be more irritable and become developmentally regressed when exposed to IPV (Bogat, DeJonghe, Levendosky et al., 2006).

IPV is therefore an important aspect of family violence, causing significant distress, and part of a common constellation of adversity and violence, which occurs in multiple directions in aggressive families. It appears to be only relatively weakly causatively linked to emotional and behavior disturbances in children and adolescents when considered in isolation, but much more significant when combined with child maltreatment, emotional unavailability and other family adversity, when the combined effects have the potential to cause significant mental health problems during childhood and into adult life. Clinically, IPV can also be considered an important marker for child abuse and other co-occurring risk factors for poor mental health outcome in children. Lastly, and most importantly, the most severe forms of intimate partner violence sometimes end in homicide of adult partners and/or children, together with accompanying bereavement.

Epidemiology

It has always proved difficult to obtain accurate figures for child maltreatment incidence and prevalence because of variations in methods of ascertainment and recording. Maltreatment is so frequently kept private by individuals, families and communities. One consequence is the wide gulf between incidence and prevalence figures for all kinds of maltreatment.

The incidence of significant violence to children has been assessed using the Conflict Tactics Scales on representative community samples. This revealed rates of 49 per 1000 children in the USA in 1995 (Strauss, Hamby, Finkelhor et al., 1998); 83 per 1000 in Italian children (Bardi & Borgognini-Tarli, 2001); and 90 per 1000 British children, using a slightly expanded version (Ghate, Hazel, Creighton et al., 2003).

The USA National Incidence Studies have used child health, education and social care professionals to record incidents of maltreatment. The third national study provided a maltreatment rate of 23 per 1000 children (Sedlak & Broadhurst, 1996). This study surveyed over 5500 professionals, and distinguished between maltreatment causing harm (36%) and significant risk thereof. Girls were three times more likely than boys to be maltreated, but when boys were maltreated the harm was more serious. There were no significant race differences. Risk was significantly elevated among single parents, those with large families and, overwhelmingly, families living in poverty. Social services departments were only involved with a minority of cases, even among the most serious.

Officially reported child abuse and neglect incidence rates are substantially lower, ranging from 2 to 12 per 1000 child population (Australian Institute of Health and Welfare [AIHW], 2004; Department for Education and Skills [DFES], 2005; Department of Health and Human Services [DHHS], 2003; Trocmé, MacLaurin, Fallon et al., 2005). Neglect was the largest category. Children with a disability are three times more likely to be maltreated than the non-impaired (Westcott & Jones, 1999). Physical abuse comprised 15–28%; sexual abuse 10–28%, emotional abuse 7–34% and neglect 34–59%. The incidence of maltreatment increases from cases reported through to cases known about by professionals working with children, to incidence rates obtained from representative samples of the general public.

Prevalence rates of physical abuse in childhood range from 3% to 28%, with most studies reporting in the 5–10% range (Berger, Knutson, Mehm et al., 1988; Stevenson, 1999; Straus & Gelles, 1986). May-Chahal and Cawson (2005) report a rate of 7% in their representative sample of 2869 18- to 24-year-olds recalling childhood experiences. Longitudinal studies have been especially useful in elucidating both prevalence rates and associated risk factors and effects. Fergusson and Lynskey (1997), reporting on the Christchurch birth cohort of 1265 children followed-up into young adult life, reported a prevalence rate of 3.9% of children overly frequently harshly punished or abused. Brown, Cohen, Johnson et al.’s (1998) longitudinal study of 644 families revealed a prevalence of 3–24% dependent upon whether, and how many, psychosocial risk factors were also present. Silverman, Reinherz, & Giaconia (1996), in another longitudinal study, found 5.3% of boys and 6.4% of girls suffering physical abuse during childhood. Mullen, Martin, Anderson et al. (1996), reporting on their New Zealand sample, found that 7.8% of women reported serious physical abuse during their childhood. Brown, Cohen, Johnson et al. (1998) drew data from both self-reported and officially recorded maltreatment and revealed an important lack of correspondence between the two, with substantial proportions of cases missing from each data source.

Neglect and emotional abuse are especially problematic to ascertain in prevalence studies. Estimates range between 5% and 12% (Hussey, Chang, & Kotch, 2006; May-Chahal & Cawson, 2005), but rise much higher when supervisory neglect is added. Emotional abuse estimates have ranged from 6% to 12% (Hussey, Chang, & Kotch, 2006; May-Chahal & Cawson, 2005).
Overall, it is clear that child maltreatment of all kinds is common across cultures, social and economic groups, and in both genders (Strauss, Hamby, Finkelhor et al., 1998; WHO, 2002). Substantial variation between studies and across time probably reflect ascertainment and reporting difficulties largely, but nonetheless it is clear that official rates of reported child abuse represent but the tip of the iceberg of maltreatment experienced by children across cultures.

Serious Abuse and Death
The indications are that rates of serious and life-threatening maltreatment have not decreased in industrialized societies, despite their child protection systems (Emery & Laumann-Billings, 2002; Sedlak & Broadhurst, 1996). Existing figures for maltreatment-related child fatalities underestimate maltreatment as a cause by at least 50% (Jenny & Isaac, 2006). Mortality rates range from 0.1 to 2.2 per 100,000 children in industrialized societies, rising to 2–3 times more than this in low-to mid-income countries (Jenny & Isaac, 2006). The WHO estimates that 57,000 children die each year from maltreatment (Krug, Dahlberg, Mercy et al., 2002). The majority are during infancy, with the neonatal period proving the most common time for maltreatment fatality (Brockington, 1996, 2004; Jenny & Isaac, 2006). Neonates and infants under 2 months are more commonly killed by their mothers, whereas unrelated males more commonly kill older children. Head trauma is the most common cause of death, followed by neglect, suffocation and poisoning (Jenny & Isaac, 2006).

Conceptual Framework
There is consensus that the developmental–ecological perspective offers a comprehensive framework for researchers and practitioners to understand the occurrence and consequences of child maltreatment (National Research Council, 1993). This approach allows for integration of risk and protective factors for maltreatment, and levels of social complexity surrounding the individual (Bronfenbrenner, 1977) to be integrated with principles of developmental psychopathology, especially those that emphasize transactions between disparate factors over time (Belsky & Vondra, 1989). Besides the integrative value of this framework for researchers, it has also informed the Assessment Framework for practitioners, advanced by the Government in England and Wales (DOH, DOEE & HO, 2000).

Factors Associated with the Occurrence of Maltreatment
A range of factors are associated with the risk of maltreatment occurring. Factors that contribute to physical abuse, neglect and psychological maltreatment are organized below, using the domains that emerge from the eco-developmental framework, above.

First, however, it is necessary to note some inherent difficulties raised by discussing factors that are associated with a raised or lowered risk of child maltreatment occurring, in addition to well-established methodological problems (for summary see Ammerman, 1998). Distinguishing statistical association from causal influence is crucial (see chapter 5). Whereas longitudinal studies have helped considerably, there remains the difficulty that if a particular factor was not examined, or if the research design did not necessarily permit its impact to be elucidated (e.g., genetic factors; Moffitt, 2005; Rutter, Moffitt, & Caspi, 2006a), then its influence on maltreatment would not necessarily be evident. Certain factors, or combinations thereof, may be more salient for the occurrence of one type of maltreatment than another. Where such combinations are known they are indicated below, but otherwise risk factors are reviewed here that apply to physical abuse, neglect and psychological abuse. A further difficulty is that the factors themselves depend upon different processes for ascertainment. For example, assessments of quality of interaction and attachment require a different level of observation and recording than, say, family income. In addition, a factor-based approach tends to conflated those operating at a very general level (e.g., neighborhood toxicity or poverty) with intra- and interpersonal factors. Further, transactions between different factors are all important (Cicchetti & Toth, 1995). Some factors may be enduring in nature, while others are present only briefly. Even longitudinal studies have difficulty detecting direction of effect, especially when young adults are being asked to recall whether they were abused in childhood, bearing in mind that abuse in the early years may be impossible to recall accurately, quite apart from the difficulty in articulating experiences of neglect or emotional unavailability retrospectively.

At this point, consideration of risk mediating factors can be viewed through a lens that integrates non-linearity of linkages between risk mediators and maltreatment; acknowledges multiple influences and complexity of processes involved (Sroufe, 2005), while accepting that no one comprehensive model of development is available (Rutter, Kim-Cohen, & Maughan, 2006b). However, mediating processes are capable of being identified (Rutter, Kim-Cohen, & Maughan, 2006b; see chapter 25).

Individual Factors
Both child and parent factors are associated with risk and resilience for child maltreatment. Child factors include children under 3 years (Emery & Laumann-Billings, 2002), those with physical or mental health and behavioral difficulties and difficult temperaments (Belsky & Vondra, 1989; Brown, Cohen, Johnson et al., 1998). Higher intelligence, easier temperament and sociability, social competence and having peer relationships all appear to reduce the risk of a child being maltreated (Stevenson, 1999; but see also Jaffee, Caspi, Moffitt et al., 2004a).

Parents with maladaptive personality characteristics such as poor impulse control, negative affectivity, heightened reactivity to stress and those with substance abuse problems are at
greater risk of maltreating their children (Dixon, Browne, & Hamilton-Giachritsis, 2005a; National Research Council, 1993). Parental personality difficulties emerge as a significant risk factor for the occurrence of maltreatment in several longitudinal studies (e.g., Brown, Cohen, Johnson et al., 1998; Mullen, Martin, Anderson et al., 1996). Emery and Laumann-Billings (2002) summarized evidence that suggests child abusers differ from non-abusers in how they perceive their children, ascribing greater negativity to their acts than do non-abusing parents; bearing unrealistic expectations concerning their development and generally finding their child’s behavior more stressful. Parental age under 19 years is also associated with a raised risk of maltreatment (Brown, Cohen, Johnson et al., 1998; Egeland, Bosquet, & Chung, 2002).

Parents who themselves suffered maltreatment during childhood are less likely to show sensitivity in caregiving towards their own children, and are more likely to maltreat, or become associated with partners who maltreat their children (Belsky & Vondra, 1989; Egeland, Bosquet, & Chung, 2002; Kaufman & Zigler, 1989). However, it is important to stress that such continuity of parenting difficulty occurs in a minority, around one-third (Emery & Laumann-Billings, 2002). It is also likely that genetic and environmental effects contribute to the continuity observed (Emery & Laumann-Billings, 2002). Such genetic effects may be individual but may also occur through assortative mating (Krueger, Moffitt, Caspi et al., 1998).

Dixon, Browne, & Hamilton-Giachritsis (2005a) examined intergenerational continuity by comparing 135 families where one parent had a childhood history of maltreatment with the remaining 4216 who did not. The authors then explored the mediational properties of risk factors for maltreatment prospectively after birth. By 13 months, 6.7% of the prior childhood maltreatment parents had maltreated their own children, compared with 0.4% of comparison families. Three risk factors stood out in the mediational analysis: parents under 21 years of age, a history of mental illness and having a violent adult partner. However, while these three factors explained 53% of the total effect, explanation was improved to 62% once parenting style (a measure of parental attributions and behavior) was also taken into account (Dixon, Hamilton-Giachritsis, & Browne, 2005b).

**Family Factors**

Poverty and low income are associated with child maltreatment, probably as risk indicators and distal markers for the factors listed below. Family-based factors associated with maltreatment include low parental involvement with the child, early separation, low parental warmth, unwanted pregnancy and maternal dissatisfaction with her child (Brown, Cohen, Johnson et al., 1998; Egeland, Bosquet, & Chung, 2002). Abusive parents are also more likely to use severe physical punishments, employ them for everyday social transgressions and to exercise power and control more frequently than non-abusive parents (Brown et al., 1998).

A further set of factors involve conflict and violence between the adult partners, together with parent–child hostility and a greater use of physical punishment, power and control (Brown, Cohen, Johnson et al., 1998; Dixon, Browne, & Hamilton-Giachritsis, 2005a). Co-parenting difficulties may accompany these features (McHale & Rasmussen, 1998). Linked with these factors are a group of parent–child relationship factors, including poor quality interaction, minimal speech, play and responsiveness when combined with unrealistic developmental expectations, negative perceptions, and low sensitivity and acceptance (Dixon, Browne, & Hamilton-Giachritsis, 2005a). These features are likely to be associated with disorganized and avoidant patterns of attachment (Sroufe, 2005). Such families are also likely to be socially isolated (Egeland, Bosquet, & Chung, 2002). By contrast, families with supportive relationships, with an extended family and friends, and containing positive relationships between siblings may be protective (Stevenson, 1999). Equally, where young adults report recalling positive interparental relationships with expressions of warmth, maltreatment was significantly less likely to occur (Mullen, Martin, Anderson et al., 1996). Parental warmth and support and acceptance of a child are also protective of future abuse (Dixon, Hamilton-Giachritsis, & Browne, 2005b; Stevenson, 1999). Families in which there was strong religious affiliation were less likely to maltreat their children (Brown, Cohen, Johnson et al., 1998; Mullen, Martin, Anderson et al., 1996). Thus, there is a group of factors, which is associated with family violence, parental lack of involvement and warmth, combined with social isolation and high parenting stress, which is linked to negative parent–child perceptions, attributions and relationships, that sets the context within which maltreatment occurs.

**Community and Social Influences**

Community factors also raise the risk of maltreatment occurring. “Socially toxic neighborhoods” (Garbarino, 1997) that lack social support networks and opportunities (Brown, Cohen, Johnson et al., 1998; Coulton, Korbin, Su et al., 1995) are associated with higher levels of maltreatment. Such neighborhoods contain greater social disorganization, lack of community identity, and higher rates of violent crime and substance abuse. By contrast, socially supportive neighborhoods with better education, health care, neighborhood friendship and support, watchfulness for harm to others and environmental safety, benefit from improved cohesive community identity and have lower rates of maltreatment, notwithstanding comparable poverty levels (Coulton, Korbin, Su et al., 1995; Garbarino, 1997).

Broader social influences also appear to affect rates of violence towards children. The WHO (2002) points to factors that create an acceptable climate for violence and also reduce inhibitions against violence. Although intuitively feasible, finding evidence to support these contentions is more elusive. However, high rates of physical abuse can be linked to areas of the world where there are high levels of conflict and war (WHO, 2002). It is also of interest that maltreatment death rates in industrialized countries are linked with homicide rates (Jenny & Isaac, 2006). These findings provide some
support for the proposition that societal influences create a context within which family violence is more common.

Outcomes and Effects

The sequelae of child maltreatment have been reviewed by Cicchetti and Toth (1995), Emery and Laumann-Billings (2002) and Stevenson (1999). These authors draw attention to methodological difficulties, yet conclude that child maltreatment is linked to a range of long-term negative psychological outcomes, which persist when other, frequently co-occurring adversities, are controlled for. A variety of symptoms are reported, and no effects specific to maltreatment, but a possible link of symptoms to types of abuse. Physical abuse and neglect have been noted to be as harmful as sexual abuse. They also note that a substantial minority of children remain resilient in the face of adversity (see chapter 25; Rutter, 2006b). Resilience is associated with dispositional aspects of the child’s behavior, including sociability, intelligence and social and/or academic competencies, family factors such as supportive emotional ties, and support from significant others outside the family (Stevenson, 1999). External potential sources of resilience include school experiences, quality alternative care and therapeutic assistance (Egeland, 1997).

For brevity, and following Cicchetti and Toth (1995), outcomes have been organized in Table 28.1 according to themes of major developmental importance: affective and self-development, socialization (including attachment), cognitive and physical development. Outcomes frequently involve more than one area of developmental salience.

Child maltreatment behaves like many other adversities that children experience: many different outcomes stem from the same adversity; and many risk factors can result in similar outcomes (Cicchetti & Blender, 2004). Further, maltreatment does not operate as an isolated factor, but normally occurs in concert with other adversities. These other adversities may potentiate, or lower, the risk of poor psychological outcome and, possibly, physical health outcomes too. For instance, the context within which maltreatment occurs, particularly poverty, family stress, poor family functioning, chaotic and disorganized home environments, plus the impact of subsequent life changes upon the child who has already suffered maltreatment, all affect subsequent outcome (Egeland, 1997; Fergusson & Horwood, 2001; Lansford, Dodge, Pettit et al., 2002). Egeland (1997), reporting on the Minnesota longitudinal study, noted that early neglect, including parental emotional unavailability, with its chronic and unremitting nature, had a particularly severe impact on social adjustment and future self-harm behaviors in adolescence.

A cumulative conceptualization of risk fits the data best, in terms of accounting for the mediating effects of factors in addition to maltreatment that pre-exist, accompany and operate subsequently to abuse and neglect experiences, and their combined effect upon outcome.

However, maltreatment is not like any other risk factor. It represents the antithesis of an expectable environment of caretaking (Cicchetti, 1989): a fundamental insult to the developing child’s need for care and nurturance. Hence, it is not surprising that consequences are observable throughout all domains of development, and remain significant even when other adversities are accounted for, in the longitudinal studies.

Severe maltreatment (degree of abuse, duration, frequency) and the occurrence of multiple types are associated with more psychological ill effects and social adjustment difficulties. Abuse starting at a young age is also associated with more severe psychological sequelae, in keeping with developmental theory.

In addition, evidence exists for a dose–response relationship for certain outcomes, such as alcohol and drug misuse, and some physical health outcomes (Felitti, Anda, Nordenberg et al., 1998), and mental health outcomes such as suicidality, depression and antisocial behavior (Brown, Cohen, Johnson et al., 1998; Dube, Anda, Felitti et al., 2001; Edwards, Holden, Felitti et al., 2003; Evans, Hawton, & Rodham, 2005; Jaffee, Caspi, Moffitt et al., 2004b). Furthermore, in the multisite Adverse Childhood Events studies, the more adverse events, the greater the number of comorbid physical and psychological health problems in adult life (Anda, Felitti, Bremner et al., 2006).

The effect of physical maltreatment is moderated by genetic risk. Caspi, McClay, Moffitt et al. (2002) provided evidence that a functional polymorphism in the MAOA gene moderated the impact of early childhood maltreatment on the development of antisocial behavior in adult males, utilizing the Dunedin birth cohort. Those who were maltreated as children but who had high levels of MAOA expression were less likely to develop antisocial problems, compared with those with low levels.

A study of over 1000 British 5-year-old twin pairs demonstrated that physical maltreatment was only weakly associated with the probability of a conduct disorder diagnosis among those children at low genetic risk for conduct disorder, but significantly increased among those at high genetic risk. Genetic risk was assessed as a function of zygosity and the cotwin’s conduct disorder status (Jaffee, Caspi, Moffitt et al., 2005). Thus, there is genetic sensitivity, both in terms of risk and protection for antisocial behavior outcomes related to physical abuse.

Jaffee, Caspi, Moffitt et al. (2004b), using the same twin sample, examined whether physical maltreatment is an environmental risk factor that is causally related to future antisocial behavior. They demonstrated that physical maltreatment predicted antisocial outcome; bore a dose–response relationship to antisocial outcome; new antisocial behavior arose subsequent to abuse; the children’s victimization experiences were not influenced by genetic factors; effects of maltreatment remained significant after controlling for the parents’ history of antisocial behavior; and that the effect of physical maltreatment was significant even after controlling for any genetic transmission of antisocial behavior risk. This study underlines the causal nature of the link between physical maltreatment and...

antigenerational transmission of violence.

Altogether, these findings indicate a causal link between child maltreatment and a range of psychosocial and physical effects in childhood and adult life. Normally, maltreatment is embedded within, and rendered more severe by, accompanying family adversity and violence. It is clear that genetic factors have the capacity to mediate the sensitivity of individual children to maltreatment, at least in terms of antisocial outcomes, and possibly affective ones too (Cicchetti & Blender, 2004).

There has been considerable debate about whether different types of maltreatment can be linked with particular outcomes. Physical abuse has been linked with aggressive and resistant behavior, and conduct disorder and depression; whereas neglect has been considered more closely linked with lower intellectual functioning, language delay, attachment problems, social withdrawal and internalizing problems (Hildyard & Wolfe, 2002; Wolfe, 1994). However, physical abuse has also been linked with language delay and poor social competence. Sexual abuse is linked with disruptive behavior difficulties and post-traumatic stress disorder.

There are a number of problems with this approach. Maltreatment is normally coded, at least in social services organizations, by predominant type. However, repeated studies have indicated that pure types of maltreatment rarely exist in isolation (Manly, 2005). Two or more subtypes of maltreatment normally occur within the same report. Furthermore, over time, the relative contribution of different subtypes changes (Sternberg, Lamb, Guterman et al., 2006). Also, within each subtype there is a wide range of caregiver omissions or commissions. Thus, the category neglect may incorporate lack of supervision and/or physical neglect. From the perspective of outcome, the relative influence of severity, frequency, duration, chronicity and co-occurrence probably differs dependent upon predominant subtype at any one time. For example, cases involving chronic low-level child physical neglect have been demonstrated to have a severe impact on later psychological adjustment (Manly, Cicchetti, & Barnett, 1994; Manly, Kim, Rogosch et al., 2001). However, a single episode of physical abuse can result in death.

The LONGSCAN multisite project in the USA has the benefit of detailed coding of a large number of child protection service reports, which have now been followed-up from infancy to age 8, with psychological and social adjustment measures of outcome. The analyses conducted so far have elucidated many of the issues connected with the type of abuse and relationship to outcome. The main weakness of the studies has been that they are based on reports to child protection services, and outcome measures do not include teacher or third-party assessments. Nonetheless, a number of useful insights emerged. In the first place, social work department categorization related poorly to that of researchers. For example, 10% of neglect cases were thought by the researchers to have physical or sexual abuse as predominant categories (Runyan, Cox, Dubowitz et al., 2005).

Interestingly, neglect alone was not found to have the severe outcome expected. This was probably because effects were masked by a frequency measure, combined with absence of teacher reports (Dubowitz, Pitts, Litrownik et al., 2005). However, when neglect was conjoined with physical, sexual or emotional abuse, effects were more striking. Interestingly, lack of supervision was not associated with poor outcome, whereas physical neglect and failure to provide were associated with poor behavioral outcomes and impoverished socialization.

The emotional abuse analyses suffered from the fact that only four cases of “pure” emotional abuse were found amongst 250 cases. However, in 246 where emotional abuse was conjoined with neglect, physical or sexual abuse, there were significant effects on psychological and social adjustment (Schneider, Ross, Graham et al., 2005). Overall, the most severe psychological outcomes were, unsurprisingly, associated with severe abuse, of whatever type, multiple types co-occurring, early onset and of chronic nature. The authors confirmed that abuse that crossed developmental stages had more severe effects. Type of abuse per se was not the determining factor.

Overall, the type of maltreatment is less important for poor psychosocial outcomes than variations within type: early age of onset, chronicity, frequency, multiple subtypes and severity.

Assessment

Health care professionals have several different functions, depending upon the nature of their working relationship with the maltreated child and family (Jones, 1996b). Professionals must clarify whether they are undertaking a forensic assessment, or clinical, or a combination. Assessment is complex because of the number of professionals and systems involved, yet it is the cornerstone for effective case planning and intervention. It needs to be ongoing, not merely initial because of the effect of established changes in the interplay of factors over time on the developing child, with the potential to raise or lower the likelihood of better outcome. In this overview of assessment some background issues are considered first, before considering what comprises assessment.

Child Mental Health Practitioners

Child mental health practitioners can operate at different systemic levels in relation to child maltreatment (Jones, 1996b). They can have an important role in overall planning and integration of services locally or nationally, ensuring that a developmental perspective and mental health contribution are made in the most expeditious way. They can contribute to the imperative for services to remain culturally sensitive, and responsive to impairment and disability. Child mental health practitioners can also bring a scientific perspective to planning services and research initiatives, and apply messages from research to planning and practice.

Child mental health practitioners have a role in teaching and training at all systemic levels, and direct practice with respect
CHAPTER 28
to investigation, assessment, treatment and liaison with other health services. Their training should also allow a contribution at different systemic levels with regard to the personal impact of maltreatment work upon all practitioners; a role requiring both personal self-awareness and awareness of the ethos and working practices of other professionals from different disciplines.

Recognition
Child mental health practitioners’ major contribution is in being sufficiently aware of the possibility of maltreatment to ask the necessary questions. When one clinic’s practice changed to routinely asking questions about the possibility of child sexual abuse, the proportion of children who reported this went up from 7% before its introduction to 31% following training (Lanktree, Briere, & Zaidi, 1991). How such questions are put to children and young people is critical in order to avoid the possibility of leading questions (see chapter 7). Some mental health practitioners may develop a specific role in relation to interviewing children suspected of being harmed, perhaps helping other professionals communicate with mentally disordered or disabled children (Jones, 2003).

Child mental health practitioners also identify maltreatment directly when working with children. They deal regularly with cases involving apparent deficits in psychological aspects of parenting, as well as psychologically unavailable parenting and sometimes frank neglect. Deciding whether to involve child protection services can be complex where there are no clear cut-off points to guide practitioners. Assessment of severity, persistence, balance of maltreatment with positive parenting, combined with a thorough assessment of the child’s mental health and developmental status and a family assessment enables conclusions to be drawn in most cases. Discussion with an informed colleague may be helpful if in doubt. Cases involving hostility, rejection and unavailability will need to be assessed for the possibility of coexisting physical or sexual abuse, or physical neglect. Subtler deficits in the psychological aspects of parenting will not need a child protection response, but it may prove helpful to consider whether psychological or other forms of maltreatment are present at review, bearing in mind that physical and sexual abuse may well not be apparent or revealed at first assessment.

Neglect has a major association with poverty. Clinically, it may be hard to distinguish neglect cases within very impoverished neighborhoods. Under-recognition can result because serious neglect becomes explained away by practitioners, overwhelmed by neighborhood deprivation in their local areas. However, here especially, decision-making can be helped by maintaining a central focus from the child’s developmental needs, mental health and physical and cognitive status, combined with using standardized measures, to encourage objectivity (HM Government, 2006; Strauss & Kantor, 2005). It is important to emphasize that the majority of the poor do not abuse or neglect their children, even if the task of parenting is rendered more stressful and difficult within disadvantaged neighborhoods (Coulton, Korbin, Su et al., 1995).

Some specialized teams will also identify maltreatment in the context of fabricated or induced illness, perhaps through non-epileptic seizure presentations (Jones & Newbold, 2001). More commonly, however, practitioners encounter presentations that are commonly linked with prior maltreatment, such as sexual behavior problems, or deliberate self-harm (Evans, Hawton, & Rodham, 2005), when exploratory questions about maltreatment are necessary (Jones, 2003).

Decision-making
If dangerous cases are not identified, serious consequences, or even death, may ensue (Department of Health, 1995, 2003). Equally, overzealous evaluations of the potential for harm can lead to false positives and severe disruption to children and families (Butler-Sloss, 1988; Jones, 2003). Maltreatment is an emotive area for public and professional alike (Cicchetti & Toth, 1995; Rushton & Nathan, 1996), yet it is known that professionals’ affective responses have an impact on the decisions they make. Similarly, emotional containment is a key factor for accurate interviewing with vulnerable children (for review see Jones, 2003). These issues may be further compounded by a lack of mutual understanding or respect between different professionals at the multidisciplinary level of decision-making (Jones, Hindley, & Ramchandani, 2006). Galanter and Patel (2005) reviewed the sources of error and bias affecting experts and novices alike. They noted that experienced practitioners generally utilize more shortcuts and come to conclusions earlier. In the maltreatment field it is critical that practitioners suspend these tendencies and keep alternative explanations in mind and continually attend to potential sources of error in decision-making (Galanter & Patel, 2005; Jones, 2003).

Structured risk assessment schemas have been introduced in order to try to overcome variations in decision-making. There has been no proven benefit from their introduction in terms of the quality of decisions made, despite practitioners generally welcoming them (for review see Knoke & Trocmé, 2005). It is probable that a greater emphasis on how assessment data are utilized and applied will be more fruitful. Additionally, the content of assessments may be lacking in direct assessment of children, involvement of men and reviews of past history. A greater emphasis on decision-making process, rather than outcome, may be more fruitful in the long term, in order to expose the root causes and sequences of decision-making (Jones, Hindley, & Ramchandani, 2006).

Legal Work
Working with maltreated children and their families often leads to subsequent family court work, where practitioners make highly valued contributions to case plans. Practitioners’ major responsibility is to maintain neutrality when different systems come together in the court arena, rather than adopting the position of advocate (David, 2004). The discipline of distinguishing history and observation from interpretation and opinion, as well as making transparent how decisions and proposals are reasoned, are all emphasized in court work (see chapter 8).
Recent concerns about expert opinions in legal settings underline the importance of court experts obtaining feedback and working within a context of continuing professional development. Written and oral legal opinions should be prefered within the same ethos of expectation of peer review and constructive criticism as presentation of work for publication or conference proceedings. Novel perspectives or opinions should be subject to peer review before being floated within a legal context, in order to avoid distorting processes of justice (Wall, 2000).

**Interdisciplinary Working**

Maltreatment is multifaceted in nature and therefore several professional systems have a stake in its detection, prevention and response (HM Government, 2006). A central tenet of child protection has been that a multiagency perspective is superior to a single-agency one, because otherwise the full situation of child and family will not be appreciated (DHSS, 1974; HM Government, 2006). However, there are significant challenges in bringing disparate professionals together, with different frames of reference, professional responsibilities, ethos and style as well as status levels within society (Hudson, 2000). The sensitive area of information sharing, particularly if one agency has confidential information, has brought these difficulties into relief. Nevertheless, principles to guide information sharing have been published in England and Wales in order to assist practitioners (HM Government, 2006). In England and Wales, both government guidance and advice from professional organizations emphasize the requirement to reveal confidentially obtained information if a child is suffering or at risk of suffering significant harm (GMC, 2004). Provided the professional acts reasonably, he or she cannot be found wanting in law if those suspicions in fact turn out to be unfounded.

It is important that child mental health practitioners contribute in written or oral form to interdisciplinary planning forums, because this is the best way to appreciate the full range of concerns raised by others as well as to influence decision-making and case planning. The Assessment Framework introduced in England and Wales (2000) provides a useful means of overcoming the varied perspectives of different professionals. It is grounded in an ecological perspective on child maltreatment, and incorporates principles of developmental psychopathology, rendering it sympathetic to mental health practitioners. Nonetheless, mental health professionals need a basic understanding of the law and procedure relating to child protection in order to operate within their particular country (e.g., for England, HM Government, 2006).

**Assessment by Child Mental Health Professionals**

Child maltreatment is not a psychiatric entity, and therefore assessments of children where this has occurred will need to consider children’s safety from future harm, the child’s future living arrangements, physical health and education, including special educational needs, as well as mental health status. The mental health component is therefore part of the whole assessment (DOH, DOEE & HO, 2000). The approach to assessment will depend on the purpose or aims; is the assessment to evaluate the child and family for the possibility of mental health disorder and/or psychiatric treatment; or is the assessment being requested for court purposes? In either situation it is assumed that all will receive a comprehensive mental health assessment; however, certain aspects will receive greater emphasis when maltreatment is present. Normally, child mental health practitioners are not involved in determining whether a child has been maltreated (although see exceptions on p. 430).

Particular aspects of child and family functioning that will need assessment where child maltreatment has occurred include the following. First, practitioners will need to have information about all types of maltreatment that the child may have experienced and any other form of family violence he or she has witnessed or experienced. This information may be obtained directly from the family, or involve review of case files (health and social work files often have rich information on parenting capacity and family functioning, recorded over time, which is particularly relevant when assessing neglect or emotional abuse).

Confidentiality constraints will need to be made explicit with both children and parents. The child’s perspective on maltreatment is an important subject of evaluation, along with how he or she has coped with or responded to the experience. Assessment of child–parent interaction is a key ingredient, including both parental caregiving and child attachment elements (Cassidy & Shaver, 1999). Collateral sources of information and different perspectives can be of particular value in maltreatment cases. History from the child’s parents will usually involve more forensic aspects than is usual for child mental health evaluations. Family relationships are also important to assess, including the quality of interparental relationships and co-parenting capacity.

Assessments undertaken for family courts will generally follow the same principles but with a greater emphasis on and awareness of forensic requirements (Budd, 2005; Jones, 2006). Budd (2005) has emphasized that family court assessments should be centered firmly on parenting capacity (rather than parental mental health per se); have a functional emphasis (assessing beliefs, knowledge, actions and capacity, in relation to an individual child), which should emphasize strengths and weaknesses, and be contextualized and consider the likelihood of remediation. Assessments should rest on an assessment of the minimal parenting standard, not the optimal. Jones (2006) emphasized the need to link data-gathering with a structured approach to decision-making in order to place relative weight on the many factors, both positive and negative, that will be derived from a comprehensive assessment (see p. 433; Jones, Hindley, & Ramchandani, 2006).

**Treatment and Intervention**

Psychological treatments have been developed for specific types of maltreatment, despite “pure” forms of maltreatment
being the rarity rather than the norm (Manly, 2005). Hence, it is important to identify treatment models that can target specific symptom clusters, accommodate different levels of severity and chronicity of maltreatment experience, and which are focused at the appropriate developmental level, rather than design treatments for specific maltreatment types (Cohen, Mannarino, Murray et al., 2006).

Intervention will have a different focus where a child has been removed, contrasted with treatment aimed at family preservation or reunification. Cicchetti and Toth (1995) emphasized that interventions should address the fundamental challenges to development that maltreatment brings; in particular, affect regulation, attachment, the evolving self-system and peer relationships. The overall aim of intervention is to avert subsequent problems with self-esteem, interpersonal relationships and social adjustment which occur when maltreatment derails developmental stage-salient progress (Cicchetti & Toth, 1995). In this section, general principles and approaches to intervention are outlined first, before considering effective interventions.

First, interventions have to address the question of safety. This requires interdisciplinary coordination and, in many cases, care planning to ensure that the child or young person is not harmed again (Azar & Wolfe, 1989; Jones, 1996b; Stevenson, 1999). There is consensus that intervention should be organized around the welfare of the child as the primary guiding principle (rather than family preservation, primarily); should emphasize the child’s physical and emotional safety; should address the child’s specific range of problems from a developmental perspective; and address parenting and caretaking deficits, simultaneously (Azar & Wolfe, 1989; Jones, 1996b, 1997; National Research Council, 1993; Saunders, Berliner, & Hanson, 2004; Stevenson, 1999). To these may be added the importance of acknowledging the children’s experience of abuse and the need to characterize it as wrong, unlawful or harmful (Jones, 1997; Jones & Ramchandani, 1999; Saunders, Berliner, & Hanson, 2004); intervention should be both abuse-informed as well as addressing general mental health issues; supportive, non-abusing carers should be included in the treatment; and treatments with the highest level of empirical support should be first-choice interventions. Parental acknowledgement of maltreatment should comprise part of the intervention (Jones, 1997; Saunders, Berliner, & Hanson, 2004); treatment goals should include prevention of likely problems associated with maltreatment, as well as relief of the current ones (Saunders, Berliner, & Hanson, 2004).

Saunders, Berliner, & Hanson (2004) review of available interventions for physical and sexual abuse assessed 24 treatment protocols, some for children alone and others that were family or parent–child focused, as well as two offenders’ treatments, rating the degree of empirical support for each. Of the 24, 16 had some degree of empirical support for efficacy with child abuse cases. These were principally behavioral and cognitive–behavioral interventions. They were characterized by being goal directed (addressing specific measurable problems within children and their families); were structured in their approach (often with sequential staging of treatment components toward therapeutic goals); and emphasized skill building to manage emotional distress and behavioral disturbance in children and parents. They note that while other treatments were commonly in use and had strong theoretical bases they lacked empirical support for claimed effects; trauma-focused play therapy being one such example. They also noted that one treatment protocol, corrective attachment therapy, was associated with an unacceptably high level of risk of harm, even being associated with deaths of children, such that the authors discouraged its use (see also Chaffin, Saunders, Nichols et al., 2006).

Trauma-focused cognitive–behavioral therapies have been shown to be significantly superior to family and general psychotherapeutic treatments with both physical and sexual abuse (Cohen, Mannarino, Murray et al., 2006; Jones & Ramchandani, 1999; Kolko, 2002; Saunders, Berliner, & Hanson, 2004). In these programs combinations of psychoeducation, exposure therapy, cognitive procedures and restructuring, as well as behavior management techniques are all employed. Techniques involve practicing skills and active therapist feedback. Children are assisted with emotion recognition and regulation, specific anxiety management skills, attention to maladaptive cognitions (e.g., that the child was not responsible for his or her victimization) and problem-solving skills. Concurrently, parents are taught to use effective behavior management skills with their children, emphasizing positive reward and curbing harsh, sometimes violent consequences or isolation (Cohen, Mannarino, Murray et al., 2006; Saunders, Berliner, & Hanson, 2004). Sometimes, additional specific treatments for parents include anger management, mental health or substance use difficulties and interparental violence.

Child–parent psychotherapy has shown significant benefit for children and their mothers, compared with individual psychotherapy among multiply maltreated preschoolers. It comprises a blend of psychodynamic and cognitive–behavioral components, delivered intensively with both children and parents over a 1-year period (Lieberman, Ippen, & Van Horn, 2006).

Parent–child interaction therapy (PCIT) has shown promise with physically abusing parents, reducing the frequency of recurrence from 49% among cases assigned to the standard community group treatment to 19% in the PCIT group, in a randomized trial (Chaffin, Silovsky, Funderburk et al., 2004). However, the impact on children’s symptoms was not assessed.

There have been fewer studies evaluating the effectiveness of treatment when neglect or emotional abuse is the predominant issue. A systematic review of treatment in neglect revealed tentative support for specific programs of play therapy (group play training and resilient peer treatment) and for a therapeutic day treatment program (Allin, Wathen, & MacMillan, 2005). There was also some support for multisystemic therapy, and a day treatment program focusing on enhancing self-esteem. However, numerous methodological problems beset the studies, reducing confidence in these con-
CHILD MALTREATMENT

As can be seen, the factors with the strongest association with recurrence of maltreatment were a prior history of maltreatment before the indexed case, neglect cases, cases involving family violence and interparental conflict, and parental mental health problems. There was a strong but less powerful link with parental substance or alcohol abuse, continuing high family stress, lack of social support and family isolation, families with younger children and where parents had histories of personal abuse during their own childhood. Jones, Hindley, & Ramchandani (2006) suggested a staged approach to decision-making based upon the following:

1. Data gathering
2. Weighing relative significance of multiple factors
3. Formulating and/or diagnostic stage
4. Identifying circumstances that might alter the child’s future welfare status
5. Identifying prospects for change
6. Establishing criteria through which to gauge effectiveness of intervention and desired outcomes
7. Outlining a timetable that is developmentally appropriate
8. Formulating a plan for the child, incorporating needs and protection, as well as the roles and responsibilities of different professionals and agencies, and a timescale for review.

They also emphasized that not all families can achieve change (Jones, Hindley, & Ramchandani, 2006), and that some families may be “untreatable.” Bringing efforts at family preservation to a halt may be stressful for professionals, but essential for children’s welfare (Saunders, Berliner, & Hanson, 2004). This concept is central to concurrent planning (Wigfall, Monck, & Reynolds, 2006), in which the possibility of substitute care is held in the minds of family members and professionals, while in parallel providing specific psychological treatments from the outset of the intervention process. If treatment is unsuccessful in achieving its goals and the child’s welfare continues to be compromised, temporary foster care is converted into permanent substitute care. In this way the child’s welfare and safety are held paramount above all other considerations.

Prevention

This section addresses primary and secondary prevention of child maltreatment; that is, programs aimed at the whole population (see chapter 60), and ones focused on those deemed at risk (see chapter 61). Primary prevention efforts include public awareness campaigns relating to family violence, encouraging non-violent approaches to discipline and raising awareness about childhood maltreatment; and at the community level, positive parenting programs and school-based programs aimed at reducing violence in adolescence (Wolfe, 2006). In addition, primary health care by nurses, health visitors and developmental child health services has a role in primary prevention. Primary prevention should also focus on social institutions for children, including training, awareness raising and overcoming myths and barriers to reporting concerns raised by children.
or staff members. The overall approach is health promotion rather than surveillance (Blair & Hall, 2006).

At the secondary prevention level, the most common approaches are home visiting and parent education for identified high-risk parents (Leventhal, 2005). A different approach aims to strengthen local communities through networks of voluntary and professional organizations, based on research linking maltreatment to neighborhood impoverishment (Daro & Cohn Donnelly, 2002; Korbin, 2002; Melton & Barry, 1994).

Home visiting programs for at-risk families have been well researched and have shown small to moderate reductions in maltreatment rates among the group receiving home intervention from trained nurses antenatally and postnatally, especially with young first-time mothers who have other risk factors for maltreatment (Fergusson, Grant, Horwood et al., 2006; MacMillan, MacMillan, Offord et al., 1994; Olds, Eckenrode, Henderson et al., 1997). Trained nurses or social workers appear more successful than paraprofessionals (Duggan, Fuddy, Burrell et al., 2004a,b; Windham, Rosenberg, Fuddy et al., 2004). However, not all programs have demonstrated benefit (see Chaffin, 2004, 2005; and special issue edited by Leventhal, 2005). Some programs have revealed an increase in maltreatment among intervention compared with comparison groups (Barlow, Davis, McIntosh et al., 2007; Rutter, 2006a).

434
this may represent a surveillance effect, and increased recognition of maltreatment seen as a positive outcome, the precise reasons for this paradoxical finding remain unanswered. Currently, prevention services incorporate many disparate elements, and it is necessary to tease apart those aspects that may benefit children from those that may increase the chances of maltreatment among some parents (Rutter, 2006a,b).

Parent education programs are similarly diverse. They reveal modest and promising improvements from educational and support efforts, taken overall (Wolfe, 1994). Daro and Cohn Donnelly (2002) identified key aspects of successful programs. They should start prior to, or close to, the birth of the first child; be tied to the child’s specific developmental level; provide opportunities for parents to model positive interactions and discipline methods; extend for several months in order to change attitudes and strengthen parenting and personal skills, as opposed to simply imparting knowledge; emphasize social supports available in the community; and be sensitive to cultural differences. Interestingly, programs that also contained individual support for those especially needy and at-risk families, in addition to the group-based parenting program, were most effective (Wolfe, 1994; Barlow & Stewart-Brown, 2005).

It is probable that existing programs need to be more adaptable to individual difference (Leventhal, 2005). For example, a menu of additional services needs to be available to add on to home visitation programs, dependent on the specific needs of the family, e.g., interventions for maternal depression, domestic violence, parental mental illness, substance abuse, or severe learning difficulties, rather than uniformity.

At this point, a universal health promotion approach for all families, plus carefully supervised and monitored home visiting for high-risk parents (young, poor, parental mental health problems) focusing on increasing parenting sensitivity and competence directly, and which can flexibly adapt and draw in other services for particular subgroups, appears the most promising approach. But programs for high-risk parents need to overcome barriers in engaging the hard-to-reach (Barlow, Kirkpatrick, Stewart-Brown et al., 2005; Blair & Hall, 2006). A good example of an integrated approach across an area is provided by North Carolina (Hughes, Earls, Odom et al., 2005). Here, primary, secondary and tertiary (intervention) services at different ecological levels are fully co-ordinated through a state-wide interdepartmental leadership team. The newly integrated children’s services in England and Wales should provide a suitable vehicle for similar initiatives. This would be a crucial antidote to uneven provision and development of individual programs, which merely focus on one aspect. The public health approach to tackling maltreatment, at the primary or secondary level of prevention, offers the best hope for a genuine reduction in the prevalence of maltreatment.

Conclusions

Child maltreatment is a major public health problem internationally, with established threat to human health, throughout the lifespan. Although maltreatment is seen as an environmental risk factor, as a phenomenon it illustrates the complex interactions between genes and environment. The key tasks now are to make further progress elucidating effective interventions and management of risk of serious harm to children. Additionally, to understand better why prevention, universally and with high-risk individuals, has not measured up to its initial hope and promise.

Child Sexual Abuse

Danya Glaser

Sexual abuse is a significant risk factor for the development of psychopathology in childhood, adolescence and adulthood. Familiarity with the phenomenon (including its presentation and treatment) is therefore of particular importance to the practice of child and adolescent psychiatry. The hallmarks of child sexual abuse are its secret nature and the very frequent denial of the abuse by the abuser, which is already experienced as a taboo. Two factors play a central part in the process of the abuse and in its aftermath. Sexual abuse includes a far wider spectrum than incest, occurs both within the family and outside it but, in either circumstance, the abuser is frequently already known to the child. Indeed, this acquaintance may be based on a deliberate befriending or "grooming" of the child by the abuser for the purposes of planned abuse. Because it involves sexuality, this form of abuse is particularly emotive.

Child sexual abuse is not a new phenomenon. The incest taboo has been in existence for over 4000 years, first recorded in the Babylonian code of Hammurabi (c.2350 BC), which referred to "a man be known to his daughter" (Handcock, 1932) where "known" has been translated as "to conceive a child" (ten Bensel, Rheinberger, & Radbill, 1997). The laws of Moses (c.3000 BC) describe incest as a sin (Leviticus 18:6). General Booth, founder of the Salvation Army, wrote in 1890: "I understand that the Society for the Protection of Children prosecuted last year a fabulous number of fathers for unnatural sins with their children" (Booth, 1890). Despite sporadic earlier pronouncements, child sexual abuse only began to be noted as a significant form of child abuse in the 1970s. Increasing recognition came with the development of the women's movement, reports by adult women survivors of their childhood abuse and a greater openness regarding sexuality. This pattern of increasing recognition has swept through successive countries, with reports appearing in the scientific press, in particular in Child Abuse and Neglect, the International Journal.

The universal disapproval of child sexual abuse is exemplified in the UN Convention on the Rights of the Child. In the UK, this disapproval is expressed by the legal prohibition of incest and sexual contact between an adult and a child, and its inclusion as various offences under criminal law. However, some of the harmful effects of child sexual abuse such as the denial of the abuse by the abuser, and guilt and self-blame by the victim, are largely consequent on this expressed disapproval by society. Moreover, the fact that child sexual abuse is a relatively common experience for children and young persons implies a lack of protection of, and care for, these vulnerable members of society. Despite the now repeated findings of very high reported rates of child sexual abuse (see p. 442), most suspicions of sexual abuse continue to be met with caution, and disclosures are often regarded with suspicion. The fact that an apparently common phenomenon is so often doubted or disbelieved is probably explained by the social taboo surrounding adult sexual contact with children and by at least two further factors. First, the absence of non-involved witnesses to this (secret) activity helps to support the frequent denial of the abuse by the alleged abuser. Second, the potentially serious consequences for the alleged abuser, if found guilty, govern the attitude to investigation. Alongside the high rate of reports of sexual abuse of children and adolescents, the rates of prosecution and conviction are low. In an English sample of 188 cases of contact abuse, the rate of prosecution was 36% with 17% convictions. A further 5% received a caution (Prior, Glaser, & Lynch, 1997). Two independent studies from the USA found that less than one in five cases of alleged abuse reached the stage of prosecution (Martone, Jaudes, & Cavins, 1996; Tjaden & Thoennes, 1992). The stringent test of the evidence in criminal law, “beyond reasonable doubt,” which is higher than “on balance of probabilities” required in civil law, may help to explain this low rate. Many children who have been abused find difficulty in comprehending the lack of more frequent criminal convictions, especially when they have been prepared to testify in court.

Heated controversy has surrounded memories recovered in adulthood of childhood sexual abuse, the veracity of which is disputed by the alleged abusers (Davies & Dalgleish, 2001). Some memories have returned spontaneously whereas others have been triggered by reminders or recalled in response to enquiry that included leading questions and other forms of suggestion (Loftus, Garry, & Feldman, 1994; see also chapter 7). A few have been induced by overzealous therapists. This debate has (inappropriately) rekindled doubts about the general truth of allegations made by children.
Definitions

A myriad of definitions for legal, research and other purposes continue to be developed and used. A recent definition guiding child protection work in England states: Sexual abuse involves forcing or enticing a child or young person to take part in sexual activities, including prostitution, whether or not the child is aware of what is happening. The activities may involve physical contact, including penetrative (e.g., rape, buggery or oral sex) or non-penetrative acts. They may include non-contact activities, such as involving children in looking at, or in the production of, pornographic material or watching sexual activities, or encouraging children to behave in sexually inappropriate ways (Department for Education and Skills, 2006). It is important to note that the abuser’s intentions or motivations are not considered necessary to be included in many definitions. The term pedophilia applies to a sexual attraction to, and arousal by prepubertal children, of either gender. It is clear that many sexual abusers are therefore not pedophiles.

Cultural Practices

Some definitions refer to social or cultural norms, making it necessary to consider what is a culture-specific practice. This is particularly relevant where ethnic minority groups are living in a majority host culture whose norms differ. Cultural practices are expected to alter with time and context, and the dominant culture tends to set prevailing childrearing standards (Korbin, 1997). However, Ahn and Gilbert (1992), for example, found that among Koreans living in the USA, a grandfather touching the genitalia of his preschool grandson was seen as expressing pride in the fact that this child would continue the family line. Cultural practices may not be benign and culturally sanctioned, and normative practices may affect adversely the well-being of children (McKee, 1984). A particular case is the issue of female genital mutilation (Powell, Leye, Jayakody et al., 2004). There is clearly also individual deviation in child care and other practices within cultures (Korbin, 1981). Whereas it is important to avoid misidentifying culture as abuse and vice versa (Abney & Gunn, 1993), this can be quite difficult in practice.

Legal Considerations

Under English civil law, child sexual abuse is recognized in the Children Act, 1989 as a form of Significant Harm. In criminal law, child sexual abuse is subsumed under a number of different offences. They include incest, which applies to vaginal intercourse between a male and a female whom the offender knows to be his (legal) daughter, granddaughter, sister or mother. Incest is thus not necessarily child sexual abuse. Under English law (Home Office, 2004) the child is defined as under 16 years of age. Offences include rape, assault by penetration, sexual assault, causing or inciting a child to engage in sexual activity, engaging in sexual activity in the presence of a child, causing a child to watch a sexual act, abuse of children through prostitution and pornography, arranging or facilitating commission of a child sex offence and meeting a child following sexual grooming. It also includes child sex offences committed by children or young persons.

In some jurisdictions, such as in England and the USA, civil and criminal proceedings can continue in parallel and independently of each other. This means that, in theory although not always in practice, a child may be protected from an abuser by being moved from their care under civil law, when there has been no criminal trial and potentially even if a criminal trial failed to convict the alleged abuser. In other jurisdictions, child protective procedures will only be undertaken following the criminal conviction of the abuser. This confers considerably less protection on children, especially as the rate of convictions worldwide is low relative to the number of allegations.

Nature of the Abuse

Within the spectrum of sexual abuse, an early distinction was made between non-contact and contact abuse (Wyatt & Peters, 1986a). However, with the advent of new technologies, this distinction is becoming more blurred.

Contact Abuse

Broadly, in western societies, any physical contact between the breasts and genitalia of a child or adult and a part of the other’s body, with the exception of isolated accidental touch (e.g., in the bath or in bed), and for developmentally and age-appropriate cleaning or for applying medication or ointment, is considered to be sexual abuse. Abusive contact includes fondling, masturbation, oral-genital contact or penetration, attempted or actual digital and penile penetration of, and the insertion of objects into, the vagina or anus. Active abuse is often preceded by an insidious process of “grooming” in which the abuser, having identified a particular child or children, finds ways of befriending the child or increasing the opportunities for being with the child unobserved. Given the addictive nature of much child sexual abuse, it is in the abuser’s interest to be able to continue to abuse a child. Therefore, there is typically a gradual progression from touching to more penetrative abuse (Berliner & Conte, 1990), so as to avoid causing initial pain or injury, which would be more likely to lead the child to complain about or report the abuse. Anal abuse is understandably more common in boys, although younger girls are not infrequently anally abused (Hobbs & Wynne, 1989). In a small proportion of cases, actual physical violence is used, either as a way of intimidating or coercing the child, or as an integral aspect of the abuse (30% in the study reported by Gomes-Schwartz, Horowitz, & Cardarelli, 1990).

Non-contact Abuse and the Use of the Internet and Mobile Phone Technology

This includes deliberate exposure of children to adult genitalia or sexual activity, either live or depicted in photographs or
CHAPTER 29

film. It also includes intrusive looking at the young person’s body, inducing children to interact sexually with each other and the taking of photographs for pornographic purposes. There has been debate about the point at which the threshold for Significant Harm or actual abuse is reached when the concerns are about non-contact sexual interaction. It is important to ascertain whether the interaction was deliberate and the extent of coercion used, with greater coercion increasing the harm. Although the most serious effects of sexual abuse are associated with contact, and especially penetrative, abuse, many young persons report the experience of being intrusively observed as humiliating and intimidating.

The Internet and mobile phone technology have become a source of sexual abuse of children (Taylor & Quayle, 2003). Children may view pornographic images by encountering them inadvertently or by deliberately searching for them. This exposure is increasing (Wolak, Mitchell, & Finkelhor, 2006). Children report being very disturbed by unwanted exposure to such material (Finkelhor, Mitchell, & Wolak, 2000). The Internet is also a means by which adults may ask for children’s pictures of themselves or groom adolescents with the intention of luring them into sexual activity (O’Connell, 2003). In addition, children are being made the subjects of abuse images (Palmer, 2005). Lastly, child pornography may act as a motivator or reinforcer of sexually abusive activity by adolescents (Quayle & Taylor, 2006). Some of this activity involves adolescent peers acting together and includes distributing images of other children, which may have been taken on mobile phones. This activity is likely to be enhanced by the normalizing effect of pornographic imagery on the Internet. As with other forms of sexual abuse, children and adolescents may be reluctant to tell about this abuse, which may be discovered rather than disclosed. Children may thus become involved in criminal investigations.

Commercial Sexual Exploitation of Children

Commercial sexual exploitation takes the inter-related forms of trafficking and prostitution. Trafficking includes movement of children for financial gain, usually across borders and largely for sexually exploitation. Abuse through pornography may also be included (Chase & Statham, 2005). Prostitution is found both in girls and boys and is now clearly recognized as a form of sexual exploitation and abuse. There is a complex relationship between sexual exploitation and drug abuse, the sexual exploitation either providing a source of money to support drug dependency or introducing the young person to addictive drugs as a means of gaining control over the child for subsequent sexual exploitation.

Epidemiology

For mental health care planning (and other services), sufficient provision needs to be made for the treatment of the consequences of a common problem. Unfortunately, the published figures for incidence and prevalence of child sexual abuse vary considerably according to the definition used, the source of data and the population studied. Whereas broad definitions point to the extent of the problem, they are less helpful in indicating severity and the kind of therapeutic services required.

Although annual reports of child sexual abuse could, in theory, indicate prevalence, such figures are inaccurate under-estimates. Many occurrences of child sexual abuse are not reported at the time of the abuse (Finkelhor, Hotaling, Lewis et al., 1990) and some are not reported at all.

Prevalence

The most accurate figures are from population studies. Even here, responses to interviews or questionnaires may be under-estimates, because of reluctance to report or a lack of recall of previous abuse, even when this had been documented at the time (Williams, 1994). It has been suggested that interviews, which tend to yield higher rates of reported abuse, may be more specific in their questions and more likely to prompt recall of abuse (Wyatt & Peters, 1986b).

In population, as opposed to victim samples, non-penetrative contact abuse is the form most commonly described (Hauggaard & Reppucci, 1988). Russell (1983), in her urban community study of 930 women, found that 38% had suffered contact abuse under the age of 18 years, and very serious sexual abuse (forced vaginal or anal intercourse and oral-genital abuse) in 27% of intrafamilial cases. In a British study of students (Kelly, Regan, & Burton, 1991), 27% female and 11% male respondents reported contact abuse. Four per cent of female and 2% of male respondents respectively reported serious penetrative or coercive abuse, with an age difference between abuser and victim of more than 5 years. In a recent study using a questionnaire with a random probability sample of 18- to 24-years-olds in the UK (May-Chahal & Cawson, 2005), 10% reported experiencing contact sexual abuse while under 16 years of age (15% girls and 6% boys). By contrast, the rate for the most serious forms of abuse in clinical samples rose to 65% (Gomes-Schwartz, Horowitz, & Cardarelli, 1990).

Rates of reporting increased over the 20 years after 1970, both in the UK (Markowe, 1988) and in the USA (Finkelhor, 1991) probably because of increased awareness, but there had been little evidence to suggest that the actual incidence had been changing significantly (Feldman, Feldman, Goodman et al., 1991). Indeed, the number of substantiated cases of child sexual abuse in the USA decreased by an estimated 49% between 1990 and 2004 (Finkelhor & Jones, 2006). The findings in Australia (Dunne, Purdie, Cook et al., 2003) and England are broadly similar. The fall could be brought about by:

1. An actual decline (Finkelhor & Jones, 2004) which might signal a positive effect of interventions for reported child sexual abuse; growing awareness of children’s rights or greater vigilance and child-focused parenting;
2. A decline in reporting caused, for instance, by fear of legal repercussions; or
3. Changes in agency responses to reported abuse, such as increased cautiousness and acting on allegations with a raised threshold for an active professional response.
The fall in rate parallels the decline in substantiated cases of physical abuse and improvements in other aspects of child welfare, at least in the USA, and it is likely that, to some extent, the fall is real (Finkelhor & Jones, 2006).

**Frequency and Duration of Abuse for an Individual Child**

Whereas population studies have shown a majority for whom sexual abuse is a single episode, in clinical samples the majority of children have been abused more than once by the same abuser. It appears that single episodes of abuse are less likely to be reported and subsequently referred to helping agencies. There is evidence that a child who has been sexually abused is vulnerable to further abuse by others, 14% in the Baker and Duncan (1985) study. This is likely to be because of a combination of the original vulnerability of the child and the added vulnerability conferred by the experience of having been abused. A distinction needs to be made between repeat victimization by the same abuser and revictimization by different abusers (Hamilton & Browne, 1999). Children subjected to organized abuse (see p. 444) are often multiply abused. Repeated abuse often continues for several years (Gomes-Schwartz, Horowitz, & Cardarelli, 1990). Duration, frequency and severity, including penetration, are thus linked factors.

**Age of Victims**

Children may be abused from infancy onwards. Children who experience intercourse tend to be older, with an average age of 11.4 years in the Gomes-Schwartz, Horowitz, & Cardarelli (1990) study, compared with 9.1 years for other forms of significant contact abuse.

**Gender of Victims**

Girls are more commonly victims of sexual abuse than boys. There is a tendency for sexual abuse of boys to be underreported (Holmes & Slap, 1998), in part because of shame and the fear of homosexuality. Adolescent boys are increasingly reluctant to talk about their abuse, even in therapy (Nasjleti, 1980). This may explain some reports that boys are abused at a younger mean age than girls (e.g., Singer, 1989). Younger boys are not infrequently abused alongside their sisters rather than in isolation (Vander Mey, 1988). Extranuclear abuse more commonly involves boys although there is no agreement about whether boys are more commonly abused by strangers (Watkins & Bentovim, 1992).

**Disability**

National statistics on child abuse do not contain data on abused children’s disabilities (Kelly, 1992). However, in studies of children with disabilities the rate of sexual abuse is two or three times that in “normal” children (Sullivan & Knutson, 2000). The reasons for this greater prevalence include: the children’s difficulties in communicating about abuse (Morris, 1999); their dependency on intimate physical care; social isolation in institutional care (Utting, Baines, Stuart et al., 1997); and care by staff rather than parents (Westcott & Jones, 1999). Kendall-Tackett, Lyion, Taliaferro et al. (2005) urge professionals to include disability as a variable in studies of abused children so as to increase awareness of their existence among abused children.

**Abusers**

The majority of abusers (85–95%) are male. Whereas male abusers who abuse prepubertal children may well target both boys and girls, there is some gender specificity in relation to adolescent girl victims. By the time a sexual abuser is identified, his pattern of abusing has often been well established. A small proportion of child sexual abuse is carried out by female abusers (Saradjian, 1996), often in conjunction with a man. Women abusers on their own are more likely to abuse boys (Faller, 1989). Age is no bar to sexually abusive interactions and older men may well continue to abuse children.

There has been much debate about a possible psychological profile of abusers or about a commonality of childhood experiences that might have led them to abuse children. Whereas many will have experienced disruption and physical abuse in their formative years (Seghorn, Prensky, & Boucher, 1987), a person’s own sexual abuse is one predisposing factor to sexually abusing children (summarized in Watkins & Bentovim, 1992) but it is not a prerequisite. A study sought differences between the previous experiences of four comparison samples each consisting of 15 boys aged 11–15 who had, respectively: (i) been sexually abused; (ii) abused other children; (iii) been abused as well as abused other children; and (iv) had a conduct disorder (Skuse, Bentovim, Hodges et al., 1998). Factors precluding the sexually abusive activity by the boys included discontinuity of care, exposure to or experience of physical violence and emotional abuse. Such findings help to explain why, in practice, sexual abusers constitute a heterogeneous group in terms of personal, social and demographic factors.

**Juvenile Abusers**

Sexual abuse by both children and adolescents, mostly boys, has become widely recognized (Abel, Becker, Mittelman et al., 1987) and is no longer considered an acceptable variant of childhood or adolescent sexual development. A significant proportion of adolescent abusers are of low intellectual ability. Most children and adolescents who sexually abuse other children have experienced psychosocial adversity. A recent study has found that for boys who had been sexually abused, predisposing risk factors to becoming a sexual abuser included material neglect, lack of supervision, sexual abuse by a female person and witnessing intrafamilial violence (Salter, McMillan, Richards et al., 2003). Adolescent abusers show heterogeneous maladaptive mental schemata regarding social interaction and abuse (Richardson, 2005). Many adult abusers report the onset of their abusive activities in adolescence and abuse by an adolescent cannot necessarily be considered safely to “burn out” in adulthood (Vizard, Monck, & Misch, 1995).

**Abuser–Child Relationship**

The majority of children know their abuser before commencement of the abuse. This acquaintance may have been
deliberately fostered by the abuser as part of a grooming process, or the abuser and child may be part of the same family or social network. In community studies, the most common relationship is stepfather–stepdaughter (Finkelhor, 1984). The same abuser may abuse children both within and outside the family, and include biological as well as stepchildren. Risk to other children in the family and in contact with the abuser is therefore difficult to predict and an assumption must be made that the proven capacity to actually abuse children renders all children in contact with that abuser at risk.

Organized Abuse
Many abusers abuse in isolation. Nevertheless, there are also organized forms of abuse involving more than one abuser and multiple children, some of whom are recruited in sex rings (Wild & Wynne, 1986). It is said that organized abuse may include formalized rituals (Frude, 1996). There are, in these cases, serious questions about the reliability, verifiability and credibility of the reports (Young, Sachs, Braun et al., 1991). Organized abuse also includes the use of children and young persons for the production of child pornography; this constitutes a more serious problem. Children in residential settings in particular may be subject to sexual abuse. These children, who are already vulnerable, are dependent on staff and often isolated from confiding contact with adults outside the residential setting (Utting et al., 1997).

Abuse by Clergy
Widespread occurrence of sexual abuse by Catholic clergy has come to light over the last few years in a number of countries including the UK, Ireland and the USA. Some of the clergy abused one or two children whereas others had multiple victims. The abuse included pedophilia as well as the abuse of adolescents, of both genders (Haywood, Kravitz, Grossman et al., 1996). This form of sexual abuse arose in an opportunistic setting which brought together potential abusers and potential victims, with clergy’s own possible sexual difficulties linked both with the choice and consequences of enforced celibacy.

Finkelhor (2003) pointed out that this discovery led to a number of consequences to the field of child sexual abuse, some of which can be regarded as positive. It has increased public belief in the existence of child sexual abuse, has reinforced the recognition of the need to enable children to talk about possible abuse and has enabled more children and adolescents to come forward with accounts of their own abuse. It has lessened the stigmatization of sexual abuse for boys. There has also been recognition of the increased need for corporate or organizational responsibility for employees’ behavior.

Ethnicity, Culture and Socioeconomic Status
Both in the UK and the USA, population-based studies have shown no ethnic differences in the rates of child sexual abuse (Fontes, 1995; Kelly, Regan, & Burton, 1991; Korbin, 1997). However, data on ethnic and cultural variations are weak, partly because details on racial and ethnic background are inadequate, and partly because shame and denial about sexual abuse within some cultures conspire against reporting.

Socioeconomic status is unrelated to the incidence of child sexual abuse in population studies (Berliner & Elliott, 1996) but there is an overrepresentation of lower socioeconomic groups in clinic samples (Bentovim, Boston, & van Elburg, 1987). This may be because these groups are more likely to come to the attention of child protective agencies than middle class families, who may find ways of hiding the abuse or avoiding its reporting (Gomes-Schwartz, Horowitz, & Cardarelli, 1990). Different forms of child abuse and neglect are not infrequently found in the same family and the same child (Mullen, Martin, Anderson et al., 1994), especially among the socially disadvantaged. Child sexual abuse is associated with troubled family life including family disruption (Russell, 1986), reconstituted families, intrafamilial violence (Bifulco, Brown, & Adler, 1991) and parents who are perceived as emotionally distant and uncaring (Alexander & Lupfer, 1987).

Risk and Causation, and Maintaining Factors for Child Sexual Abuse
There is no unitary theory of causation to explain child sexual abuse (Glaser & Frosh, 1993). Although it involves an interaction between the abuser and the child, or the perpetrator and the victim, intention and responsibility rest with the abuser. The abuser’s wish for power and sexual gratification are the two main aspects. Sexual arousal to prepubertal children or pedophilia is likely to be a strong motivating force for abusers of prepubertal children.

Finkelhor (1984) has brought together several factors in a systemic model of four preconditions that, he postulates, are necessary for child sexual abuse to occur:
1. Motivation to sexually abuse children;
2. Absence of internal inhibitors;
3. Absence of external inhibitors;
4. Absence of child’s resistance (or a child’s vulnerability).

Preconditions for Potential Abusers
Motivations refer to the abuser’s sexuality and sexual development and include pedophilia, fear and/or avoidance of peer sexual relationships and sadism. They also address interpersonal motivators such as a need to overpower or gain mastery over more vulnerable persons, arising as a result of one’s own past abuse and low self-esteem. It is noteworthy that in a survey of male undergraduates, 5–9% expressed sexual interest in children (Briere & Runz, 1989). This suggests that the predisposition to sexual abuse is far more common than the action, supporting the postulated need for other factors to exist before abuse will actually occur. Some of the motivations for female abusers are discussed by Welldon (1988) who described incestuous mothers as simultaneously attacking and emotionally engulfing or possessing their children.
Absence of internal inhibitors includes the effects of alcohol and stress. It also refers particularly to the cognitive distortions or rationalizations that abusers employ in continuing to perpetrate abuse and which have been studied by those treating sexual abusers. These cognitive distortions include minimization of the harmful effect of the abuse on the child; conceptualizing the abuse as “love” or “education”; and placing responsibility on the child or adolescent, who is described as inviting or requesting the abuse.

**Child Risk Factors**

External inhibitors of sexual abuse include protective family structures and relationships surrounding the child, in particular a secure attachment to primary caregiver(s), good monitoring of the child’s whereabouts and the existence of confiding relationships for the child. Their lack provides a risk for sexual abuse. The child’s vulnerability by virtue of age, disability, neglect or social isolation increases the likelihood of sexual abuse. Indeed, abusers recognize these factors as rendering a child suitable for abuse (Conte, Wolfe, & Smith, 1989). This explanatory schema does not remove the abuser’s responsibility for the abuse, whatever the nature of contributory risk factors.

**Maintaining Factors**

Summit (1983, 1992) used his clinical experience to hypothesize a Child Sexual Abuse Accommodation Syndrome or Pattern to explain how children progressively adjust to sexual abuse by a trusted person, by accommodating psychologically to the inherent contradictions, confusions and enforced secrecy accompanying the experience, and the way in which many children come to disclose sexual abuse. He postulated five stages:

1. Secrecy;
2. Helplessness;
3. Entrapment and accommodation;
4. Delayed, unconvincing disclosure; and
5. Retraction.

This conceptualization carries plausibility in social contexts in which child sexual abuse is a secret and unwitnessed activity, in which children are told not to talk about it and in which they are often not believed (but see chapter 7 for strong reservations). It may constitute a coping strategy, enabling some children to remain asymptomatic during the abuse and leaving the abuse undiscovered. The abuser’s own pattern of denial of the abuse through cognitive distortions lessens his potential discomfort and enables him to continue the abuse. By the time sexual abuse is discovered in childhood, it has usually occurred many times. Not all disclosures are unconvincing and they are not necessarily retracted. Moreover, in some societies, there is now a growing recognition and acceptance of the fact of child sexual abuse. This may counteract the need for psychological accommodation by the child and may be contributing to the decreasing rate of substantiated sexual abuse, by allowing for earlier disclosure.

**Effects of Child Sexual Abuse**

A majority of children who have suffered sexual abuse experience a variety of problems (Beitchman, Zucker, Hood et al., 1991; Kendall-Tackett, Williams, & Finkelhor, 1993), some of which extend into adulthood (Wyatt & Powell, 1988); there is no specific post child sexual abuse syndrome (Kendall-Tackett, Williams, & Finkelhor, 1993; Paolucci, Genuis, & Violato, 2001). Some effects are direct consequences of the sexual experience, such as age-inappropriate sexualized behavior. Others develop as a response to the abusive nature of what happened. The actual effects are shaped by the child’s gender, age, family circumstances, ethnicity and social class. In non-clinical samples, adolescents report higher levels of depression and anxiety than younger children (Gidycz & Koss, 1989), suggesting that with increasing maturity, the adolescent more fully comprehends the implications of having been abused sexually. This is also supported by the finding that distress following child sexual abuse is greater in girls with higher cognitive functioning (Shapiro, Leifer, Martone et al., 1992). This is despite the fact that, in general, higher innate ability and the capacity to understand are considered to be protective factors in overcoming adverse life experiences.

**Effects in Childhood and Adolescence**

Sexual abuse may lead to unwanted pregnancy or sexually transmitted disease. Rarely, it may cause genital injuries. However, less than 50% of children with documented sexual abuse have physical findings (Muram, 1989). Deleterious psychological effects constitute the starting points for suspecting sexual abuse, but often they are recognized only retrospectively, because many are non-specific. About 1 in 3 young people show no outward indicators (Kendall-Tackett, Williams, & Finkelhor, 1993), allowing abuse to be undetected over prolonged periods. This is particularly likely with children compared to adolescents (McLeer, Dixon, Henry et al., 1998). Although most findings derive from clinical samples, studies of non-clinical adolescents also show raised rates of emotional and/or behavioral difficulties (McLeer et al., 1998).

**Sexualized Behavior**

A majority of children include in their activity and play some aspects of exploration of their body and its functions including genitalia, pregnancy, “mummies and daddies” and “doctors and nurses,” peaking at age 5. Friedrich, Fisher, Broughton et al. (1998) developed the Child Sexual Behavior Inventory (CSBI) based on parent reports. Observations of preschool children have also shown that masturbation in preschool children is a part of normal development, many preschool children touch women’s breasts, look at or touch each other’s genitalia and some simulate sexual intercourse while remaining fully clothed (Lindblat, Gustafsson, & Larson, 1995). A significant proportion add genitalia to their figure drawings at some point in their early years. Sexual talk and some
preoccupation with sexual touching can be found within the autism spectrum.

Age-inappropriate sexualized behavior is found significantly more commonly in, although not in most, sexually abused children (Cosentino, Meyer-Bahlburg, Alpert et al., 1995; Friedrich, 1993) and is an important unwanted outcome of child sexual abuse. It refers to genitally orientated and sexual behavior, often involving another child, a doll or sometimes an adult. These inappropriate behaviors include inserting fingers, objects or a penis into the vagina or anus, and oral–genital contact (Lloyd Davies, Glaser, & Kossoff, 2000). It also includes more commonly seen genitally oriented behaviors such as looking at, touching or drawing genitalia or simulating sexual intercourse fully clothed, and when these are repeated they become a preoccupation for the child, or are accompanied by coercion or intimidation of another child in the activity. This troubling behavior is particularly likely to follow abuse at an early age (McClellan, McCurry, Ronnei et al., 1996). In boys, it may be regarded as a way of reasserting their masculinity (Rogers & Terry, 1984). It may also be a form of re-experiencing the abuse as part of a post-traumatic response (Kiser, Ackerman, Brown et al., 1988). It is often intractable, a challenge to treatment (see p. 451) and leads to serious difficulties in finding alternative placements for these children, who are considered to pose a risk to other children and who may become socially excluded as a result. In some children, this behavior comes to be regarded as actual sexual abuse of another child.

Unplanned Pregnancy

In adolescence, there is an association between early pregnancy and a history of sexual abuse (Mullen et al., 1994). This reflects the sexual vulnerability of these girls to sexual abuse, which is expressed in a number of ways including: low self-esteem, which leads to a lowered threshold to, or welcoming of, sexual approaches; a confusion between affectionate approaches and sexual attention towards the girls; and actual behavior that is perceived by others as inviting sexual approaches. A history of child sexual abuse is also frequently found in both boys and girl child prostitutes.

Psychological Sequelae

Despite clinical experience, Tremblay, Herbert, and Piche (1999) among others, have found that a majority of 7- to 12-year-old children who had been sexually abused maintained a relatively high sense of global worth. Post-traumatic stress disorder (PTSD) has been found as a sequel of child sexual abuse, the frequency varying from 44% in an abused group being evaluated for psychiatric disorders and treatment needs (McLeod, Deblinger, Henry et al., 1992) to 71% in a clinical symptomatic sample (Trowell, Ugarte, Kolvin et al., 1999). Depression is found more commonly among sexually abused than non-abused children (Wozencraft, Wagner, & Pellegrin, 1991). Whereas depression is found in all age groups, suicidal ideation and self-injurious behavior are mainly confined to adolescence (Lanktree, Briere, & Zaidi, 1991), where they are found to be associated significantly with a history of child sexual abuse in boys (Oates, 2004). Anxiety is encountered in both sexually abused boys and girls, and in both clinical and non-clinically referred children post abuse.

Children with a history of sexual abuse have subsequently been found to show more bulimic symptoms and a significant proportion of children with eating disorders report a history of child sexual abuse. This more commonly takes the form of bulimia (binging and purging) than the more calorie restrictive form of anorexia nervosa (Carter, Bewell, Blackmore et al., 2006). Aggression and disruptive behavior may also follow sexual abuse (Kendall-Tackett, Williams, & Finkelhor, 1993). Difficulties with peer relationships may arise due to sexualized behavior, low self-esteem, shame and lack of trust (Mannarino, Cohen, & Berman, 1994). Running away, substance abuse usage and involvement in prostitution are found in boy and girl adolescents following sexual abuse.

Patterns and Continuities

Charting the “natural history” of sexual abuse-related symptomatology is difficult, because prognosis depends not only on the child’s coping and adaptation (Friedrich, Beilke, & Urquiza, 1988), but also on the nature of the response that the child encounters. This includes treatment which, if successful, will modify outcomes. Moreover, some difficulties are related to age and developmental stage so that new difficulties may arise with maturation. Some children become more symptomatic than when initially seen (Kendall-Tackett, Williams, & Finkelhor, 1993). Some symptoms resolve more rapidly than others; dissociation, post-traumatic phenomena and sexualized behavior all attenuate only slowly (Beitchman et al., 1991), even with treatment (Lanktree & Briere, 1995). Improvement in family functioning, particularly in the domain of problem-solving, correlates with improvement in children’s behavior while maternal coping through avoidance strategies correlates with deterioration in behavior (Oates, O’Toole, Lynch et al., 1994). If the abuser is a close family member, and especially if he is denying the fact of the abuse, the family will be more troubled. Whereas there is an overall trend towards improvement in children’s functioning, the path is neither smooth nor is its direction straight or entirely predictable. There has been little systematic study of the effects of child sexual abuse on people with learning disability. Findings suggest that the effects are similar to those in the general population (Sequeira & Hollins, 2003).

Effects in Adulthood

Studies of male and female adult survivors of child sexual abuse show a clear pattern of interpersonal and intrapsychic difficulties (Nelson, Heath, Madden et al., 2002) although this does not constitute a syndrome (Fontes, 1995; Stein, Golding, Siegel et al., 1988). A longitudinal study of a birth cohort of more than 1000 children in New Zealand has shown a significant association between childhood sexual abuse in both boys and girls and psychiatric disorders in young adulthood, which held when possible confounding variables were allowed for (Fergusson, Horwood, & Lysaker, 1996).
The most commonly reported symptom is depression; deliberate self-harm is significantly higher in women abused in childhood than in non-abused women (e.g., 16% versus 6%) even in community samples (Saunders, Villeponeaux, Lipovsky et al., 1992). Anxiety is also reported but less commonly. Drug and alcohol abuse are important long-term sequelae (Mullen, Martin, Anderson et al., 1993), found more commonly in men survivors (Stein et al., 1988). An adult female twin study has concluded that the significant association found between a history of child sexual abuse and major depression, anxiety, drug and alcohol abuse is a causal and direct one, rather than being confounded by genetic factors or mediated by common environmental factors (Kendler, Bulik, Silberg et al., 2000).

A history of child sexual abuse has been found significantly more often in adults with PTSD, dissociation and psychotic symptoms, including hallucinations and delusions, particularly as part of a diagnosis of schizophrenia (Read, van Os, Morrison et al., 2005; see also chapter 42). With respect to the claimed specific risk for schizophrenia see Morgan and Fisher (2007) for a balanced critique. A dose effect appears to operate, relating the severity of adult psychopathology to the severity of the child sexual abuse.

Mullen et al. (1994) have also found difficulties in the sexual functioning and intimate interpersonal relationships, and distrust of men in women who had been abused, and all the deleterious effects were exacerbated by abuse that had included intercourse. Less disturbance of sexual functioning has been found in men survivors (Stein et al., 1988). Only a minority of homosexual men has been sexually abused in childhood, and they have no greater sexual interest in children than heterosexual men.

One study that tested the validity of Finkelhor and Browne’s traumagenic model (see p. 448) in a sample of 192 adult women survivors, found that stigma and self-blame, but not betrayal and powerlessness, mediated the effects of sexual abuse on adult psychological functioning (Coffey, Leitenberg, Henning et al., 1996). Some of these difficulties, including low self-esteem, impact on the parenting functions of adult survivors and contribute to the explanation of intergenerational continuities of child abuse. Continuing low self-esteem is also reflected in higher rates of unskilled or semiskilled work among women sexually abused in childhood (Mullen et al., 1994). Eating disorders have been reported as occurring more commonly in women survivors of childhood sexual abuse (Mullen et al., 1993).

### Factors Contributing to the Effects of Sexual Abuse

Tremblay, Herbert, & Piche (1999) found that abuse variables, parental support and the child’s coping strategies contributed independently to the psychological outcome for a group of 50, 7- to 12-year-old children. Pre-abuse circumstances, child characteristics and post-abuse responses were also relevant.

### Abuse Variables

Abuse variables include the nature, duration and severity of the abuse, and the relationship between the abuser and the child. Abuse factors that are associated with more severe psychological sequelae include prolonged duration and greater frequency of abuse (Caffaro-Rouget, Lang, & van Santen, 1989), penetration of mouth, anus or vagina and abuse accompanied by threats or force (Gomes-Schwartz, Horowitz, & Cardarelli, 1990).

Closeness in the relationship between the abuser and the child adversely affects prognosis. Clinical impression suggests a worse prognosis when there have been several abusers, although empirical findings are equivocal on this point (Kendall-Tackett, Williams, & Finkelhor, 1993). Abuse by mothers of their boy neonates (e.g., by sucking their penises) has shown a powerful sexualizing effect on the boys at a very young age (Chasnoff, Burns, Schnoll et al., 1986). There are few available data about the specific effects on girls of abuse by women.

### Child Variables

There is no consistent difference in the magnitude or severity of response between boys and girls. Contrary to expectations, there is no conclusive empirical evidence indicating that boys who have been sexually abused show more disruptive behavior than girls. However, boys experience more anxiety about becoming homosexual or about latent homosexuality within them that, they sometimes believe, had been detected by the abuser (Watkins & Bentovim, 1992). The evidence on effects of age at onset of abuse is inconclusive when studied independently of duration of abuse. However, many studies indicate that older children are more symptomatic at the time of presentation. Early sexual abuse, before the age of 7 years, appears to be a risk factor for later inappropriate sexualized behavior (Mian, Marton, & LeBaron, 1996).

Interestingly, the child’s coping strategies and cognitive evaluation of the abusive experiences have been shown to contribute less to the child’s later functioning than severity of the abuse and the support of the non-abusing carer (Spaccarelli & Kim, 1995). On the other hand, Bal, Van Oost, De Bourdeaudhuij et al. (2003) suggest that for adolescents, avoidant coping strategies following sexual abuse are associated with more distress.

### Pre-abuse and Family Circumstances

The child’s family and the nature of caregiving experienced by the child influence the outcome for the child (Waterman, Kelly, McCord et al., 1993). Pre-existing adverse family relationships and circumstances may have increased the child’s prior vulnerability to abuse as well as contributing to the adverse impact of the abuse on the child (Conte & Schuerman, 1988). This includes neglect of supervision; lack of provision for basic needs, which renders the child more vulnerable to predatory abusers; the formation of insecure attachments by the child, which lessens the likelihood of the child talking about worrying experiences such as sexual abuse; and social isolation. In some cases, sexual abuse can be regarded as a marker for other
CHAPTER 29

detrimental factors in the family which in themselves contribute significantly to later psychopathology (Mullen et al., 1993; Mullen, Martin, Anderson et al., 1996).

Post-abuse Response
The post-abuse response includes the investigation, the response of the non-abusing caregiver(s) and the abuser, as well as protective steps taken to ensure the child’s future safety. Denial of the allegation by the alleged abuser naturally leads to a stringent testing and even discrediting of the child’s verbal descriptions (Summit, 1992). Child protective steps, which may include removing the child from their home, are often necessary because of the denial of the abuse by the abuser (Glaser, 1991).

Many mothers remain supportive of their child following discovery of sexual abuse (Sirles & Franke, 1989). The non-abusing carer’s belief, support and active protection of the child are significant determinants of a good outcome for the child regardless of the nature of the sexual abuse (e.g., Everson, Hunter, Runyan et al., 1989). Conversely, the mother’s emotional distress adversely affects outcome for the child (Cohen & Mannarino, 1998). This points to the need to ensure that at the time of discovery of sexual abuse, help and support are directed at the non-abusing caregiver(s) who are often faced with a conflict of interests, between the abuser and the child. The closer the relationship between the abuser and the non-abusing caregiver, the less supported will the child be by the mother (Elliot & Briere, 1994).

Belief in the child’s account of abuse is the first step towards support for the child. It is not, however, synonymous with consistent protection of the child; this requires the primary carer(s) to distance themselves and the child from the abuser, both emotionally and physically. This is particularly difficult when the abuser is the mother’s partner (Heriot, 1996).

Model for the Effects of Child Sexual Abuse
Finkelhor and Browne (1985) developed a model to explain the effects of child sexual abuse. This eclectic and comprehensive model reflects the complexity, and consequently the heterogeneous nature of the effects of child sexual abuse. It comprises traumatic sexualization, betrayal, stigmatization and powerlessness.

**Traumatic sexualization** refers to the abuse experience and combines the trauma and the developmentally inappropriate sexual aspects of the abuse. Finkelhor (1988) postulated that the process of the abuse fetishizes children’s genitalia in a developmentally inappropriate way, rewards children for, and confuses children about the meaning and involvement of their sexual behavior, and leads to an association of sexuality with trauma. These aspects are considered to be unique to child sexual abuse.

**A sense of betrayal** refers to aspects of the child–abuser and child–caregiver relationships. It reflects the fact that abusers have usually been trusted by the child, either inherently by the nature of the relationship, or by the relationship that has been created by the abuser, sometimes deliberately, prior to the abuse. The sense of betrayal also extends to the experience of not being believed by their non-abusing caregivers, especially mothers (Herman, 1981). Young children, who believe in the power of their parents to protect them from harm, lose this sense of safety and protection when they become abused.

**Stigmatization** concerns the child’s emotional response and self-view. It includes the sense of shame, blame and guilt and worthlessness which are both communicated to the child in the process of the abuse and by the way sexual abuse is regarded. Children often seek to “explain” why they were targeted and ascribe self-denigrating meanings. Boys sometimes believe that they must have been recognized as homosexual in order to have been “chosen.” Many girls express feelings of having become “spoilt goods” (Rogers & Terry, 1984).

**Powerlessness** refers to the child’s experience of threat or overwhelming fear sometimes associated with sexual abuse and the origin of post-traumatic stress responses. Less traumatically, it also encompasses the child’s experience of being overruled and their body invaded and spoiled.

Shapiro (1989) discussed a reciprocal relationship between self-blame and helplessness or powerlessness in sexually abused children. If the child’s perception of helplessness is confined to the abuse situation, this may mitigate against self-blame for the abuse. Conversely, if the child blames themself, this may help to overcome the perception of themself as powerless.

Role of Child and Adolescent Mental Health Services in Child Sexual Abuse
Child sexual abuse is sometimes part of the referral presentations and sometimes its occurrence is discovered incidentally during assessment or treatment. Also, some troubled parents will have been sexually abused in childhood. The possibility of abuse in family members therefore always needs to be considered; familiarity with its effects as well as with its investigation, and with protection and legal aspects, is important. Sexual abuse needs to be considered especially in children showing age-inappropriate sexualized behavior and in depressed or suicidal adolescents. At times, an unsolicited disclosure is made by a child during therapeutic work. Child psychologists, psychiatrists and psychotherapists may contribute to investigations of child sexual abuse, particularly in assessment interviews of young or very traumatized children, or in children with communication difficulties. Consultation to social services in case management and to carers of children who have been sexually abused is often requested. A particular role is the provision of individually appropriate treatment for abused children and their families.
Child sexual abuse may also call for forensic work. This includes assessments for Children Act, 1989 proceedings, providing expert reports and oral evidence (Wall, 2000). Comments are usually requested on the presence or absence of Significant Harm and on the nature of the Care Plan, which includes the future care and residence of the child, contact with family members including the abuser, and the child’s and family’s therapeutic needs. Risk assessments on adolescent abusers may also be required. In the UK, children who have been sexually abused are eligible for Criminal Injury Compensation Authority awards, and child mental health professionals may be requested to provide reports about the nature and extent of the harm to the child and their treatment needs.

Initial Professional Encounters With Child Sexual Abuse – Suspicion, Recognition, Investigation, Validation and Protection

Principles
Whenever sexual abuse is suspected or presented explicitly to a professional, including child mental health practitioners, multidisciplinary professional involvement follows inevitably. Its broad aims are to ascertain what, if anything, has happened to the child and to gain an understanding of the child’s development and family context and needs. If the child has been abused, the child’s needs will include:

1. The immediate and long-term protection of the child from sexual abuse.
2. The amelioration of the effects of the abuse including:
   (i) reduction of distress and the resolution of internal conflicts for the child;
   (ii) resolution of interpersonal conflicts surrounding the child;
   (iii) treating physical consequences of the abuse.
3. Ensuring optimal development for the child following cessation of abuse.

Although these aims are clear, their achievement in practice is fraught with difficulties. Suspicions need to be verified and a child’s account tested, because protection comes at a cost and therapy can only follow protection. Because there are rarely witnesses to the abuse, establishing whether it has occurred will rest heavily on the child’s verbal description, which may be retracted even if it was true. Discovery of abuse is often accompanied by denial by the alleged abuser, and some doubt or disbelief, and usually constitutes a crisis for the family and a challenge to the professional system. The child’s ultimate well-being will, to a significant extent, be determined by the support given by the family. The nature of the early intervention by professionals and their consideration of the position and needs of the mother or non-abusing caregivers will have long-lasting effects on the child’s and the family’s subsequent expectations and attitudes towards professionals with whom they may need to continue to work (Sharland, Seal, Croucher et al., 1996).

In some countries, including the UK, the responsibility for child protection rests with social services to whom suspicions of, or actual abuse are reported. The subsequent multidisciplinary and multiagency process involves, in addition, the police, health and education and the courts. In other countries, the responsibility for child protection remains with the courts. A number of well-established steps in the process have been identified (Department for Education and Skills, 2006), each step depending on the outcome of the previous one:

1. Suspicion or recognition leading to referral to (child protection) social services.
2. Establishing whether there is a need for immediate protection.
3. Planning the investigation, including:
   - interagency discussion;
   - interviewing the child;
   - medical examination of the child;
   - initial assessment of the family.
4. Validation and initial child protection meeting (conference).
5. Protection plan and a more comprehensive assessment.
7. Prosecution.
8. Therapy.

Different combinations of agencies are involved in the many stages.

Suspicion, Recognition and Disclosure
Suspicion is based on one or more indicators, both specific and non-specific (Glaser & Frosh, 1993). Specific indicators include: inappropriate sexualized behavior (see p. 445), genital physical signs (Hobbs & Wynne, 1989) including sexually transmitted diseases, and pregnancy in a young girl or when the identity of the father is unclear, running away and deliberate self-harm in adolescence, sexual abuse of other children in the family, and known contact with a sexual abuser. Non-specific indicators include a variety of behavioral, emotional and educational difficulties. Sexual abuse needs to be considered especially when there is a sudden onset of difficulties in a previously untroubled child and when no other obvious explanations are available. These difficulties include inability to sustain attention, deterioration in educational progress, social isolation or aggressiveness, indicators of low self-esteem, marked unhappiness or depression, disturbed sleep and nightmares, fearfulness and separation anxiety, and eating disorders.

In child and adolescent psychiatric practice, it is important to consider the possibility of sexual abuse as one explanation for those difficulties that are recognized as effects of sexual abuse. This includes, for instance, sexualized behavior and talk for which a source of exposure needs to be sought. Rather than an initial direct enquiry about sexual abuse, it is preferable to enquire about upsetting and unwanted experiences and previous contact with social services. With adolescents, a direct enquiry could be made, especially following deliberate self-harm. Careful notes should be made of such assessment interviews (Jones, Hopkins, Godfrey et al., 1993) and it is
always advisable to discuss one’s concerns and suspicions with a colleague. It is also possible to request an “anonymous consultation” with a social worker, in which the child’s identity is not divulged. As a result of such assessments, sexual abuse may come to light that may or may not already be known about by child protection agencies. If it is a new disclosure, the child needs to be listened to, avoiding interruptions and questions and the conversation needs to be carefully recorded in writing. Talking about an event enables a child to organize the experience in a more coherent way and enhances the laying down of a more coherent account and memory of the experience (Haden, Haine, & Fivush, 1997). Although the fact of a conversation will distort the memory to some extent, talking improves the later capacity to recall an experience as well as to make sense of it, especially when the experience is stressful or traumatic (Goodman & Quas, 1997).

Although in the UK, unlike in the USA, there is no mandatory reporting of seriously suspected or actual sexual abuse, it is considered to be good professional practice to report serious suspicions or disclosures to child protective or social services (Department for Education and Skills, 2006). This overrides the usual rules of confidentiality. A child may not wish for their disclosure to be divulged to another agency. When it is not possible to accede to the child’s wishes, the child’s misgivings need to be explored, the reasons given for the need to report the abuse, and the child needs to be involved in the process of notifying social services. Referral is usually made with the knowledge of the family, unless there are indicators that this will place the child at increased risk, including pressure on the child to retract an allegation. Abuse more usually comes to light when a child talks about it to a relative, friend or teacher (Bradley & Wood, 1996). Children who spontaneously describe sexual abuse and who make an intentional disclosure are likely to be accurate in their account.

The need for immediate protection is a decision of social services in consultation with other professionals and agencies and might require an emergency protection order in respect of the child (Children Act, 1989).

Investigation and Formal Interview

The next step in the investigative and protection process is a professionals (or strategy) meeting, which is convened by the statutory agencies – police and social services. It will also include any professionals with immediate relevant knowledge about the concerns and about the child and the family, including a professional to whom an allegation or disclosure has been made. This could therefore be a child psychiatrist or other mental health professional. The purpose of the strategy discussion is to plan the investigation, the approach to the family, the formal interview with the child and the medical examination (Heger & Emans, 2000). Children will be interviewed formally if there are clear suspicions of abuse or if the child has already disclosed the abuse informally. Both clinical experience and empirical evidence (Keary & Fitzpatrick, 1994) show that children (especially younger ones) will not usually describe sexual abuse during a formal interview, unless they have previously spoken about it. (However, the converse is not true.) Submitting a child who has not yet actually disclosed abuse to a formal interview may not yield a description of abuse which may, nevertheless, have occurred.

The formal interview is video recorded and may be used both as prosecution evidence in a subsequent criminal trial, and in civil child protection legal proceedings. It is therefore carried out by police and social services according to strictly specified guidelines. Rarely, children are encountered whose distressed or traumatized mental state, or whose difficulties in communication, indicate the need for the interviewing skills of a child mental health professional. Some people have used facilitated communication with autistic children who are suspected of having been abused, but systematic studies have made it clear that what is communicated usually does not derive from the child (Howlin & Jones, 1996). This is an unsafe procedure.

In chapter 7 Bruck, Ceci, Kulkovsky et al. discuss what is known about children’s memory and their reliability as witnesses. Among many other factors not associated with memory but which may, nevertheless, be misinterpreted as poor recall is the extent to which the child is motivated to talk about past events. The child may well continue to be cared for by, or be in close contact with an abuser, and may therefore consider disclosure of the abuse to be a betrayal of the abuser. Silence may be one way of dealing with this dilemma (Freyd, 1996). Children who are interviewed some time after the abuse and who may be suffering from PTSD may find difficulty in talking about the abuse.

The child’s responses are by no means related only to the strength of memories or the power of recall. As well as challenging the child’s capacity to recall, the child’s truthfulness, clarity of thought as opposed to confusion and the child’s capacity to withstand misleading suggestions are all often questioned. There is now much research evidence to show that the circumstances in which the child’s account is sought and obtained, and the power differential in the relationship between the interviewer and the child, have a significant bearing on the child’s “performance” (for a review see Lamb, Sternberg, Esplin et al., 1997). Interviewing styles and forms of questioning are capable of significantly distorting children’s accounts which do not then reflect what the child had previously recalled. For instance, when the rapport-building stage of the interview consists of open questions, children’s response to the first, open question regarding a past experience yields 2.5 times more details and words than following a closed question. Moreover, this initial pattern continues in response to open questions throughout the interview. Repeated occasions per se, in which the child is simply invited to describe past experiences, without pressure or suggestion, do not compromise accuracy of recall (Fivush & Schwarzmueller, 1995) but there are concerns regarding repeated interviews (see chapter 7). By contrast, closed questions requiring a forced choice, yes or no answers (and not infrequently used by advocates in court) yield far less accurate information. However, in order to obtain optimal information and verify certain facts,
closed questions can be alternated with open ones. There are now evidence-based guidelines for obtaining information which is optimal in terms of accuracy and amount of detail (Hershkowitz, Horowitz, Lamb et al., 2004; Orbach, Hershkowitz, Lamb et al., 2000).

There has been much debate about the use of anatomically correct dolls in interviewing of children. There is little evidence that young non-abused children proceed beyond exploration of the dolls’ genitalia to enact sexualized behavior (Glaser & Collins, 1989). Nevertheless, the dolls should not be used as a screening tool (Boat & Everson, 1994) or cue (Everson & Boat, 1994), but rather to enable young children to illustrate what they have conveyed verbally.

Validation
Validation of child sexual abuse requires assessment of the evolution of suspicions, and the circumstances as well as the content of the child’s first description or disclosure of abuse. The outcome of a formal interview and the findings in a medical examination receive obvious scrutiny, particularly in legal proceedings, both civil and criminal. Other factors include family circumstances; the child’s relationship with the alleged abuser; and the responses to the allegation by the mother or the non-abusing caregivers, and by the alleged abuser. In a retrospective review of 551 case notes of reported concerns about possible child sexual abuse, 43% were substantiated, 21% were inconclusive and 34% were not considered to be abuse cases. Only 2.5% were erroneous concerns emanating from children, and included only eight (1.5%) of false allegations originating from the child, and three made in collusion with a parent (Oates, Jones, Denson et al., 2000). In other studies, false allegations are found to be most commonly made by a parent in the context of contact or residence disputes between warring parents, or rarely under the influence of a parent in the context of interparental disputes (Faller, 2005).

The Nature of Protection
A child who is believed to have been abused is deemed to be protected providing all contact with the alleged abuser is either fully supervised or stopped. A child can only be protected in a context in which there is belief in the child’s allegations, without explicit blame of the child and where there is a commitment by the child’s non-abusing caregiver to protect the child. Children abused by persons outside the family tend to be excluded from child protective services on the, sometimes erroneous (Tebbutt, Swanston, Oates et al., 1997), assumption that they will be protected by their families. If protection is achieved, and if no legal proceedings ensue, there may never be a formal record of the validated fact of the abuse.

Child Protection Conference and Planning
A multidisciplinary child protection conference is convened if there is a reasonable likelihood that a child has been abused and remains unprotected. The purpose of a conference is to determine, on the basis of information gathered, whether the child continues to be at risk of Significant Harm and, if so, the nature of the protection plan that will ensure the child’s safety. This plan will include a comprehensive assessment of the child’s and the family’s needs and commencement of therapeutic work, to both of which child mental health services are often required to contribute.

Legal Proceedings
There are both civil and criminal proceedings in which the question of child sexual abuse is at issue (see chapter 8). Civil proceedings concern the future safety of the child. In England under the Children Act (1989) the child’s welfare is paramount. The child does not attend court or give evidence; hearsay and expert evidence are allowed. Civil proceedings include:

1. Public law care proceedings in which Significant Harm is determined and a finding may be made about sexual abuse having occurred. The court may grant an order (care or supervision) to ensure the child’s well-being and a care plan is required, for which the local authority is responsible.

2. Private law family proceedings in which residence and contact disputes between parents are sometimes based on allegations of sexual abuse of the child while in the care of one of the parents.

In criminal proceedings, the child is an accessory to the court process, whose interest is the determination of the guilt or innocence of the alleged abuser. Unless the alleged abuser pleads guilty, both the child’s account of the abuse (which may have previously been video recorded) and cross-examination of the child are required. Expert evidence and opinion regarding the child’s credibility is not permitted in English courts, that being an issue for the jury and the judge to decide.

Therapeutic Work
A systematic treatment approach to the effects of child sexual abuse requires consideration of the child’s needs, both individually and in the context of the family, but no single programmatic universal treatment is appropriate. Each case needs individual consideration. A starting point is consideration of the individual needs of, and relationships between the three participants in the “abuse triangle” – the abuser, the child and the non-abusive caregiver (Glaser, 1991).

The fulfillment of the child’s and family members’ needs often requires social work support as well as more formal psychological therapy and psychiatric treatment. An integrated multi-disciplinary and multiagency approach is required (Furniss, 1991) in which therapy both deals with needs as they arise and according to their severity, and is offered at appropriate points in the post-abuse process (Jones, 1996). For instance, it is not appropriate for a child to receive group or individual therapy for the effects of the abuse while the child remains unprotected; children in transition from one family to a new permanent home are often more preoccupied with their impermanence and their family’s response than with the
CHAPTER 29

sexual abuse; it may be inadvisable for a child to join a therapeutic group before testifying in impending criminal proceedings; therapy might need to await the outcome of criminal proceedings if a child has retracted allegations and the alleged abuser denies the abuse. Furthermore, work with the child is most beneficial when undertaken in parallel with work with the parent(s) or carers and family (Monck, Bentovim, Goodall et al., 1996). Some of the child’s needs can only be addressed by work with the non-abusing carers alone or with the child and mother/patents together (Celano, Hazard, Webb et al., 1996). For other difficulties, it is appropriate to work with the child alone or in a peer-group setting.

Children’s Therapeutic Needs

Not all children who have been sexually abused require prolonged or even systematic therapy. However, as a minimum requirement it is important to ascertain that the child is able to talk about their experiences to a parent or other identified person, who believes the child and is able to listen to the child supportively and uncritically. Coping by avoidance, which includes not talking about the abuse, is a predisposing factor for the later development of PTSD (Kaplow, Dodge, Amaya-Jackson et al., 2005). Children who have been sexually abused also require age-appropriate education about sexuality and the nature and risks of sexual abuse. Many children are symptomatic and therefore require treatment. Whereas some symptoms such as sexualized behavior are readily apparent, others such as PTSD or depression may need to be actively sought. Specific instruments such as the Children’s Impact of Traumatic Events Scale – Revised (CITES-R; Wolfe, Gentile, Michienzi et al., 1991), the Trauma Symptom Checklist for Children (Briere, Johnson, Bissada et al., 2001) and measures of depression such as the Childhood Depression Inventory (Kovacs, 1983) are of particular help. It is important to include children who have been abused by strangers or by someone outside the family (Grosz, Kempe, & Kelly, 2000; Van Scoyk, Gray, & Jones, 1988), whose therapeutic needs may be overlooked when protection from reabuse is not considered to be an issue (Sharland et al., 1996).

Overall, treatments that are directed at specific difficulties have been shown to be more effective than no treatment (Finkelhor & Berliner, 1995), or the mere passage of time (Deblinger & Helfin, 1996), and length of treatment has been found to be predictive of outcome for depression (Lanktree & Briere, 1995). There are some findings of no effect (Oates et al., 1994; Tebbutt et al., 1997) or some deterioration for a minority of children during therapy (Jones & Ramchandani, 1999). It is not clear what the relative contribution of intercurrent developments in the child’s life or the therapy itself made to the reported deterioration. In the light of the mostly positive outcome for therapy, it would not be appropriate to withhold treatment from symptomatic children. However, these findings point to the importance of monitoring the child’s psychological state during treatment and a preparedness to halt therapy if necessary.

There are several ways by which treatment approaches for children can be categorized. Children may be treated individually or in groups; treatment may be directed at specific symptoms; and specific therapeutic approaches such as psychodynamic or cognitive–behavioral therapy (CBT) (Deblinger & Helfin, 1996) may be selected.

Group and Individual Therapy

The shared membership of a group offers an alternative to the secretiveness, isolation and shame experienced by most sexually abused children; this may explain findings from a small sample of children who expressed a preference for group over individual therapy (Prior, Lynch, & Glaser, 1994). The group setting is appropriate for learning about sexuality and for developing a socially appropriate “story” about one’s own abuse. The observation of children in groups enables professionals to assess children’s further therapeutic needs, which may include longer-term individual psychotherapy.

It is preferable for a group to have more than one child with a particular attribute such as minority ethnicity, abuse by a stranger or living away from home. Groups for children aged over 7 are more appropriately offered separately for boys and girls, and broadly age-banded (Nelki & Watters, 1989). Groups require two therapists of whom one should be a woman. Groups for pre-adolescent children are usually activity-based and follow a program that addresses issues commonly encountered by children who have been abused. These include a range of distressing feelings such as shame, guilt, anger and low self-esteem; sexuality; confiding and secrets (Berliner, 1997). Adolescents are able to use groups for a more reflective exploration of their feelings (Furniss, Bingley-Miller, & Van Elburg, 1988).

Children’s attendance in therapy, whether group or individual, is dependent on their parents’ psychological and physical support. The provision of support or therapy for the accompanying parent or carer in conjunction with the child’s therapy is therefore useful in addressing both emotional and practical issues of the parents (Damon & Waterman, 1986). This can be offered individually or in a group. It also enables the parents to remain involved in, and informed about relevant aspects of the child’s therapy, in order to support that process (Rushton & Miles, 2000).

Whereas groups are widely used and their process well documented (e.g., Berman, 1990), a review of published outcome studies of therapy for sexually abused children (Jones & Ramchandani, 1999) found overall little difference in effect between group and individual treatments in improving children’s symptoms. In one of the studies reviewed (Trowell, Kolvin, Weeramanthri et al., 2002), the outcome for very troubled girls randomly assigned to individual psychodynamic psychotherapy or group therapy showed significant improvement in a number of symptoms including depression and PTSD of a comparable extent at 1 and 2 year follow-up after both forms of therapy. The only significant difference was a greater decrease in PTSD re-experiencing of trauma, and persistent avoidance of stimuli dimensions, for girls receiving individual therapy.
Specific Symptoms: Sexualized Behavior, PTSD, Anxiety and Depression

Sexualized behavior (e.g., Trowell et al., 1999) and PTSD have been found to be particularly difficult to alleviate. However, CBT directed at particular difficulties has now been shown in a number of randomized treatment studies to be significantly more efficacious than non-directive supportive therapy in improving outcome for sexually abused children. This has included a significant decrease in sexualized behavior (Cohen & Mannarino, 1997), where the effects of therapy have been shown to be enduring for at least a year after completion of treatment (Cohen, Mannarino, & Knudsen, 2005), anxiety and depression. CBT offered to the mother as well as to the child is overall more beneficial and including the family in the CBT has been shown to decrease anxiety in sexually abused children (King, Tonge, Mullen et al., 2000).

An extension of CBT has been shown to be very effective in treating PTSD (Cohen, Mannarino, & Deblinger, 2006). This programmatic, trauma-focused work involves the child and parent. It includes psychoeducation, parenting skills and relaxation for the child. It moves on to recognition of feelings and learning to master and modulate affect, followed by cognitive coping. A narrative about the trauma is then created and leads to the beginning of reprocessing of the traumatic experience, while correcting inaccurate recollections and unhelpful cognitions, and mastering traumatic reminders.

Therapeutic Work with Caregivers and Family

Mothers and Non-abusing Caregivers

The mental health of the non-abusing mother or caregiver, as well as her belief in and support of the child are important factors determining the outcome for a sexually abused child. In the absence of parental support, children may not remain living with their biological family, because of both blame and lack of protection. There are many obstacles to maternal or paternal support following the discovery of abuse, which are amenable to change through specific therapeutic work, either individually or in a group. The obstacles include the nature of the relationship between the carer and the abuser and the need for an imposed distance or termination of that relationship; the mother’s or carer’s guilt about not protecting the child; anger towards the child; and memories of some mothers’ own abuse. The discovery of sexual abuse and its aftermath also offer opportunities for helping parents with parenting issues (Celano et al., 1996).

Siblings and the Family

Siblings are sometimes the silent witnesses of abuse and their needs and feelings may be overlooked in the process of attending to the sexually abused child and the mother. Meetings with the whole family can redress this balance, also enabling the family to talk openly about the fact of the abuse, whose mention is often avoided despite the fact that family members are acutely aware of it. However, family meetings would not include the abuser unless they have taken responsibility for the abuse and are receiving treatment. Family work is important when there is indication of blaming or scapegoating of the abused child. Other dysfunctional aspects of family interactions that are associated with child sexual abuse include, in particular, inappropriate intergenerational boundaries, disorganization, parental neglect and unavailability (Bentovim, 1992; Madonna, Van Scoyk, & Jones, 1991). They require more formal family therapy (Elton, 1988).

Work with Abusers

Child and Adolescent Abusers

The treatment of child and adolescent abusers is important in order to prevent progression of abuse into adulthood. The prognosis may be more encouraging than with adult abusers because the adolescent may be less defensive and at a developmental stage when he or she is emotionally vulnerable and responsive to change. Moreover, the child protective and youth justice systems can be instrumental in encouraging attendance at therapy. A particularly important factor is the support, by the young abuser’s parents, for the adolescent to own up to the abuse. Without this, it is difficult to offer therapy. Because of the heterogeneous nature of maladaptive cognitions found in adolescent abusers, a number of issues will need addressing in therapy. An approach is required that encompasses both the young abuser’s responsibility for the abuse and his likely past emotional, physical or sexual victimization. The indicated therapeutic approach for the abusive behavior is CBT (Kolko, Noel, Thomas et al., 2004), which may be offered individually (Woods, 1997) or in groups (Smets & Cebula, 1987). Using activities as well as words, a group can offer peer support, challenging denial and minimizing of the abuse and responsibility for it, sex education, development of social skills, victim awareness, recognition of cognitive distortions concerning the abuse, mapping the abuse cycle (Hawkes, 1999) and learning to halt its progression.

Adult Abusers

The issue of treatment for adult abusers is important for those children who are closely related to their abuser and who wish to resume a meaningful relationship with them. Central to treatment, often carried out in group settings, is reduction of denial by the abuser (Salter, 1988). Initial denial of their involvement is encountered in the majority of abusers. There is commonly also denial of the extent of the abuse, responsibility for the abuse, the harm caused to the child or the inappropriate nature of the sexual contact. CBT has been shown to reduce recidivism in sex offenders (Hanson, Gordon, Harris et al., 2002). Therapy needs to recognize the emotional comfort that denial offers and to acknowledge the cost of assuming responsibility. A metaanalysis of treatment for sex offenders has shown significant reductions in recidivism using CBT (Hanson et al., 2002). The issues described above in adolescent abuser groups also apply to adult abusers. Common to both is the recognition that the risk for returning to child sexual abuse remains a possibility.
CHAPTER 29

Conclusions

Child sexual abuse is a discrete, definable and often repeated event that is embedded in a complex web of contextual factors, both historical and relational. Its antecedents and consequences are manifold and not necessarily specific. For these reasons, specific prevention is particularly difficult and alertness to the possibility and early recognition offer the best hope for damage limitation. Children cannot be relied upon to protect themselves. Secrecy, denial and disbelief are integrally related to sexual abuse and exert a very significant influence on the professional response and outcome for the children and their families.

CHAPTER 29

At one time, major mental disorders were subdivided into those that were “organic” and those that were “functional.” This subdivision has been dropped from official classifications because of the evidence that the supposedly “functional” disorders (e.g., schizophrenia) involved major neural dysfunction (see chapter 45). The same applies to neurodevelopmental disorders such as specific language impairment (SLI), dyslexia, autism and attention deficit/hyperactivity disorder (ADHD; see chapter 3). Moreover, empirical findings also showed that disorders that involve a strong environmental influence (such as post-traumatic stress disorder [PTSD], see chapter 42; stress reactions, see chapter 26; or attachment disorders, see chapter 55) included neural effects. The old fashioned dichotomy between brain and mind provides a most misleading simplification (see chapter 12). Nevertheless, there are conditions in which the brain dysfunction effects on psychopathology are more obviously direct (Harris, 1998a,b). It is these disorders that are discussed in this chapter – taking as exemplars acute confusional states (delirium or acute organic reactions), degenerative disorders and fetal alcohol syndrome (FAS), together with the psychopathological effects of cerebral palsy, epilepsy and head injury. Before considering these in turn, it is necessary to discuss the epidemiological evidence on the possible role of brain disorders, considered as a group, in the causation of psychiatric disorders in childhood and adolescence. The psychopathology associated with medical disorders resulting from a chromosomal anomaly or a Mendelian condition is discussed in chapter 24 and will not be dealt with here.

**Psychopathology in Young People with Overt Brain Disorders**

The first solid epidemiological evidence was provided by the Isle of Wight neuropsychiatric study, which involved total population coverage (Rutter, Graham, & Yule, 1970a). The rates of psychiatric disorder were compared across four groups: 1 those without any form of physical disability (of whom 7% had a psychiatric disorder); 2 those with a physical disability not involving the brain (rate of 12%); 3 those with uncomplicated epilepsy (rate of 29%); and 4 those with cerebral palsy or some other form of structural brain disorder (rate of 44%).

Children with a severe intellectual disability were excluded from all four groups. The findings were clear-cut in showing that the major psychopathological risk was associated specifically with brain dysfunction and not just with a physical disability. However, this risk applies almost as strongly to uncomplicated epilepsy as to structural brain disorders. A further separate study (Seidel, Chadwick, & Rutter, 1975) confirmed the specific risk effect associated with cerebral dysfunction by comparing children with disorders above and below the brainstem. Similar conclusions derived from Breslau's (1985) study of psychiatric disorder in children with physical disabilities.

There can be no doubt that overt brain disorders provide a major risk for psychopathology but, equally, the Isle of Wight studies showed that such disorders were found in less than 10% of the children with psychiatric disorders (Rutter, Graham, & Yule, 1970a; Rutter, Tizard, & Whitmore, 1970b). The latter finding has relevance with respect to the medical study of children presenting with some psychiatric disorders (see chapter 22). Detailed neurological study or investigations should not be a routine. Nevertheless, clinicians need to be alert to the psychopathological effects of key brain conditions that they are likely to encounter – particularly in pediatric liaison work (see chapter 70).

**Developmental Perspective**

Three elements must be considered in development from infancy to old age: the maturation of the brain (see chapter 12); everyday life experiences at home, at school, and at work (the facilitating environment); and the capacity to master developmental challenges and tasks. Brain disorders may disrupt the consecutive series of reorganizations of brain connections from one developmental stage to the next, and constrain the interplay between nature and nurture (Rutter, 2006).

Changes in the brain are accompanied by changes in the capacity to make sense of the world, to speak and to learn. The prefrontal cortex is one of the last parts of the brain to develop and is particularly vulnerable to environmental insult. Damage or disrupted development of the prefrontal cortex impacts on executive function: planning, anticipating change, regulating emotion and behavior over time. Although brain disorders may be non-progressive, the effects are unlikely to be static because the brain continues to develop right into early adult life.
Brain disorders may also have a psychopathological impact through effects on life experiences and on the capacity for emotional and cognitive coping and mastery. In typical brain development, the capacity to plan, self-regulate and adapt emerges during the preschool years and continues into adolescence. Working memory, behavioral inhibition and cognitive flexibility are essential components of executive functioning. Through working memory, one holds information in mind, manipulates it mentally and decides what actions to take. Thus, action can take place based on choice and not impulse. The capacity to inhibit allows self-control and self-regulation to resist inappropriate behaviors and urges. Cognitive flexibility results in quick and effective adaptive responses (Davidson, Amso, Anderson et al., 2006; Rubia, Smith, Woolley et al., 2006). In brain disorders, problems with inhibitory brain processes that are important in task mastery are common and may be linked to inattention and hyperactivity (Foden & Stuss, 2006).

The richness of environmental experience facilitates the maturation of the brain. As the brain develops, the individual makes use of new-found capacities to master developmental tasks. The term mastery motivation refers to goal orientation and persistence in completing a task. Task completion, solving a problem or engaging a person is, in itself, intrinsically rewarding and motivates new behavior. In brain disorders, persistence in task mastery is commonly affected and may be delayed or disrupted. A person with a brain disorder may become frustrated by restrictions imposed by others concerned about their safety and by their own difficulty in controlling their impulses, emotions and behavior.

Associations between brain disorders and behavior may be direct; for example, brain systems involved in attention, emotion regulation and inhibition are dysfunctional in children with traumatic brain injury or FAS disorder. Other associations are more indirect, involving psychological effects on self-image such as unrealistic expectations at home and school, family cohesion, parental overprotection and rejection, peer discrimination, inadequate educational programming, and overt physical or sexual abuse. Other stresses relate to medical procedures and repeated hospitalizations that disrupt family life. Both direct and indirect effects must be considered in clinical care; attention also needs to be paid to the ways in which the young person is tackling key developmental tasks and to the manner in which these may be influenced by stigma as well as brain pathology.

Acute Confusional States: Delirium

Young children are especially vulnerable to changes in mental state during medical illness and may be confused by unexpected and unpredictable experiences related to medical care. The most severe change in mental state linked to illness and hospitalization is delirium.

Delirium is a disturbance of consciousness with an acute onset and fluctuating course. It is characterized by disorientation, impaired attention, distortions in language and visuospatial functioning and deterioration in cognition not explained by an underlying dementia (Turkel & Tavare, 2003). Infections and medication use are the most frequent causes but it may result from toxic exposures, metabolic disorder, acute brain injury or fever of any cause.

Clinical Presentation

Developmental factors that make young children vulnerable to confusional states include a poorly established sense of self and of time, and limited verbal ability and narrative capacity to discuss their experiences. Because, with delirium, there are fluctuations in consciousness with lucid intervals alternating with periods of confusion, the time of assessment is critical and repeated interviews may be needed. Children and adults may differ in their presentation (Turkel, Trzepacz, & Tavare, 2006). Children more often are confused, agitated, emotionally labile, oppositional, socially withdrawn, unduly suspicious and have disturbed sleep. In adults, impaired memory, speech problems and depressed mood receive greater emphasis. Impaired alertness, apathy and hallucinations are common to both children and adults. Without careful evaluation, symptoms in children with delirium may be confused with depression (non-verbal, irritable and withdrawn), oppositional defiant behavior (agitation, non-compliance) or paranoia (suspiciousness). Delirium may occur in children, especially in young children, as they emerge from anesthesia; it is more likely to occur when there is excessive anxiety before medical or surgical procedures requiring anesthesia. Delirium is a risk in intensive care units where social isolation (restricted visiting by family members), immobilization, excessive noise and sleep deprivation may occur. Finally, the use of anticholinergic drugs may elicit delirium.

Treatment

Medical treatment of the underlying illness, controlling fever and adequate hydration are essential. The management of delirium involves restoring orientation, providing comfort, soothing the child and helping to make daily experiences more predictable, and restoring the normal day–night rhythm. Familiar toys and photographs of home and family may facilitate orientation. Although low doses of neuroleptic medications used in adults are also used for treatment in children, there are no prospective or retrospective studies regarding their use for this indication in childhood. Delirium rating scales may be used to monitor response to treatment (Turkel, Braslow, Tavare et al., 2003). To prevent emergent delirium following anesthesia, special attention must be paid to reducing preoperative anxiety, providing treatment for postoperative pain and offering a quiet environment for postanesthesia recovery.

Dementia and Other Neurodegenerative Disorders

Clinical psychiatrists and psychologists may encounter dementing conditions as part of pediatric liaison work, when the key
issue is how to deal with the psychopathological disturbance. However, when there has been a loss of skills without, as yet, an identifiable neurological disorder, the presentation may lead to an assumption that it is a hysterical conversion disorder (see chapter 57). A loss of skills may also constitute a prominent aspect of certain autism spectrum disorders (see chapter 46). Clinicians therefore need to be aware of how to respond in these various circumstances.

Childhood dementia is characterized by an overall deterioration in mental functioning – with progressive loss of established language, social, self-care and cognitive skills following a period of normal development. Unlike acute confusional states (in which complete recovery tends to follow resolution of the acute medical condition giving rise to the state), dementia is progressive, although the course may involve ups and downs in the level of functioning. The diagnosis of dementia needs to be particularly considered when there are other features suggestive of a brain disorder (e.g., epileptic seizures, visual impairment, tremor and postural disturbance) or when there are relevant risk factors (e.g., a close relative with Huntington disease, a mother with AIDS, recent severe brain trauma or an attack of measles).

The degenerative disorders are fortunately rare; psychiatric or psychological involvement with them ordinarily occurs most commonly on consultation services to help families cope with the diagnosis and ongoing care for the affected child. It is also relevant that dealing with degenerative disorders provides stress for the clinicians. In most circumstances, those working in child and adolescent mental health services do not need to be concerned with the details of specific disorders but, because these are helpful in providing a context, these are provided at the end of this chapter (see p. 469).

**Pervasive Developmental Disorder–Autism Spectrum Disorder**

The possibility of a neurodegenerative disorder arises in pervasive developmental disorder (PDD) in four main circumstances. First, about one-third of children with autism show a temporary loss of language skills – usually at about 18–24 months (Lainhart, Ozonoff, Coon et al., 2002; see also chapter 46). This phase of regression seems to be particularly characteristic of autism, but there are no published systematic comparisons with other conditions involving language delay. This regression is not dementia because ordinarily it is not progressive and its occurrence neither differentiates it from other cases of autism nor indicates any form of neurodegenerative disorder. The neural basis of the regression is not known, but it might reflect a change in the neural underpinning of language in that age period.

Second, there is a disorder involving a marked decline in cognitive, language and social functioning – usually after age 3 years (but certainly after age 2 years), following a prior period of apparently normal development (Volkmar, Koenig, & Slate, 2005). This was first described by Heller a century ago, using the term “dementia infantilis,” but it is now usually called childhood disintegrative disorder. At first sight, this appears to be a neurodegenerative disorder and numerous cases have been investigated for the possibility of some underlying neurological condition. Very occasionally that has been found, but the usual experience is that investigations are non-contributory. Once established, the clinical picture and course is that of other cases of autism spectrum disorder (ASD).

Whether or not the disintegrative disorder is an unusual variant of autism (it is far less common), or something different, remains uncertain but despite surface impressions to the contrary, it does not appear to represent any known kind of dementia.

Third, Rett syndrome is a phenotypically distinctive progressive X-linked dominant disorder that almost exclusively affects females (for a detailed description see chapter 24). What is most distinctive clinically is that, following an apparently normal development in the first 6 months of life (and a normal head circumference at birth), there is a slowing or cessation of acquisition of developmental milestones, associated with a failure in head growth and a loss of purposeful hand movements. Later there is kyphosis/scoliosis, epilepsy and severe intellectual disability. The great majority of cases are caused by mutation in the MECP2 gene (Moretti & Zoghbi, 2006).

Finally, there may be occasional confusion with the Landau–Kleffner syndrome (see chapter 47), in which there is loss of language associated with electroencephalogram (EEG) abnormalities and/or epilepsy, but the maintenance of non-verbal IQ.

These disorders involving developmental regressions are clinically important but they do not follow the pattern of childhood dementia.

**Fetal Alcohol Spectrum Disorder**

For more than a century, clinicians have been concerned over the possible damage to the fetus associated with the mother’s very heavy drinking. The turning point, however, came with the observation by Jones, Smith, Ulleland et al. (1973) of a characteristic pattern of dysmorphic facial features. The causal role of prenatal alcohol exposure was supported a few years later by the reproduction of similar dysmorphic features and behavioral sequelae in an animal model (Becker, Diaz-Granados, & Randall, 1996). The importance of FAS disorder was that it represented identification of a prenatal risk factor giving rise to an apparently distinctive anthropomorphic and behavioral pattern. The three main criteria for the diagnosis of the full FAS syndrome are:

1. prenatal and postnatal growth retardation with short stature;
2. a triad of facial features: flat philtrum and flat midface, thin upper lip and small palpebral fissures; and
3. evidence of central nervous system dysfunction (behavioral, neurological and/or cognitive disabilities); (American Academy of Pediatrics, 2000; Chudley, Conry, Cook et al., 2005; Hoyme, May, Kalberg et al., 2005).

Since the early reports, a range of studies has shown somewhat similar associations between prenatal alcohol exposure and developmental impairment and psychopathology in individuals without the diagnostic dysmorphic features (Henderson,
CHAPTER 30

Gray, & Brocklehurst, 2007; Stratton, Howe, & Battaglia, 1996; Streissguth & O’Malley, 2000; Streissguth, Bookstein, Barr et al., 2004). Animal studies have clearly shown the neurotoxic effect of prenatal alcohol exposure and have also indicated that there is no clear threshold above which there are sequelae and below which there are not. Human studies too indicate the high likelihood of adverse psychological sequelae even in the absence of dysmorphic features. This recognition led to the subclassification of effects in terms of the full syndrome, a partial syndrome and alcohol-related effects – collectively referred to as fetal alcohol spectrum disorder (Stratton, Howe, & Battaglia, 1996).

The problem is how to recognize this spectrum when the dysmorphic features are absent. Obviously, there must be a history of prenatal alcohol exposure – but how heavy must the exposure be? The full FAS syndrome is most likely with exposure in the first trimester, but there might be risk later in the pregnancy. Does the damage come from cumulative alcohol exposure or from short episodes of very high exposure (as with binge drinking)? We do not know; this remains a matter needing further research.

A normal birth weight would tend to argue against FAS disorder but how much notice should be paid to a low birth weight and impaired postnatal growth? Similarly, cognitive deficits would be in keeping with the possibility of FAS disorder but most instances of cognitive deficit are not caused by alcohol exposure and the pattern of deficits is not clearly distinctive. The deficits may particularly involve executive functioning (Rasmussen, 2005), but this is very broad. There is an ongoing effort to define a cognitive–behavioral phenotype (Nash, Rovet, Greenbaum et al., 2006) but, at least as yet, there is nothing diagnostic at an individual level. Brain imaging findings showing a disproportionate reduction in the size of the corpus callosum have been suggested as a possible biological marker (Bookstein, Connor, Covell et al., 2005), but it is not yet useful at an individual level. The same applies to psychopathology. ADHD, disruptive behavior and poor psychosocial adaptation are all particularly common in children born to women who drank heavily during the pregnancy, but these are common in any group of children. Most critically, if the women continue drinking heavily (as will often be the case with alcoholism), it is extremely problematic to separate the prenatal risks from the postnatal risks associated with an adverse rearing environment. Studies of alcohol-exposed children who have been adopted or fostered (Moe, 2002) point to the reality of prenatal effects (as do animal studies), but in ordinary clinical practice the importance of the postnatal environment has to be assessed.

Given the huge problems in defining the limits of the FAS disorder, it is scarcely surprising that there are equally huge differences in clinicians’ willingness to make the diagnosis. In the USA, Sampson, Streissguth, Bookstein et al. (1997) estimated a prevalence of 1 per 1000 for the full FAS and nine times that for the partial syndrome. The figures in the UK are a tiny proportion of those in the USA. It is scarcely likely that, given the rates of alcohol consumption in the two countries, these reflect true variations in incidence. It is much more likely that they represent diagnostic practice. It would seem that UK physicians require a lot of evidence before being willing to diagnose FAS disorder, whereas US physicians are willing to make the diagnosis when the probability of a disorder being truly part of the spectrum is much weaker, and are inclined to view the situation in Europe as underdiagnosis. Nevertheless, it has to be agreed that, at present, there are no satisfactory data from which to decide what prevalence figure for the spectrum is correct, or what criteria should be sufficient to diagnose disorders on the spectrum. The concern in the two countries is much the same (Mukherjee, Hollins, & Turk, 2006) and regardless of the diagnostic uncertainties, the preventive needs are great.

Cerebral Palsy

Definition and Classification

Cerebral palsy is the term applied to a non-progressive, but not unchanging, group of disorders of movement and posture that are the consequence of insult to, or anomaly of, the immature nervous system (Neville & Goodman, 2000; Stanley, Blair, & Alberman, 2000). Symptoms usually become apparent in the first months of life when the cerebral palsy is severe, but they are not apparent until after the age of 1 year in about half of mild cases (Stanley, Blair, & Alberman, 2000). Although it is described as a static rather than progressive motoric disability, there are changes that occur as the brain continues to develop. For example, a hypotonic infant may develop spasticity or rigidity and a child who was initially diagnosed as choreoathetoid may subsequently become increasingly dystonic and develop contractures. Such musculoskeletal problems are pervasive and affect the quality of life. With intervention there can be gradual improvement; however, some children reach a plateau. Some may require bracing and surgery. Cognitive functioning ranges from severe intellectual disability to above average intelligence with comparable academic achievement. Epilepsy is common, occurring in about one-quarter to one-third of cases, especially in the more severe varieties of cerebral palsy.

Spastic hemiplegia (one side of body affected, upper extremity involvement greater than lower) is the most common variety of cerebral palsy – followed by the other spastic forms involving both sides of the body and sometimes all four limbs. Less commonly, ataxia and dyskinesia are the main features.

Epidemiology

The incidence of cerebral palsy is estimated to be 1–2 per 1000 live births (Neville & Goodman, 2000; Stanley, Blair, & Alberman, 2000). The overall rate has not changed greatly over time but over the last three decades there has been an increase in the proportion with severe cerebral palsy.

Etiology

One of the striking findings with cerebral palsy is that it
is very rare to find both twins affected, whether the pair is monozygotic (MZ) or dizygotic (DZ). Family studies too find that it is uncommon for cerebral palsy to run in families (Neville & Goodman, 2000). The implication is that genetic influences have a negligible role in causation and the same applies to environmental factors that affect siblings equally. There are recorded cases of cerebral palsy affecting all four limbs that appear to be genetic in origin, but they constitute rare exceptions.

The one clearly established risk factor for cerebral palsy is extreme prematurity. Infants born before 32 weeks' gestation have a risk of cerebral palsy that is up to 13 times higher than that for a term infant. The risk for bilateral spastic cerebral palsy is even greater than that. At one time, birth complications were thought to have a major role but both epidemiological findings (Nelson & Ellenberg, 1986) and brain imaging findings (Neville & Goodman, 2000) have made it clear that they have a very minor role. About 5–15% of cases arise from a central malformation reflecting neuronal migration defects — probably arising in the second trimester. Periventricular pathology accounts for 40–50% of cases; periventricular leukomalacia (a white matter abnormality) is typical (Kuban & Leviton, 1994). In term infants this probably arises pre-term, but in very preterm infants the damage may arise in the first weeks of life. About 10–15% of hemiplegic cerebral palsy cases have had a vascular catastrophe in the third trimester. In addition, in about one-third of cases there is no obvious clinical antecedent and the imaging findings are normal. Nevertheless, a variety of neuroimaging techniques are valuable to understand structural and functional brain abnormalities in prematurity (Hoon, 2005), and it is recommended (Bax, Tydeman, & Flodmark, 2006) that children with cerebral palsy should always have magnetic resonance imaging (MRI) to establish the timing and extent of lesions. In medico-legal cases, scans can be reviewed regarding the relationship of pathological findings to prenatal events and those occurring at the time of delivery.

**Psychopathology**

Both questionnaires and clinical assessments of epidemiological samples have been consistent in showing that psychiatric disorders are found in about half of all individuals with cerebral palsy (Goodman & Yude, 2000). They take a varied form, including both emotional and disruptive disorders to an equal extent. Within a hemiplegic cerebral palsy group, the strongest predictive factor is a lower IQ, but some evidence of bilateral brain involvement and the occurrence of epilepsy also both add to the risk. Various studies have investigated the associations, within a cerebral palsy group, between family functioning and psychopathology. Findings have shown that disorder is associated with higher rates of parental anxiety and depression, more parental criticism of the child (Goodman & Graham, 1996) and a lack of family cohesion (Breslau, 1990).

Two main uncertainties remain. First, do the associations reflect the impact of the family on the child or the other way round? Goodman and Yude (2000) concluded from longitudinal observation that the main explanation was that the parental distress reflected a reaction to the child’s problems, and Raina, O’Donnell, Rosenbaum et al. (2005) made much the same inference, but evidence on causal direction remains extremely limited. Second, does the presence of cerebral palsy render children more vulnerable to psychosocial adversity? Breslau (1985, 1990), on the basis of a case-control study, concluded not. There was a risk effect from cerebral palsy and from family adversity but there was no evidence of synergism between the two. Again, more evidence is needed to resolve the issue.

It would be a mistake, however, to assume that psychosocial risks always involve the family. Goodman’s studies of children with hemiplegic cerebral palsy (and controls) in ordinary schools (Goodman & Yude, 2000; Yude & Goodman, 1999; Yude, Goodman, & McConachie, 1998) found that those with cerebral palsy were more often rejected by their peers, had fewer friends and were more often victimized. Studied over time, lower IQ, disruptiveness and hyperactivity were risk factors for continuing difficulties with peer relationships. Parents also described some of the children with cerebral palsy as naïve in their interpersonal relationships, and as having difficulty understanding social situations. Sorting out cause and effect from epidemiological findings of this kind is difficult, but the implication would seem to be that the brain disorder both increased the likelihood of peer difficulties and decreased the children’s ability to understand their meaning and, thereby, to cope with them successfully. It may be, too, that the educational difficulties experienced by some children with cerebral palsy add to the children’s stresses.

The conclusions on the origins of the increased rate of psychopathology in children with cerebral palsy are that the main risk usually arises from the brain disorder itself and from the associated cognitive impairment and epilepsy. These features also much increase the risk of peer relationship problems which, in turn, may have a contributory role in the risk for psychopathology. Family dysfunction, when present, doubtless adds to the risk, as it does in all groups of children, but family problems are not exceptionally frequent and probably, at most, play a minor part only in causation. On the other hand, the children’s behavior is likely to create stresses for the family (Raina et al., 2005) and a key therapeutic challenge is helping the family function well as a unit.

Goodman and Yude (2000) argued that, in most respects, the treatment of psychiatric disorders in children with cerebral palsy needed to use the same principles and same techniques as those found to be effective in children without the disorder. Nevertheless, there were three differences. First, it is important to help parents realize that it is the child’s brain disorder that has created the main reason for the psychiatric problem. Equally, the fact that the brain disorder cannot be removed definitely does not mean that the psychological complications cannot be alleviated. Second, the frequent co-occurrence with epilepsy means that an important need is to
CHAPTER 30

ensure proper control of the epileptic attacks and to ensure that the anticonvulsant medication being used does not have an adverse effect on behavior. Third, attention may need to be paid explicitly to the young person’s attitude to and method of responding to their disability. This attention should also include ensuring that inappropriate or excessive help from professionals or family is not adding to the child’s burden. Clinical experience suggests that parental overprotection can sometimes be an issue.

Epilepsy

The term epileptic attack (or seizure) is applied to an episode of altered brain functioning that is associated with an excessive self-limited neuronal discharge. The diagnosis of epilepsy applies when repeated episodes of this type occur without a detectable extracerebral cause (e.g., diabetic hypoglycemia or anoxia resulting from breath-holding attacks). This definition also excludes the 3% of preschool children who have one or more convulsions provoked by fever. That is because nearly all such febrile convulsions (about 98%) do not develop into true epilepsy.

Epilepsy is necessarily of major interest to child psychiatrists for several different reasons. First, it is a common occurrence in both intellectual disability (see chapter 49) and autism (see chapter 46), both of which result in referral to child and adolescent mental health services (CAMHS). Some psychotropic drugs (particularly chlorpromazine, olanzapine and clozapine) lower the seizure threshold, making the occurrence of epileptic seizures slightly more likely (Besag & Berry, 2006). Also, some have risks in pregnancy because of their teratogenic effects. Psychiatrists may be asked to help differentiate between true seizures and pseudoseizures. Young people with epilepsy have a much increased rate of psychopathology. In most societies, epilepsy is a source of stigma and those working in CAMHS may be asked to advise on its prevention or the alleviation of the consequences. Finally, in some countries, psychiatrists are expected to be responsible for the diagnosis and treatment of epilepsy. This chapter is not intended to provide what is needed for those clinicians, who should consult more specialized texts.

Varieties of Epileptic Seizure

The official classification of epileptic seizures (Commission on Classification and Terminology of the International League Against Epilepsy, 1989) uses a scheme that combines clinical features, EEG ictal pattern and EEG interictal pattern. It has a logic but, for present purposes, a strictly clinical classification is used because it focuses attention on the features that clinicians need to be able to recognize.

1 Generalized tonic-clonic seizures ("grand mal"), in which there is loss of consciousness and a characteristic type of convulsion which most people know about.
2 “Petit mal”, the much briefer absence attacks, in which mental functioning is interrupted so that the individual seems to “lose touch” but neither falls nor passes out. It is important to appreciate that, uncommonly, these may recur repeatedly in what used to be termed petit mal status. When this happens, there will be a more prolonged episode of impaired and altered mental functioning, which initially may not be recognized as epileptic in origin.
3 Partial seizures, involving localized clonic phenomena not associated with loss of consciousness, but which may proceed to a full generalized tonic-clonic seizure.
4 Atonic “drop attack” seizures that, again, may not initially be recognized as epileptic.
5 Temporal lobe epilepsy (TLE) attacks, in which the onset may involve a rising epigastric feeling of fear. Other complex distortions of higher cognitive functioning follow. There is associated EEG evidence of a temporal lobe origin. The TLE complex partial seizures are usually, but not always, accompanied at other times by generalized seizures. The particular importance of temporal lobe epilepsy is that it is a risk factor for a schizophrenia-like psychosis in adult life (Davison & Bagley, 1969; Ounsted, Lindsay, & Richards, 1987). The evidence is contradictory on whether or not there is also a particularly high risk of psychopathology in childhood.
6 Rarer complex partial seizures deriving from a frontal lobe focus, which tend to be brief (less than a minute) but which are associated with odd movements, postures and vocalizations that may be particularly difficult to differentiate from pseudoseizures (Stores, Zaiwalla, & Bergel, 1991).

There are other varieties of seizure (e.g., myoclonic) but the one that is of most psychiatric interest involves “infantile spasms” in which there are runs of brief jack-knife spasms beginning in infancy, accompanied by a loss of acquired skills, the presence of a hypsarrhythmic EEG and a high rate of psychopathological sequelae (Riikonen & Amnell, 1981). In most cases, a clear cause, such as a major brain malfunction, can be identified. The most important cause to recognize is tuberous sclerosis (Hunt & Dennis, 1987). Where such a cause is absent, the prognosis may be better.

With respect to epilepsy as a diagnosis, a key differentiation is between uncomplicated epilepsy and epilepsy that is associated with some overt brain disorder such as cerebral palsy or severe intellectual disability. The psychopathological consequences are more frequent with complicated epilepsy and cognitive deficits are much greater.

Pseudoseizures

Stores (1999) suggested the following criteria be considered in the diagnosis of pseudoseizures:

1 The attack follows a non-physiological progression or pattern with variable involvement of parts of the body; unusual visual and sensory complaints must arouse suspicion.
2 There is prompt recovery following what is apparently a generalized convulsion.
3 There is disorientation “in person” after the attack.
4 Attacks are never witnessed by others.
5 Attacks are easily induced by verbal suggestion.
6 There is similarity to seizures witnessed in other people.
Most easily mistaken for pseudoseizures but it is helpful that they have true epileptic seizures. Frontal lobe attacks are the ones that are particularly difficult is that pseudoseizures often occur in children who also have true epileptic seizures. Frontal lobe attacks are the ones most easily mistaken for pseudoseizures but it is helpful that these (unlike pseudoseizures) frequently arise during sleep.

**Epidemiology and Psychopathology**

The prevalence of epilepsy in the general population is about 1%, or slightly less. The peak age of onset is early childhood, but the epilepsy associated with autism is different in having its peak in late adolescence or early adult life (see chapter 46). It is highly likely that this difference has an important pathophysiological meaning, but what that might be remains unknown.

The Isle of Wight survey (Rutter, Graham, & Yule, 1970a) showed that children with epilepsy had a rate of psychiatric disorder (29%) that was four-fold that in children without a physical disorder, and twice that in children with a physical disorder not involving the brain. The findings of the much more recent British Child and Adolescent Mental Health Survey (Davies, Heyman, & Goodman, 2003) were similar. They canvassed over 10,000 children and adolescents and identified 0.7% of 5- to 15-year-olds with a diagnosis of epilepsy. Rates of psychiatric disorder were 37% in persons with epilepsy, 11% in a comparison group with diabetes and 9% in another control group. Clinic studies provide similar findings on the whole (Jalava, Sillanpaa, Camfield et al., 1997; Ott, Siddarth, Gurbani et al., 2003; Pellock, 2004). Claims have been made for particular associations with depression (Baker, 2006) and psychosis (Kanner & Dunn, 2004) but the epidemiological findings are consistent in showing that what is distinctive about epilepsy is the high rate of psychopathology, and not an association with any particular psychiatric disorder (other than with rare exceptions).

Most studies have found that children with uncomplicated epilepsy have a mean IQ that is slightly, but only slightly, below 100. However, the meaning of this association remains uncertain. The National Collaborative Perinatal Project, which followed a large general population sample from before birth to 7 years (Ellenberg, Hirtz, & Nelson, 1986), found an overall 10-point IQ deficit, but this dropped to 4 points when comparison was made with sibs rather than population norms. It seems that much of the deficit is probably a result of family factors of some kind rather than the epilepsy as such. In so far as there is minor cognitive impairment, it could reflect the adverse effects of anticonvulsant medication or, very occasionally, the effects of subclinical seizure activity. There does not seem to be a particular pattern of cognition associated with uncomplicated epilepsy but, not surprisingly, there are differences in the cognitive pattern associated with frontal lobe and temporal lobe epilepsy (Culhane-Shelbourne, Chapieski, Hiscock et al., 2002). What is clear from the epidemiological evidence is that, even after taking IQ into account, children with uncomplicated epilepsy have a much increased rate of reading difficulties (Rutter, Graham, & Yule, 1970a).

**Etiology of Epilepsy**

Twin studies (Berkovic, Mulley, Scheffer et al., 2006; Prasad & Prasad, 2007) have shown a major genetic influence on all varieties of epilepsy – both generalized and focal, plus febrile seizures. EEG patterns, similarly, show a much greater concordance in MZ than DZ pairs. What seems to be different with both focal and febrile seizures is that the DZ concordance rate is much less than half the MZ rate. This points to the likelihood of some kind of synergistic interaction among genes or among allelic variations. Family studies, together with the twin findings, make clear that most cases of uncomplicated epilepsy reflect multifactorial causation, with genetic effects probabilistic rather than determinative (Tan, Mulley, & Scheffer, 2006). Nevertheless, there are rare families showing epilepsy that follows a Mendelian pattern and, in several cases, genes affecting ion channels have been identified (as they have in animal models). The channels are diverse, including those concerned with potassium or sodium and those concerned with glutamate metabolism. Appropriately, but speculatively, the findings have led to suggestions that channelopathies may also be involved in the causation of idiopathic multifactorial varieties of epilepsy (Scott & Neville, 1998; Wong, 2005).

**Etiology of the Psychopathology Associated with Epilepsy**

The main risk factor involves the brain disorder itself. The finding underlines the reality of the risks associated with abnormal neurophysiological functioning of the brain, although the precise mechanisms involved remain unclear. The rate of psychiatric disorder is twice as high in epilepsy associated with manifest neurological problems (Rutter, Graham, & Yule, 1970a) but it is nevertheless much raised even when these are absent. The evidence is contradictory on whether either high frequency of seizures, or particular types of seizures, increase the risk (Goodman, 2002), as it is too with respect to the adverse effects of inappropriate multiple anticonvulsant use (Hermann, Whitman, & Dell, 1989). Cognitive impairment and associated reading difficulties add to the risk (Rutter, Graham, & Yule, 1970a) and family adversity does too (Grunberg & Pond, 1957; Hermann, Whitman, & Dell, 1989). Social stigma is common too (Gordon & Sillanpaa, 1997); its role in psychopathological risk is unclear but probably it is both a consequence and a cause. Finally, witnessing a seizure is a frightening experience for family members, who also have to cope with the stigma and the effects on them of the child’s disturbed behavior (Ellis, Upton, & Thompson, 2000; Hoare, 1984). It must be expected...
— although it has not been systematically evaluated — that such impact on the family may also have implications for the development, or course, of psychopathology in the child.

It follows that the handling of psychiatric disorders in young people with epilepsy requires the same broad-based approach as with any other child. Nevertheless, there are several key differences. First, clinicians will need to help families understand the nature of epilepsy and appreciate the psychiatric risks that stem from the disorder itself. Second, it is necessary to be aware of the ways in which some forms of epilepsy (especially frontal lobe and temporal lobe seizures and petit mal status) may not at first sight be recognized as epileptic in nature. Third, careful attention needs to be paid to both adequate seizure control and possible adverse behavioral effects of anticonvulsant medication. Both are well reviewed by Guerrini (2006), Guerrini & Parmiggiani (2006) and Besag (2004a, b). In addition, it will be crucial to ensure an effective liaison and coordination with the neurologist or pediatrician primarily dealing with the epilepsy, and with the psychologist mainly concerned with educational issues.

**Traumatic Brain Injury**

Traumatic brain injury (TBI) is the most common neurological cause of death and disability in childhood. It has been estimated that in the USA, 185 children per 100,000 under the age of 14 are hospitalized each year for TBI (Kraus & Nourjah, 1988). The comparable figure for the 15–19 age group is 550 per 100,000. The UK figures are probably broadly similar (Middleton, 2001). The assessment of TBI needs to encompass three rather different sets of risk factors. First, there are the features of the TBI itself with respect to both type and severity. The measurement of the duration of both coma and post-traumatic amnesia are well-validated indices, and scales are available for quantification. In recent times, brain imaging is taking over as a more direct index of neural consequences of the injury and of compensatory reorganization of the brain during the recovery process (Munson, Schroth, & Ernst, 2006; Wilde, Chu, Bigler et al., 2006).

Second, there is the cause of the TBI, where the key distinction is between those resulting from physical abuse and those not (Keenan, Runyan, Marshall et al., 2003). The children whose TBI has been inflicted as part of abuse have been found to have more sequelae (Keenan, Hooper, Wetherington et al., 2007). This is likely to reflect both the greater likelihood of previous TBI when the injury has been inflicted (Ewing-Cobbs, Kramer, Prasad et al., 1998) and also the associated psychosocial adversity and the abuse and/or neglect that has not resulted in TBI.

Third, there are the pre-injury circumstances — meaning both the child’s own behavior and his or her psychosocial situation. The TBI may result from impulsive risk-taking behavior (more common in boys) leading to falling out of trees or off garage roofs. In some cases the risk-taking may be part of a psychiatric disorder such as ADHD. A severe closed head injury may result in a secondary ADHD (Gerring, Brady, & Chen, 1998; Schachar, Levin, Max et al., 2004) but the ADHD that is evident post-injury may have been present before (Brown, Cladwick, Shaffer et al., 1981) and pre-injury behavioral problems have been found to predict a worse outcome post TBI (Schachar et al., 2004). Also, Max, Schachar, Levin et al. (2005) found that psychosocial adversity before the TBI was an independent predictor of secondary ADHD in the second year after injury. The adversity may encompass family dysfunction, parental mental disorder and socioeconomic disadvantage. In summary, the clinical assessment of psychiatric disorder post TBI needs to cover all of these features.

**Concussion**

A concussion is an alteration in mental status following trauma that may or may not involve a loss of consciousness (Quality Standards Subcommittee, 1997). The term refers to a mild head injury generally occurring after blunt head injury or from whiplash if there is sufficient force applied to the brain. The force of the injury is not sufficient to fracture the skull. In children aged 7–13 years, brain injuries, primarily concussions, are reported in 1–2% of sporting events. Concussions make up approximately 1% of 300,000 sports injuries per year in the USA. Around 3–8% of US high school and collegiate football players experience a concussion each season (Guskiewicz, McCrea, Marshall et al., 2003; McCrea, Guskiewicz, Marshall et al., 2003). There may be no loss of consciousness or a brief loss of consciousness.

Concussion is characterized by transient headache, altered sensorium (dizziness, confusion), fatigue, somnolence, nausea and vomiting that occurs immediately after the injury. The altered mental state results from shear strain on the upper brainstem although no morphological abnormality may be demonstrated in the brain with neuroimaging. There is functional neuronal impairment that is thought to result from abrupt neuronal depolarization, release of excitatory neurotransmitters, ionic shifts, altered glucose metabolism and cerebral blood flow, and impairment in axonal function culminating in axonal injury and neuronal dysfunction (Kelly, 1999).

Children with mild head injury tend to recover without sequelae but problems may ensue with repeated concussions, even if separated over time from one another. Second-impact syndrome refers to a second blow to the head that takes place while still symptomatic from an earlier concussion. The second-impact syndrome may affect the autoregulation of the brain’s blood supply. The immature brain may be more vulnerable to diffuse injury with second impact than the adult brain. Considerable caution is required in regard to when an athlete may return to play after a head injury; guidelines are available (Kirkwood, Yeates, & Wilson, 2006; McCrea et al., 2003). Generally postconcussive symptoms will resolve quickly without treatment. Still, there are no accurate neurobiological markers, so recovery must be monitored by repeated physical examination along with standardized behavioral ratings. McCrea et al. (2003) prospectively studied the natural recovery from concussion in 1631 football players.
in 15 US colleges and found that several days may be needed for recovery from symptoms, cognitive dysfunction and postural instability. If there is loss of consciousness, amnesia may occur; it may be temporary and retrograde antedating the injury. Permanent retrograde amnesia for the few seconds or minutes prior to the injury may occur. Moreover, temporary post-traumatic memory loss (anterograde), linked to the ability to form new memories, may last for hours after the injury. With loss of consciousness, late symptoms may occur, so monitoring over time is necessary. Brown et al. (1981), in a 2½-year prospective study, reported that head injuries resulting in a post-traumatic amnesia of less than 1 week did not appreciably increase the long-term psychiatric risk.

Severe traumatic brain injury
TBI is classified as open or closed; the types differ in the pattern of injury and neurobehavioral outcome. Closed head injury results from acceleration, deceleration or rotation of the brain within the skull. Different parts of the brain have different densities and therefore shearing stresses arising during rapid brain movement cause injury. Moreover, compression of blood vessels against the falk cerebri or tentorium may result in infarction of the areas that these blood vessels supply. Open head injury refers to penetration of the skull (e.g., a depressed skull fracture or bullet wound); the extent of damage depends on the specific brain regions damaged. Penetrating traumatic brain injury causes specific and direct loss of neural tissue.

Direct brain injury results in bruising or contusion or tearing (i.e., a laceration of brain tissue). There may be loss of consciousness and post-traumatic amnesia lasting over 24 hours. The damage occurs at the site of impact or more remotely under the skull surface opposite the area of impact (contrecoup injury). Brain laceration in the mediotemporal, posterofrontal and anteroparietal areas is associated with focal signs including post-traumatic seizures; there may be hemorrhage into the brain. Neuroimaging techniques such as computed tomography (CT) or MRI are used in the evaluation.

The most important landmarks for recovery are related to the time of emergence from coma and the time of emergence from post-traumatic amnesia. Immediately after emergence from coma, the child will not be able to form new memories. The time from the accident to the time when new memories emerge is referred to as post-traumatic amnesia. The frequency of post-traumatic amnesia is most likely related to concurrent injury to the temporal lobes. Children with severe head trauma will rarely have specific memories of the accident itself.

Cerebral edema, hematoma formation both inside and outside the brain, and infection are complications of traumatic brain injury that may result in neurological deficits and their effects may be widespread. Moreover, compensatory mechanisms involved in the recovery process itself may alter brain function. Traumatic brain injury is likely to have both neurological and psychiatric complications. Both psychosocial and physiological factors are involved.

Children are more likely than adults to develop early seizures and status epilepticus. Post-traumatic seizures do not necessarily increase the risk of later epilepsy. They are most likely to occur in the first 2 years after injury; approximately 80% occur in the first year and 90% by the second year. For those with penetrating head trauma, up to 50% may develop seizures (Agrawal, Timothy, Pandit et al., 2006). Hydrocephalus may be a late neurological complication, particularly when there is subarachnoid or intraventricular bleeding. Spasticity occurs only in severe brain injury. Post-traumatic hypothalamic dysfunction with endocrine dysfunction can be associated with appetite disturbance, precocious puberty and short stature.

Cognitive and Behavioral Sequelae
Cognitive and behavioral sequelae are common. The length of coma and the duration of post-traumatic amnesia are major factors. Early studies (Brink, Garrett, Hale et al., 1970) that found a strong inverse relationship between duration of coma and subsequent IQ have been confirmed. Psychiatric sequelae may be divided into those that occur during early and late phases of recovery. In the acute phase, behavioral and affective symptoms are related to the neurological presentation. The earliest sequelae appear before the termination of post-traumatic amnesia. Those associated with mild injury include transient symptoms of dizziness, headaches, confusion and fatigue. The most common psychiatric diagnosis is delirium with agitation, loss of orientation and limited attention span. Symptoms commonly noted with more serious injury are transient short-term psychopathological symptoms such as loss of initiative, forgetfulness, emotional lability and irritability. More severe symptoms include extended periods of amnesia, psychotic symptoms, including hallucinations and delusions, and disturbances in the sleep–wake cycle.

In the chronic phase, specific impairments include agnesia, apraxia and aphasia. Persistent symptoms may result in a diagnosis of dementia, with behaviors similar to a frontal lobe syndrome in adults or a post-traumatic change in personality. Social disinhibition, poor impulse control, hyperactivity, attention deficits, disinhibited talk and forgetfulness are among the chronic sequelae. Rutter, Chadwick, and Shaffer (1984) reported that children showed behavioral disinhibition after severe closed traumatic brain injury, with overtalkativeness, ignoring social conventions, impulsiveness and poor personal hygiene. After severe head injury, new psychiatric disorders may be seen in children who were without disorder before the accident. Essentially, there is a dose–response relationship that depends on the severity of brain injury; this suggests a causal relationship. The development of psychiatric disorders in children with severe head injuries is also influenced by pre-accident behavior, intellectual level and psychosocial background. With the exception of social disinhibition and a tendency to show greater persistence of behavioral disturbance over time, psychiatric disorders attributable to head injury do not show specific features (Brown et al., 1981). Max, Levin, Schachar et al.s' (2006) detailed follow-up study of
children who suffered TBI showed that MRI-diagnosed superior frontal lobe damage was the strongest predictor of personality change but pre-injury poor adaptation also had some predictive value.

Injuries involving focal frontal lobe dysfunction are associated with impulsive aggression and behavioral dyscontrol (Brower & Price, 2001), and most often focal orbitofrontal injury. However, the rate of actual aggression is less than often assumed. When forensic issues are raised regarding violent behavior each case should be studied individually, taking into account the type of head injury along with other risk factors, especially a history of physical abuse.

Transient psychotic features may occur occasionally. Hallucinations tend to be less bizarre and more concrete than the typical hallucination in schizophrenia. Nevertheless, post-traumatic psychosis and mania do occur. Moreover, head injury in childhood may accelerate the expression of schizophrenia in families where there is strong genetic predisposition (AbdelMalik, Husted, Chow et al., 2003).

Chadwick, Rutter, Brown et al. (1981) correlated the persistence of cognitive deficits with the duration of post-traumatic amnesia. The more persistent deficits were found if there were more than 2 weeks of post-traumatic amnesia. However, when post-traumatic amnesia lasted less than 24 hours, no cognitive sequelae—either transient or persistent—were documented. In the 1-day to 2-week range, the threshold for impairment was associated with the severity of injury. The extent of impairment in intellectual functions depended on the degree of brain damage. Non-verbal test measures (visuospatial and visuomotor) were more highly correlated with the extent of injury than verbal scores. There may be a loss of skills and slower rate of learning with reduced speed of information processing that affect other cognitive skills following the injury. This may be particularly noticeable in school where rapid processing of complex information is required. Recovery was most rapid in the early months following the injury; however, substantial recovery continued for 1 year and into the second year in some children who were severely injured. Age, sex and social class did not significantly affect the course of recovery.

Communication impairments include problems in expressive and written language, naming and deficits in verbal fluency. Persistent verbal memory impairment has been reported as long as 10 years after injury in one-quarter of those studied (Gaidolli & Vignolo, 1980). Slowed speech, articulation difficulties and lack of prosody may be noted. Preschool children may have problems in syntax and grammar, and older children with more complex language tasks. In school, failure to remember instructions, absentmindedness, attention problems and limited on-task behavior are common complaints. Following moderate to severe TBI, clinical neuropsychological assessment should be used to assess executive functions and their impact on everyday life (see chapter 21). Executive functions may be disturbed because of effects on frontally guided neuronal networks that affect environmental adaptation to changing demands. Slowing of information processing seems to be specifically linked to brain trauma (Levin & Hanten, 2005). Of particular concern in school are deficits in attention and orientation, working memory, semantic representation and self-regulation. These deficits affect educational achievement and are associated with reading problems, difficulty with written language and/or deficits in arithmetic skills.

There is increasing recognition that executive function is frequently impaired by traumatic brain injury in children and may be important in mediating the neurobehavioral sequelae (Levin & Hanten, 2005). Children injured at a younger age may be at greatest risk for impairment. Performance on tests of executive function does not depend only on the frontal lobes. Damage to parietal or temporal lobes can disrupt visuospatial or verbal processing, leading to impaired performance on executive function tests. Finally, the association between total number of lesions and executive function may be linked to disconnections and disruption of frontal–subcortical systems (Slomine, Gerring, Grados et al., 2002).

**Family Adjustment and Support**

One study of long-term adjustment (Ponsford, Olver, Ponsford et al., 2003) measured family functioning, anxiety and depression, anger control and psychosocial functioning 2–5 years after the injury. Most families were functioning normally. However, anxiety and depression were commonly found in those responsible for the care of their injured relative. The presence of cognitive, behavioral and emotional sequelae was the strongest predictor of anxiety and depression and of unhealthy family functioning. Long-term support and care should be particularly targeted on families whose children have emotional and behavioral problems. Long-term intervention is particularly important when there has been traumatic brain injury induced by child abuse.

**Treatment of Traumatic Head Injury and its Consequences**

Multidisciplinary cognitive rehabilitation teams (Broman & Michael, 1995; Levin & Hanten, 2005) include physicians (pediatricians, psychiatrists, neurologists), occupational, speech and physical therapists, neuropsychologists and social workers. Although controlled trials are lacking, there are reports of successful interventions for executive function deficits and the teaching of adaptive thinking strategies (Limond & Leek, 2005). Intervention through retraining and the use of cognitive memory aids is targeted to improve areas of cognitive functioning such as memory, attention, language and perception (Limond & Leek, 2005).

Behavioral management focuses on skills training and contingency management. Family intervention focuses on helping family members, including siblings (for a meta-analysis of sibling effects see Sharpe & Rossiter, 2002), to accept the nature of the illness, understand the prognosis and to live with uncertainty. Educational interventions are best based on neuropsychological assessment and may require adaptation of the school curriculum. Psychopharmacological interventions for attention disorder, mood lability, anxiety disorders, depres-
sion and psychosis may be indicated. However, such interventions are provided with the understanding that children with brain injury may be more sensitive to side-effects of these drugs.

Conclusions and Future Prospects

The importance of brain disorders for clinicians working in CAMHS stems from both the frequency with which they have a role in some of the conditions encountered in CAMHS (such as intellectual disability or autism), and from the more general messages about how the abnormal functioning of brain systems may predispose to psychopathology of the same types seen in young people without a manifest brain disorder. As yet, we have a very limited understanding of the mechanisms involved in the interconnections between brain and mind (but see chapter 12), but important progress is being made. A better understanding will require research on groups with brain disorders (as considered in this chapter), those with somewhat distinctive behavioral phenotypes associated with chromosomal anomalies or genetic disorders (see chapter 24), those with psychopathology that has no manifest connection with a diagnosable brain disorder but which may nevertheless prove to have a neural underpinning that has some role in liability, and in young people without psychopathology – because we need to learn much more about normal development if we are to understand the mechanisms involved in age-related (or age-specific) psychopathological features. Genetic advances (see chapter 23) and advances in imaging (see chapter 11) constitute two vital technologies but, particularly with respect to epilepsy, neurophysiological advances (see chapter 17) and gains in an understanding of basic neuropsychopharmacology (see chapter 16) will also be important. Precisely where such research advances will lead is unclear but what is apparent is that developmental neuropsychiatry is relevant for all practicing clinicians in CAMHS and not just those working in specialized tertiary referral centers.

Appendix

Key Details of Individual Neurodegenerative Disorders Arising in Childhood

HIV Encephalopathy

Considered worldwide, it may well be that human immunodeficiency virus (HIV) is now the most common cause of dementia in childhood (see chapter 58). The extent of the neurotoxic effects of HIV depend on the viral load, the age of the child at the time of the infection, and associated risk features such as malnutrition (Willen, 2006). Some infected children make slow developmental progress; others reach a plateau and fail to advance; and still others have a progressive encephalopathy with gradual and insidious loss of cognitive and motor skills. With improvements in treatment, many children are surviving into adolescence and young adulthood. The young people need to cope with the implications of the diagnosis as well as with the adolescent developmental tasks in coping with a chronic illness (see chapter 57). Adaptation may also be influenced by family stress associated with the death or illness of the primary caregiver.

Subacute Sclerosing Panencephalitis

Subacute sclerosing panencephalitis (SSPE) is a progressive brain disease caused by an infection of the brain by a mutant measles virus (Campbell, Levin, Humphreys et al., 2005). The onset (generally 5–15 years) usually starts with an insidious intellectual deterioration and personality change. The behavior varies markedly from irritability to withdrawal, and from oppositional defiant behavior to inappropriate affection. Myoclonic epilepsy without interruption of consciousness usually follows some months later – the jerking often progresses to frequent gross movements (accompanied by characteristic EEG changes). High titers of measles antibodies are found in the cerebrospinal fluid. In industrialized countries with routine measles immunization programs, SSPE is exceedingly rare, but it is much more common in developing countries that lack such immunization. Even in countries with good immunization procedures, the existence of SSPE is a reminder that measles can be a very serious disease, and that there are significant dangers associated with any reduced take-up of immunization stemming from real or supposed risks.

Batten Disease (Juvenile Onset Neuronal Ceroid Lipofuscinosis)

This diagnosis is applied to a group of neurodegenerative disorders, usually inherited as an autosomal recessive. Its incidence is about 1 per 25,000, making it the most common of the childhood neurodegenerative disorders (Elmslie, Gardiner, & Lehesjoki, 2002). Usually it presents first with visual failure in middle childhood, but obvious dementia follows some years later. The greatest diagnostic difficulty arises at the predementia phase, when “hysterical” blindness may be wrongly identified. Epilepsy usually develops but hard neurological signs are a late event. Because the mutated gene has been identified, DNA tests can confirm the diagnosis.

Wilson Disease

Wilson disease is an autosomal recessive disorder occurring in about 1 person per 30,000 (Packman, 2007). It involves defective copper metabolism (giving rise to reduced copper and caeruloplasmin in the blood and increased copper in the urine). The Kayser–Fleisher ring on the iris is diagnostic. Liver damage is characteristic in the early school years but, after about age 10, neurological features, cognitive decline and non-specific changes in emotional responsiveness and behavior become apparent. Dystonic movements and posturing may be misdiagnosed as conversion hysteria. Early diagnosis is important because administration of the copper bonding agent 6-penicillamine may succeed in halting the disease, although side-effects of this treatment can be serious. A mutant gene on chromosome 13 has been identified.
CHAPTER 30

Childhood-Onset X-linked Adrenoleukodystrophy

This X-linked recessive metabolic disorder results from the accumulation of very long chain fatty acids (Moser, Mahmood, & Raymond, 2007). It has a very variable pattern of manifestation in which either adrenal failure or dementia may predominate. Restlessness, inattention, poor concentration and cognitive perplexity are common – very occasionally giving rise to confusion with ADHD (if the adrenal failure is not recognized). Early identification is important because of the possibility of therapies being developed (Moser, Raymond, & Dubey, 2005).

Huntington Disease

Huntington disease is a rare autosomal dominant disease with an incidence of about 3–7 per 100,000 (Hayden, Pouladi, & Kremer, 2007). The typical age of onset is about 40 years, but some 5–10% of cases begin in childhood (Gonzalez-Alegre & Afifi, 2006). The first manifestation in adults usually involves minor motor abnormalities, proceeding to gross chorea, but rigidity tends to be more common in childhood, as do orofacial symptoms. Epilepsy occurs in some 30–50% of children with Huntington disease. Mental deterioration is usually first evident in declining school performance but this goes on to a severe progressive dementia. Various forms of disruptive behavior are common. The gene contains a trinucleotide CAG repeat (see chapter 23), with some tendency for a high number of repeats to be associated with an earlier age of onset. The diagnosis is usually signaled by the family history, of which most members of the family are likely to be aware.

Sanfilippo Syndrome

This is a rare mucopolysaccharidosis – almost always inherited as an autosomal recessive (Spranger, 2007). The syndrome is the only mucopolysaccharidosis that commonly presents with cognitive decline and behavioral problems in childhood. It is clinically suspected on the basis of abundant coarse head hair (often with slightly coarse facial features and mild skeletal changes; see chapter 22). Loss of speech and a severe progressive dementia follow – usually with epilepsy. The diagnosis can be confirmed by measuring urinary mucopolysaccharides.

BRAIN DISORDERS

9781405145497_4_030.qxd  29/03/2008  02:50 PM  Page 472

War and organized violence bring death and misery to combatants and civilian populations, especially those who are most vulnerable, such as women and children. Direct attacks may have devastating physical effects, including death and injury, and fear of further violence may cause the flight of surviving communities, with resulting disruption to family and cultural life. It is self-evident that such adversities bring great psychological distress. The massive scale of these events makes this an important topic in understanding international child and adolescent mental health (UNHCR, 2000, 2006).

This chapter reviews some of the major trends in population movements and the backgrounds of asylum seekers and refugees, and then focuses on psychopathology that may occur in young refugees. Factors associated with increased risk and continuity of disorder, as well as those that enhance resilience, are considered. Finally, there is a brief overview of some key issues and implications for mental health service and psychiatric treatment provision.

### Population Movements

Population movements to escape persecution, organized violence and economic hardship that may be severe enough to cause famine are long-standing phenomena in human history. However, the 20th century witnessed migrations of far greater numbers of people (Kushner & Knox, 1999). The number of international migrants (defined as those who live outside their country for at least a year) has increased from 75.9 million in 1960 to 174.9 million in 2000 (United Nations Department of Economic and Social Affairs, 2004). Most of the migration is within regions.

War and organized violence have been important causes of migration. It has been estimated that since 1945 there have been at least 160 wars and 24 million war-related deaths (Pedersen, 2002). During the 1970s and 1980s there were proxy wars of the Cold War conflict in South-East Asia, the Horn of Africa, Afghanistan and Central America (UNHCR, 2000). In the 14-year period after the Cold War ended, 1990–2003, there have been 59 major armed conflicts in 48 locations, although only four have involved war between countries (UNICEF, 2004). The collapse of Soviet communism was associated with a reduction of power of many states, and the 1990s saw the destruction of Yugoslavia, an increase in wars in Central Asian areas such as Afghanistan, Chechnya, Tajikistan and Georgia, as well as war and genocide in central Africa including Rwanda (UNHCR, 2000). Since 1991 there has been increased war in the Middle East, especially in Iraq, and continuation of conflict in Gaza and the West Bank involving Israelis and Palestinians.

The United Nations, created in the aftermath of World War II, has had an important global role in monitoring and supporting populations. It defines a refugee as a person who “Owing to well-founded fear of being persecuted for reasons of race, religion, nationality, membership of a particular social group or political opinion, is outside the country of his/her nationality and is unable or, owing to such fear, is unwilling to avail him/herself of the protection of that country; or who, not having a nationality and being outside that country of his/her former habitual residence as a result of such events, is unable or, owing to such fear, is unwilling to return to it” (UNHCR, 2000). A displaced person may experience the same kinds of threat but remains within his or her national borders.

People of concern to the UNHCR include those who leave their own countries (refugees, whose legal rights are recognized, and asylum seekers who are applying for refugee status) as well as those who are displaced within their national borders, or are returning refugees. From 1995 to 2005, the overall number had been fluctuating at around 20 million. In 2006 32.9 million people were of concern, of whom 9.7 million were in Africa, 14.9 million in Asia, 3.4 million in Europe, and 3.5 million in Latin American and the Caribbean (UNHCR, 2007). From 2000 to 2004, the numbers of asylum applications submitted to the top five European countries were: UK 393,800; Germany 324,100; France 270,300; Austria 144,800; and Sweden 127,300. The main countries of origin of asylum applicants in the top 10 European receiving countries were Serbia and Montenegro, Iraq, Turkey, Afghanistan and the Russian Federation (UNHCR, 2006).

Over the 15 years until 1998 it was estimated that approximately 300,000 refugees and asylum seekers came to the UK (Bardsley & Storkey, 2000). In 2004, there were 33,960 asylum applications in the UK. Most of the applicants were from Iran, Somalia, China, Zimbabwe and Pakistan (Home Office, 2005). In the same year, 54,310 people, including
Refugee and Asylum Seeking Children

Refugees are a heterogeneous group, and this has major implications for research. In addition to the usual demographic variables, age and sex, the refugee population may also be ethnically and linguistically diverse. This introduces considerable complexity for carrying out research as instruments need to be selected according to the age of the subjects and translated. There are standard procedures for translating instruments used in psychiatric research, and these are generally applicable to work with young people (Westermeyer & Janca, 1997). The legal status of the subjects may be an important issue, as this is associated with different rights and will influence economic status and housing provision (e.g., asylum seekers in the UK are unable to work, while those with the legal right to remain have this entitlement, and also have access to permanent housing). A further factor is the duration of settlement. Over time, asylum seekers, some of whom will acquire legal rights to settlement, will build up social networks and acquire greater linguistic ability in the language of the host country (Hauff & Vaglum, 1997).

Asylum seekers and refugees generally have a high level of mobility, although there are exceptions (e.g., people who are displaced but forcibly settled). This means that care is needed over sampling for studies. While random sampling may be the ideal for epidemiological studies (Mollica, Poole, Son et al., 1997), the sample may need to be derived from municipality (local government) lists or areas (Thabet, Abed, & Vostanis, 2002). Research with children and adolescents is facilitated as children who are asylum seekers, as well as refugees, have entitlement to many welfare services including education. Many studies have used school registers as a way of defining the sample (Fazel & Stein, 2003; Leavey, Hollins, King et al., 2004; Smith, Perrin, Yule et al., 2002; Toussignant, Habimana, Biron et al., 1999). Other studies have selected children on the basis of agency support, such as social services that have responsibilities for unaccompanied asylum seeking children (Wade, Mitchell, & Baylis, 2005). Other techniques may be needed to access refugees, such as targeted sampling (e.g., recruiting from ethnic or religious centers), convenience sampling and snowball sampling. Interestingly, in one of the few studies that has looked at these methods, the sample characteristics were only slightly different according to method of recruitment, probably because of the care with which the study was carried out, including adequate sample size (Spring, Westermeyer, Halcon et al., 2003).

Refugees will be heterogeneous with respect to the kinds of war events and other adversities they have experienced (see Chapter 25), and so consideration needs to be given to the way these are assessed. A number of instruments have been developed for the assessment of exposure to war and torture, initially developed for use with adults but since widely used for the investigation of adolescents (Hollifield, Warner, Lian et al., 2002). Some instruments such as the Harvard Trauma Scale (Mollica, Caspi-Yavin, Bollini et al., 1992) have been widely used, their brevity makes them accessible, and they show statistically significant associations with health status (Hollifield et al., 2002; Willis & Gonzalez, 1998). Interview methods of assessments of past traumatic events and adversities may be preferable (Rutter & Sandberg, 1992; Sandberg, Rutter, Giles et al., 1993), but their benefit with this population which has often experienced very high levels of trauma has not yet been established. One particular issue is that memories of past events may be unstable (Herlihy, Scragg, & Turner, 2002; Spinhoven, Bean & Eurelings-Bontekoe, 2006).

There are a number of ethical considerations for research with refugees, who are a vulnerable population (Leaning, 2001). Asylum seekers in particular may have fears regarding disclosure of information, in view of their insecure legal position, and so assurances of confidentiality are important. Specific care is needed in research with unaccompanied children seeking asylum, especially with regard to consent (Thomas & Byford, 2003). Nevertheless, refugees may regard participation in research as a positive experience (Dyregrov, Dyregrov, & Raundalen, 2000). Furthermore, it has been argued that research may be used to challenge the oppression and inequalities experienced by refugees (Kirmayer, Rousseau, & Crepeau, 2004).

Conceptual Issues in Refugee Mental Health

A number of controversies, mostly focused on post-traumatic stress disorder (PTSD), in view of its association with exposure...
CHAPTER 31

to violent events, have arisen in the refugee mental health field (see chapter 42). These partly relate to issues in psychiatric research with culturally diverse populations. It has been argued that PTSD is a culturally constructed psychiatric disorder that does not have validity in non-western cultures (Bracken, Giller, & Summerfield, 1995; Eisenbruch, 1991; Summerfield, 2000, 2001). Rather, it is suggested that suffering and psychiatric symptoms should be described on the basis of local meanings, to produce a more culturally “embedded” understanding (Eisenbruch, 1991; Kleinman, Das, & Lock, 1997). The social use, and indeed abuse of the concept of PTSD has been blamed as a contributory factor for the poor organization and inappropriate development of psychological trauma services in the aftermath of disasters (Summerfield, 1999, 2000).

There are numerous reasons for rejecting this critique (Hodes, 2002a). PTSD has been found in all cultures in which people have been exposed to violent events, and there have been no reports of a “culture-specific illness associated with mass violence and torture experienced by refugees” (Mollica, 2000). Numerous studies attest to the validity of the disorder (e.g., the recognition of symptoms across cultures and feasibility of translating instruments; de Jong, Komproe, van Ommeren et al., 2001; Elsas, 2001; Sack, Seeley, & Clarke, 1997), the association of PTSD with the degree of exposure to past war events (rather than all adversities; Heptinstall, Sethna, & Taylor, 2004; Sack, Clarke, & Seeley, 1996), the stability of the disorder and a trajectory different to that of other comorbid disorders such as depression (Sack, Him, & Dickason, 1999).

It is important to bear in mind that an approach that includes psychopathology, such as recognition of PTSD, does not determine the kind of mental health service provision, which should be influenced by many social factors such as the level of infrastructure development and human resources, and cultural influences regarding treatment appropriateness (see p. 481; de Jong, 2002; van Ommeren, Saxena, & Saracena, 2005).

**Epidemiological Findings**

**Community Studies**

The studies in this section are described according to the sequence of refugee experiences: before flight from the home community, in-flight and on arrival in resettlement countries (Hodes, 2000; Lustig, Kia-Keating, Knight et al., 2004). There have been an increasing number of community-based studies regarding the pre-flight and in-flight phases (e.g., those in refugee camps) with young people in recent years, especially those from Vietnam (Felsman, Leong, Johnson et al., 1990) and Cambodia (Mollica et al., 1997; Savin, Sack, Clarke et al., 1996), the former Yugoslavia, mainly Croatia (Zivic, 1993; Kuterovac-Jagodie, 2003) and Bosnia-Herzegovina (Jones & Kafetsios, 2005; Smith, Perrin, Yule et al., 2001; Smith et al., 2002), and also the Middle East, focusing on Palestinians (Garbarino & Kosteln, 1996; Punamaki, 1996; Quota, Punamaki, & El Sarraj, 2003, 2005; Thabet, Abed, & Vostanis, 2002, 2004; Thabet, Karin, & Vostanis, 2006) and people from Iraq (Ahmad, Sofi, Sundelin-Wahlsten et al., 2000), and other countries such as Afghanistan (Mghir, Freed, Raskin et al., 1995) and regions in Africa (Paardekooper, de Jong, & Hermanns, 1999). They have assessed psychopathology mainly using questionnaires, with report by parents and sometimes self-report by older children (but there are rare interview-based studies, e.g., Ahmad et al., 2000). The studies described here are selected on the basis of methodological quality.

There are a number of considerations in interpreting epidemiological studies of young refugees. Many have been designed to investigate post-traumatic stress, anxiety and depressive symptoms following exposure to traumatic events and most have confirmed high levels of these symptoms. These studies do not reflect the psychiatric heterogeneity that occurs amongst this population. For example, high levels of disruptive behavior have been found amongst populations exposed to ongoing war events and hardship (Quota, Punamaki, & El Sarraj, 2005). Other symptoms such as nocturnal enuresis which might arise from stress are often not assessed. Severe disorders such as psychoses that may occur at higher prevalence amongst some refugee populations such as those from Africa have not been systematically investigated (Fearon, Kirkbride, Morgan et al., 2006). Many studies have relied on questionnaire measures that identify symptom levels rather than psychiatric disorder. While high levels of symptoms indicate high risk of disorder, the questionnaires are rarely calibrated against interview-based measures in the populations under investigation, so that estimates of prevalence are somewhat inaccurate. Another consideration relates to the frequent absence of measures of psychosocial impairment, which may elevate estimated rates of disorder. The studies are varied with respect to duration of exposure to war events and also time delay until participation in the studies (Table 31.1). Thus, the study of Bosnian children (Smith et al., 2002) did not find elevated rates of depressive symptoms, perhaps because the study was carried out years after the cessation of hostilities. By contrast, investigation of Palestinian children living in a situation of ongoing conflict showed a strong association between post-traumatic and depressive symptoms (Thabet, Abed, & Vostanis, 2004).

The high-quality interview-based studies carried out in western resettlement countries add to the findings regarding pre-flight and displaced populations, and reveal high rates of psychiatric disorder and comorbidity. A systematic review of interview-based studies carried out in resettlement countries identified five surveys of 260 children and adolescents younger than 18 years (Fazel, Wheeler, & Danesh, 2005). The prevalence rate for PTSD was 11%, approximately 10 times the rate in non-refugee peers.

Numerous surveys have been carried out in resettlement countries using questionnaire methods of assessment, investigating ethnically diverse refugee populations (Espino, 1991; Leavey et al., 2004; Montgomery, 1998; Rousseau, Drapeau, & Corin, 1996). Some surveys of ethnically mixed refugees

have been carried out in the UK. A survey of primary school children found that the refugee children were more distressed than their peer group (Fazel & Stein, 2003). Another study of refugee children, mean age 11 years, mainly non-referred, used self-report measures of post-traumatic stress and depressive symptoms (Heptinstall, Sethna, & Taylor, 2004). A high level of post-traumatic and depressive symptoms was found, with more than half of the children being at risk of PTSD and depression.

A different picture emerges of multiethnic refugee adolescents who were living in Montreal, most of whom had not been exposed to war (Table 31.1; Tousignant et al., 1999). The greatest differences occurred amongst females, who had elevated rates of over-anxious disorder and phobias compared with non-refugee peers. Psychosocial impairment was greatest amongst those with conduct disorder.

Clinic- and Service-Based Studies

It is well known that only a small proportion of children and adolescents in the community with psychiatric disorders are attending mental health services (Ford, Sayal, Meltzer et al., 2005; Verhulst & van der Ende, 1997). A number of factors influence who gets help, including the severity of the disorder and level of social impairment. Only a small number of studies of young refugees who have accessed mental health services have been published.

Young refugees often present with disorders that reflect exposure to past violence and disruptions of relationships such as PTSD, adjustment disorders and depression (Arroyo & Eth, 1985; Howard & Hodes, 2000). Interestingly, a report from Kosovo of child mental health service users soon after the war (1998–99) found that in addition to stress-related disorders such as PTSD and adjustment disorder, enuresis was a frequent problem (Jones, Rustremi, Shahini et al., 2003). Psychosocial impairment of the refugee children may be similar to that of other children in the same service, and certainly much greater than would be expected in a community comparison group (Howard & Hodes, 2000).

Young refugees using services may have disorders that have multifactorial causation, but may be precipitated by experience of adversities and cultural change. Eating disorders, anorexia nervosa (Kope & Sack, 1987) or bulimia nervosa (Stein, Chalhoub, & Hodes, 1998) have been reported, as well as rarer severe problems such as somatoform disorders associated with depression, in which children become withdrawn and lose the ability to eat and talk (Bodegard, 2005). High levels of stressful events including intrafamilial abuse may also precipitate violent deliberate self-harm (Patel & Hodes, 2006). Young refugees were highly represented in a survey of adolescent psychiatric in-patients in London, largely because of psychosis (Tolmac & Hodes, 2004). This group were predominantly African adolescents who had experienced a high level of war exposure, including witnessing the killing of family members, and had low social support, reflected in the fact that they were less likely to be living with a parent than other in-patients (Hodes & Tolmac, 2005).

It should be remembered that young refugees could have psychiatric and developmental difficulties (e.g., learning difficulties, pervasive developmental disorders, obsessive compulsive disorder and hyperkinetic disorder), which can occur independently of adverse experiences and displacement (Howard & Hodes, 2000; Williams & Westermeyer, 1983).

Risk and Resilience for Psychopathology

Some theoretical considerations are important in considering the variation in children’s psychological response to organized violence and associated adversities. First, in relation to risk events, as can be seen from the account already given, isolated events in “refugee” experiences are relatively unusual, and adversities typically cluster, occurring in close temporal proximity and perhaps also as a protracted process. Available evidence suggests that greater psychological harm comes from an accumulation of risk factors. This refers both to the type of event and duration of exposure, with increasing risk associated with increasing personal threat (Espino, 1991; Garbarino & Kostelny, 1996; Kinzie, Sack, Angell et al., 1986; Mollica et al., 1997; Sack, Clarke, & Seeley, 1996; Sack, Seely, & Clarke, 1997). Second, with regard to resilience, it has been cogently explained that “Resilience does not constitute an individual trait or characteristic. . . . Resilience involves a range of processes that bring together quite diverse mechanisms operating before, during or after the encounter with the stress experience or adversity that is being considered . . .” (Rutter, 1999). The succinct account that follows, which cannot bring out all the subtleties of the findings, might appear to be organized as if risk and resilience are characteristics of events or individuals, but a tendency to interpret the data this way should be resisted (see chapter 25). Some of the main influences on mental health that have been investigated in young refugees are shown in Table 31.2.

Many of the risk factors described here are also considered in chapter 42 with regards to PTSD. Individual attributes such as age and gender may influence psychological adjustment in complex ways. Age and developmental level influence cognitive function, including appraisal of events, as well as biological processes such as responses to stress. Gender may be associated with differing war exposure (Ahmad et al., 2000; Derluyn, Broekaert, Schuytens et al., 2004; Montgomery, 1998; Somasundaram, 2002). Research investigating associations between war events and psychological distress has often controlled for number of events, rather than looking at the links between types of events and gender (Smith et al., 2002; Vizek-Vidovic, Kuterovac-Jagodic, & Aarambasic, 2000). Some reports have found greater levels of post-traumatic and anxiety symptoms among girls than boys (Jones & Kafetsios, 2005; Smith et al., 2001; Vizek-Vidovic, Kuterovac-Jagodic, & Aarambasic, 2000), but other studies did not find this (Thabet, Abed, & Vostanis, 2002).
The individual's understanding of events is also important. This will be shaped by beliefs and ideologies that may be shared with the social or cultural group, including specific attitudes to preparedness for war events (Jones & Kafetsios, 2005; Punamaki, 1996). Realistic expectations are associated with better adjustment (McKelvey & Webb, 1996).

Positive effects of the family were observed during World War II, when it was noted that the presence of parents protected against psychological distress during bombing (Freud & Burlingham, 1943). Investigation of unaccompanied asylum seeking children suggest that they may be more distressed than those who are accompanied (see p. 480; McKelvey & Webb, 1995). Large surveys have shown that children's distress is related to parental distress, although the studies have largely focused on mothers rather than fathers (Smith et al., 2001). There may be an interaction between a child's gender and the effect of maternal distress. A study of Palestinian children in Gaza found that boys were at special risk for post-traumatic and emotional symptoms when the mothers and the boys themselves were exposed to a high level of war, whereas for girls these symptoms were more associated with mothers' exposure (Quota, Punamaki, & El Sarraj, 2005). The quality of family relationships is also important, as children in cohesive well-functioning families experience less distress from external war events (Garbarino & Kostleny, 1996; Laor, Wolmer, Mayes et al., 1996).

Societal response to those who have experienced organized violence and displacement can influence psychological adjustment. In societies where there have been abductions and suspected but not confirmed killings, grieving is not possible, and this heightens distress for children (Quirk & Casco, 1994). Those who have fled their own communities and live in refugee camps may experience very difficult conditions with regard to the physical environment, such as overcrowding and inadequate facilities for children. For asylum seekers in resettlement countries, detention policies (Fazel & Silove, 2006; Reijneveld, De Boer, Bean et al., 2005) and long delays and uncertainties regarding their application for refugee status may increase psychiatric disorders such as anxiety, depression and somatoform disorders (Laban, Gernaat, Komproe et al., 2004). Ongoing daily hassles, or resettlement stressors have been shown to increase depressive symptoms in children (Heptinstall, Sethna, & Taylor, 2004; Sack, Clarke, & Seelye, 1996). Greater resilience for parents and well-being of children is seen amongst those who have stronger social networks, usually associated with greater ethnic density, more opportunities for work and greater residential stability (Ahearn, 2000).

The individual's understanding of events is also important. This will be shaped by beliefs and ideologies that may be shared with the social or cultural group, including specific attitudes to preparedness for war events (Jones & Kafetsios, 2005; Punamaki, 1996). Realistic expectations are associated with better adjustment (McKelvey & Webb, 1996).
CHAPTER 31

Course and Intergenerational Effects

The persistence of psychopathology has been identified from studies with children with diverse cultural backgrounds. A cohort of 46 children from Cambodia, 40 of whom had experienced the Pol Pot regime in primary school years, were followed up while living in the USA (Sack, Clarke, Him et al., 1993; Sack, Him, & Dickason, 1999). Six years after the initial assessment, 48% had PTSD and the figure was 35% at 12 years. Regarding depression, the figures at the same time points were 7% and 14%, respectively. Other studies have found the persistence of PTSD but lower levels of depression with resettlement (Hubbard, Realmuto, Northwood et al., 1995). The persistence was also found in a report of Kurdish children who had PTSD years after experiencing a military campaign against their communities and experiencing displacement at a later time (Ahmad, Sofi, Sundelin-Wahlsten et al., 2000). Many of the young people in the studies had quite good social function with respect to school attendance and attainment despite the presence of psychopathology.

Very long-term psychiatric outcomes have been described in survivors of the Holocaust, experienced in adolescence or early adulthood. Emotional distress, including anxiety symptoms, lower mood and psychiatric service use were much higher in middle-aged Holocaust survivors than immigrant controls (Carmil & Carel, 1986). In old age, the Holocaust survivors continued to have more distress with regard to post-traumatic symptoms and general psychopathology (Joffe, Brodaty, Luscombe et al., 2003). The Holocaust survivors were also more likely to experience further post-traumatic symptoms when retraumatized by bombing (Robinson, Hemmendinger, Netanel et al., 1994).

The catastrophic losses and abuse experienced by survivors of the Holocaust will often have long-term effects on feelings of safety or insecurity, self-esteem and development and maintenance of relationships. For this reason, attention has been given to the children of Holocaust survivors, as many reports suggested that they were at increased risk of psychopathology (Felsen, 1998). However, a meta-analysis has found that children of Holocaust survivors are no less well-adjusted than their peers, and had not experienced secondary traumatization (van Ijzendoorn, Bakermans-Kranenburg, & Sagi-Schwartz, 2003).

Aggregation of disorders in families has been investigated with regard to the association between child and adult psychopathology, especially PTSD and war trauma (see above). A report regarding PTSD across two generations of Cambodian refugees living in the USA found a significant relationship between parent–child PTSD, but not depression (Sack, Clarke, & Seeley, 1995a). Clustering of disorders in families may occur because of genetic factors, but these have not been investigated amongst refugee populations.

The changes associated with migration, adaptation to new cultures and communities will affect generations in different ways. Adult asylum seekers may have limited rights, be unable to work, their acquisition of the language of the resettlement country may be slow and they may be socially isolated. By contrast, their children will attend school, will rapidly have a peer group and opportunity to learn the new language. Thus, the children will assimilate and adapt much more quickly than their parents. They may take on tasks to support the family, and in some case they may become carers of parents who are unwell (e.g., because of torture or psychiatric impairment). These changes can also create tensions, in part because of the burden for the children, but also because the usual family organization and parental authority may diminish (Tobin & Friedman, 1984). This may result in poor boundaries and containment for younger children, and reduced surveillance and advice for adolescent offspring (Westermeyer, 1991). These factors might in part explain the higher level of psychiatric disorders including conduct disorder amongst the refugee adolescents in Canada who had largely not been exposed to war experiences (Table 31.1; Tousignant et al., 1999).

Unaccompanied Asylum Seeking Children

During the course of war and organized violence, family members may become separated and children orphaned. Some children are sent away from imminent danger, and may experience harrowing journeys, with further risk of abuse or illness. In some regions of the world, such as Sri Lanka and North Uganda, abduction of children has been common, and many of them are then forced to become soldiers (Derluyn et al., 2004; Somasundaram, 2002). It has been estimated that there are 300,000 child soldiers worldwide (Human Rights Watch, 2006). It is unclear how many unaccompanied asylum seeking children there are globally. Estimates of the numbers in the UK suggest the number has increased since 1990, and over the first part of the decade, 2000–2005, has been around 5500.

Unaccompanied asylum seeking children can be regarded as at special risk. They have experienced high levels of war events and separations (McKelvey & Webb, 1995; Thomas, Thomas, Naftes et al., 2004). Journeys may have been harrowing, and their arrival in resettlement countries may be associated with great uncertainties. It is expected that child asylum seekers will be offered special protection (UNHCR, 1994). In the UK they are entitled to care under the Children Act 1989, and so are supported by local authorities (Wade, Mitchell, & Baylis, 2005). However, the initial assessment and level of support, including accommodation, may be poor (Wade, Mitchell, & Baylis, 2005).

Available evidence suggests that unaccompanied asylum seeking children and young adults have high levels of psychological distress even after controlling for traumatic events (Bean, Eurelings-Bontekoe, Mooijaart et al., 2006; McKelvey & Webb, 1995). A study from Finland of 46 adolescents mainly from Somali background, found that on the basis of the Child
Behavior Checklist, nearly half were in the clinical or borderline range (Sourander, 1998). Younger children were significantly more distressed than the older ones. Studies of child soldiers from Uganda and Sri Lanka who had experienced very high levels of war events, including killing someone themselves, found high levels of post-traumatic stress, anxiety and somatization (Derluyn et al., 2004; Somasundaram, 2002).

Agencies that provide care for these children have considered the importance of foster care or group homes that might mitigate the effects of losses and increase resilience, by increasing social links with an ethnically and linguistically similar peer group and community (Geltman, Grant-Knight, Mehta et al., 2003; Porte & Tomey-Purta, 1987; Wade, Mitchell, & Baylis, 2005). Same ethnic group foster families, or perhaps group homes, are much preferred to fostering with culturally different families (Geltman et al., 2005; Wade, Mitchell, & Baylis, 2005). The preferred arrangement has been found to be associated with significantly less risk of depression, in the case of South-East Asian youngsters (Porte & Tomey-Purta, 1987), and PTSD, in the case of Sudanese adolescents (Geltman et al., 2005).

**Implications for Services and Interventions**

There has been debate regarding the best means of intervening and promoting the welfare of displaced people. Primary prevention of conflict sadly seems to be unattainable, but concerted international efforts have been made over years to regulate the treatment of prisoners and detained people (UNHCR, 2006). Children’s special needs and rights have been identified (UNHCR, 1994). Recruiting children into armies has been condemned by the United Nations, but that organization has been criticized for not being adequately effective (Editorial, *Lancet*, 2004).

When it is feasible after cessation of hostilities, there is a need for general welfare provision which should include schools and other services (Inter-agency Standing Committee 2007; van Ommeren, Saxena, & Saraceno, 2005). In this tiered approach to the provision of services, community support will benefit large populations. Services that might specifically help children include family reunification programs, adequate protection and care – including medical care – for orphans or unaccompanied asylum seeking children. In the more affluent countries such as the UK, general services that target excluded communities with children may include refugees within their remit (Hodes, 2002b). Strengthening families is likely to promote the mental health of parents and children. Initiatives in Kosovo that promote family strengths, using psychoeducation and multifamily groups (Griffiths, Agani, Weine et al., 2005), have been reported. Other useful approaches may focus on maintaining continuities in family life, and coping with change including reunification with separated family members (Rousseau, Rufagari, Bagilishya et al., 2004; Weine, Dheeraj, Merita et al., 2003). A well-designed study from Bosnia offered weekly group meetings with mothers over 5 months, with the provision of psychoeducation regarding their children’s needs and helping the children to describe traumatic experiences, in addition to medical care, which was the only intervention for the control group (Dybdahl, 2001). Those who received the psychosocial intervention made greater progress: mothers had better mental health, children gained more weight and had better psychosocial functioning.

Controversies have arisen regarding the extent to which mental health services in disaster zones, including areas where there are refugees, should be established to focus on post-traumatic psychopathology. Trauma services have been criticized for focusing on psychological distress outside of a context that considers the whole infrastructure and resource provision, and may neglect cultural factors and other disorders (Eisenbruch, de Jong, & van de Prut, 2004; Summerfield, 1999; van Ommeren, Saxena, & Saraceno, 2005). The criticism is especially cogent in view of the absence of evidence of effectiveness in support of primary prevention of post-traumatic stress symptoms for those exposed to traumatic events, and failure to show benefit for non-refugee populations suggest this would be an inappropriate use of resources.

A preferred option is to integrate trauma-based care into general mental health care (Eisenbruch, de Jong, & van de Prut, 2004; Inter-agency Standing Committee 2007; Summerfield, 1999; van Ommeren, Saxena, & Saraceno, 2005). The benefit of this is apparent from the report from Kosovo described previously, in which by the second year after the war ended, frequent reasons for attending were learning difficulties (intellectual disability) and enuresis (Jones et al., 2003). However, even in affluent countries, mainstream services including primary care may have organizational difficulties meeting the mental health needs of refugees. Access should be facilitated by using interpreters, and consider the fact that asylum seekers may live in homeless accommodation and experience high mobility (Lamb & Cunningham, 2003).

More targeted services can be established for special populations such as unaccompanied asylum seeking children. This group will have health screening and ideally this should include screening assessment of mental health difficulties (Geltman et al., 2005; Wade, Mitchell, & Baylis, 2005). Preschool children may be prioritized by health visitors and others working with this age group.

In view of the difficulties that might arise for young refugees in gaining access to clinic-based child and adolescent services, outreach programs in schools have been described, with some encouraging data available from evaluations (Ehntholt, Smith, & Yule, 2005; Hodes, 2002b; O’Shea, Hodes, Down et al., 2000; Stein, Jaycox, Kataoka et al., 2003). Such services have been provided in communities such as Bosnia following the war, with the involvement of teachers as therapists, in view of the dearth of child mental health professionals there (Udwin, 1995). One advantage of school-based work is that all refugee children, regardless of legal status, are expected to attend. Teachers can identify those who are psychologically distressed and make referral to the school-based mental health
CHAPTER 31

service, so bypassing reliance on primary care which may be
difficult for refugees to access. Families may also experience
school-based services as less stigmatizing than clinic-based ser-
vices. A further advantage is that child mental health practi-
tioners working in the schools will establish good liaison with
teachers, and can also provide a consultation model to reach
more children. Given resource limitations, it may only be
feasible to provide child mental health outreach to schools
that have significant numbers of refugee pupils, and adequate
infrastructure including effective school referral systems and
support from interpreters.

The psychiatric heterogeneity of young impaired refugees,
including some with high levels of distress and poor social func-
tion, means that some will need referral to specialist child
and adolescents mental health services. Despite the difficulties
the young refugees and families may have had in accessing
services, and the very frequent need for interpreters, they may
not have a higher dropout that non-refugees in the same
service (Howard & Hodes, 2000). Impressions are that newly
arrived asylum seekers are more likely to be seen because
of post-traumatic stress, anxiety and mood disorders but, as
the communities become more settled, children will be increas-
ingly referred because of disruptive behaviors. The clinical
assessment may be complex as it is necessary to consider
development in environments that may have been very ab-
normal (e.g., absence of schooling, prison, multiple moves
between countries, homes and carers). The high level of back-
ground stressors may have contributed to behavioral, conduct
and attentional problems, making the differential diagnosis
among hyperkinetic, conduct disorders and adjustment dis-
orders difficult. For some children a symptomatic treatment
approach and regular reassessments may identify stable spe-
cific symptom clusters, and clarify diagnostic difficulties. In
these situations, psychometric testing for intellectual ability
and physical examination to assess in particular coordination
disorder, which is commonly comorbid with hyperkinetic
disorder (Gillberg & Kadesjo, 2003), may point towards a
neurodevelopmental basis for the attentional and conduct
problems.

Some children will require psychiatric admission for fur-
ther assessment and treatment. This group may have experi-
enced high levels of past war traumatic events and current
low family support. This combination may in part explain
the high rate of involuntary admission for adolescents with
severe psychopathology including psychosis (Tolmac & Hodes,
2000).

Clinical work may require an expanded role for child and
adolescent mental health professionals. Requests may be made
for reports to access housing and school, and legal reports to
support asylum applications (Tufnell, 2003). Attention needs
to be given to parental mental health difficulties (Ahearn &
Athey, 1991; Howard & Hodes, 2000). Intervention often needs
to be multiagency, and draw on the range of services from
social services as well as other heath services such as child
health (Geltman et al., 2005; Wade, Mitchell, & Baylis,

There are specific skills in working with interpreters, and
key points are given here (Faroq & Fear, 2003; Raval,
2005). First, it is generally not appropriate to involve a child
as an interpreter, in part because of the responsibility this gives
to the child, and also because of the effect on family rela-
tionships, as parents become dependent on their child’s skills
and integrity for accurate interpreting. If an interpreter is
needed, it is necessary to consider their gender and ethnicity,
and their suitability for the particular family. Discussion with
the family, perhaps involving the interpreter (e.g., over the
telephone), might be useful. There are techniques for inter-
viewing with the interpreter. During the session, eye contact
and questions should be directed to the person who is being
addressed, not the interpreter. Speech should be at an approp-
riate speed, and technical words and terms that elicit
feelings or particular psychological experiences may require
discussion with the interpreter. Following the session it is often
useful to speak to the interpreter to identify any difficulties
that might have arisen.

Asylum seeking families in particular may have fears regard-
ing the “assessment” process, which may be reminiscent of
interrogations. Furthermore, there may be unease, perhaps not
voiced, regarding the degree of confidentiality in the clinic
setting. A further feature of work with refugees is that many
things may be “unknown” for the clinician. Families may find
it hard, or unthinkable, to disclose background adversities (e.g.,
the rape of females in the family).

Regarding treatments, given the heterogeneity of psychiatric
disorders and problems, it is not possible to provide an
adequate account here, but summary accounts are available
elsewhere for specific disorders such as PTSD (see chapter 42;
Hodes & Diaz-Caneja, 2006). A number of general points
can be made (Hodes, 2000). Culturally shaped attitudes may
influence the way parents explain their children’s adjustment
and responses to the changes they have encountered, and this
may affect attitudes to specific treatments. One aspect of this
is the wish to look forward, rather than back. This may be
manifest as a preference to deal with current difficulties (e.g.,
school problems) rather than look back and address past
traumatic events, which would be required for cognitive–
behavioral work. Another related feature is the extent to which
evidence-based treatments can be provided for this culturally
heterogeneous population. Evidence available for PTSD is
that existing treatments are effective (see chapter 41; Neuner,
Schafer, Klaschik et al., 2004; NCCMH, 2005; Onyut,
Neurer, Schauer et al., 2005; Paunovic & Ost, 2001; Stein,
Jaycox, Kataoka et al., 2003). However, treatment needs to
be adapted to be culturally congruent with families’ under-
standing and beliefs.

Conclusions

The scale of war and organized violence globally has had
a major impact on child and adolescent mental health. In recent
years, increasing attention has been paid to this area but
there are still significant gaps in knowledge. From a research perspective, there is a need to investigate further young peoples’ risk and resilience for psychopathology, as well as the effectiveness of available interventions. It continues to be important to plan services for this vulnerable population.

Hodes, M. (2002b). Implications for psychiatric services of chronic civilian strife or war: Young refugees in the UK. Advances in Psychiatric Treatment, 8, 366–376.

All societies need to decide how to respond when children lose or are abandoned by their parents, when parenting breaks down, or when serious abuse, neglect or family dysfunction means that children need to be safeguarded by removal from their biological families. At one time, extensive use was made of orphanages but, for good reasons, most countries have sought greatly to reduce or eliminate the use of residential care for very young children. Countries differ in their approaches to child welfare and major variations exist in policy and practice among countries. The threshold at which intervention in family life is justified by the child welfare agencies differs. The length of time spent in care away from home, the type of placement that is favored and the extent of moves between placements vary. Children enter public care for a variety of reasons in the UK but the majority do so because of abuse, neglect and family dysfunction. Sixty-eight percent are placed in foster care, 13% in residential care and about 9% are placed with their birth families. The remainder are placed for adoption or in more specialist placements (DfES, 2006).

This chapter focuses on mental health aspects of residential and foster family care. It deals with the mental health of children in residential and foster family care in countries with modern child welfare systems and considers assessment and intervention in both settings. It covers the effects of orphanage care where it still exists and recent attempts to improve its quality. Finally, it deals with comparisons of residential and foster family outcomes, cost-effectiveness and future directions.

Much of the published research on residential care and foster family care concerns the provision and management of children’s placements. Research funds are largely raised to answer policy and economic questions rather than developmental ones and studies often resemble audits of the local child welfare agency’s activities. This kind of research is crucial to the provision of good quality care but less illuminating regarding children’s mental health. We will therefore only be attending in passing to issues of recruitment, assessment, retention and remuneration of foster and residential care staff; policies to raise standards and eradicate abuse in care settings and the growing attention to children’s rights. Kinship care will not be dealt with here (see chapter 33) and only brief mention will be made of short-term foster placements with a view to return home.

### Institutional Care in Early Life: Assessing Effects and Improving Environments

#### Effects of Institutional Care in Early Life

It is over 50 years since the first studies drew attention to the negative effects on children raised in institutions (Goldfarb, 1945; Spitz, 1945) and since Bowlby (1951) published *Maternal care and mental health*, where he voiced his concerns about the importance of secure early attachment relationships. Subsequent empirical investigations have refined our understanding of what kind of effects, including disorders of attachment, are produced by what kinds of environment.

Two influential studies have been conducted in the UK on children with different amounts of exposure to residential care. Tizard and colleagues studied infants who had experienced residential nursery care for the first 2 years of life, involving high turnover of caregivers, and compared those who went home with those who were adopted or who remained in institutions. When they were assessed at 4½ years (Tizard & Rees, 1975), those who remained in institutions had higher mean behavior problem scores and had not formed deep attachments. This study suggested that early institutional care can have enduring effects.

Quinton and Rutter (1988) studied outcomes of children who had disrupted early years, were taken into public care and then spent prolonged periods in group homes in the 1960s. The regimes were not harsh, but multiple changes of staff resulted in little consistent affection. The adult follow up of this ex-care sample (Rutter, Quinton, & Hill, 1990) showed that one-third were faring poorly. With regard to the ex-care women, 30% had a poor general psychosocial outcome and 40% had a rating of poor parenting, much higher than in the general population comparison group. However, it was evident that many did not show poor parenting and a minority, surprisingly, showed good parenting. These studies indicate that an institutional environment, when involving lack of consistent personalized care, can contribute to harmful effects on...
CHAPTER 32

development but also that later positive experiences can divert some from negative outcomes.

Continued Use of Institutional Care for Very Young Children

Despite recognition of the significance of the caregiver–child relationship and the known ill effects and costs of prolonged residential care, the lessons have not been equally absorbed in all countries. Browne, Hamilton-Giachritsis, Johnson et al. (2006) have recently conducted a survey on the use of institutional care for children under 3 years in 46 countries in the European region. The data were all based on official government figures, with the usual limitations, but the overall rate of institutional care was estimated at 14.4 per 10,000 children under 3 years. This amounts to nearly 44,000 very young children. The countries with the highest use of institutional care in proportion to the population under 3 years were Bulgaria (69 per 10,000), Latvia, Belgium, Romania and Serbia and Montenegro. These data provide a useful benchmark figure with which to compare the highest use with countries with no institutional care for very young children and in order to compare future efforts at replacing institutional with family-based care for this group. It was suggested that low spending on health and social care was related to a higher proportion of institutionalized children.

As understaffed poor-quality group residential care still exists in many countries, this has afforded the possibility of conducting studies on the development of children raised in extremely depriving circumstances. Chisholm’s (1998) follow-up study revealed more insecure attachment and indiscriminately friendly behavior in children adopted from Romanian orphanages than among never-institutionalized and early adopted comparison groups. Vorria, Papaligoura, Dunn et al. (2004), in a study based in the Metera babies’ center in Greece, showed much higher rates of disorganized attachment in residential care infants compared with infants living in birth families. Follow-up in adoptive placements at age 4 showed that the institutionalized children continued to have poorer cognitive development, were less secure and had poorer understanding of emotions compared to family controls (Vorria, Papaligoura, Sarafidou et al., 2006). The Bucharest early intervention project group (Zeanah, Smyke, Koga et al., 2005) has also shown that an institutionalized Romanian group exhibited serious disturbances of attachment (see chapter 55) compared with a never-institutionalized community group. Furthermore, variation in the quality of caregiving was related to the attachment status of children in the institutional group.

Other researchers have begun to investigate the effect of early maltreatment and institutionalization on the hypothalamic–pituitary axis and results suggest that deficiencies in early care may be associated with abnormal patterns of diurnal cortisol production (Dozier, Manni, Gordon et al., 2006). The neuro-endocrine system appears susceptible to relationship disturbance and periods of long-term exposure to stressors may result in damage to areas of the brain and this may confer vulnerability for later disorder. Low levels of cortisol seen in older foster

children may result from a system that has been downregulated through continuous response to stress (Dozier & Rutter, in press).

A major question is whether these are enduring effects, or whether a radical change of circumstances following institutional care, especially by means of adoption, can erase the effects of early adversity. The English Romanian Adoptees (ERA) Study Team have followed up children \( (n = 144) \) who were placed in institutions, mostly in the first month of life, and who had very poor early experience with little stimulation or interaction with caregivers and with inadequate nutrition. It was shown that these children can achieve significant developmental catch-up, depending on their age at adoptive placement (O’Connor & Rutter, 2000; Rutter et al., 1998). In terms of psychological functioning assessed at 6 years of age, 70% of those entering the UK at less than 6 months showed no impairment, but of those entering later, 24–42 months, only one-quarter had no impairment. However, when compared with a UK adoption sample who had not experienced institutional care, they exhibited cognitive impairment, quasi-autistic patterns, inattention/overactivity, disinhibited attachment disorder symptoms and poorer peer relations. It was concluded that psychological deficits persist in a substantial minority. Cognitive functioning and disinhibited attachment disorder symptoms were strongly related to poor quality institutional care that persisted beyond the age of 6 months (Rutter, Beckett, Castle et al., 2007). It was suggested that disinhibited attachment disorder symptoms were related to a relative failure to develop selective attachment, whereas cognitive impairment was more likely to be related to neural impairment. However, both outcomes could reflect some form of programming effect on brain development (see chapter 12; Rutter et al., 2007).

Further follow-ups are planned for many of these early institution-reared samples. Catch-up appears to be more possible with regard to physical development and cognitive ability, but with an enduring impact for some children on behavioral and social development. Questions remain as to what contribution is made to longer-term differential outcome by genetic inheritance, mother’s physical and mental health during pregnancy, perinatal factors, child temperament and the benefit of subsequent high-quality environments.

Longer-Term Consequences of Institutional Care on Young Children

So far, few follow-up studies have been undertaken to see how early privation affects development into later phases of the adult years. However, follow-up studies of children who remained in, or were adopted out of, orphanages in the 1950s and 1960s offer the prospect of lifespan studies to examine group outcomes. Although tracking representative samples may be problematic, this could reveal whether subsequent favorable experience can modify or remove the risks, or whether there are subgroups with poor adjustment, in particular having continuing social relationship problems.

There appears to be only one very long-term study of orphanage infants followed up into later adulthood and com-
pared with a matched community group (Sigal, Perry, Rossigol et al., 2003). The ex-institutional adults were found to be more isolated and had more stress-related physical illness. However, the study was based on a convenience sample of litigants in a self-help group and this may have contributed to sample bias.

**Improving the Environments of Young Children in Institutional Care**

As the pattern of short- and long-term negative effects continues to be worked out, so policies on what is best for children are being developed. In those countries where institutional rearing continues to be the main form of care for unwanted or relinquished babies and children, efforts are now being made to reduce the carer–infant ratio in order to provide greater contact time and continuity of relationships. Better training for staff will emphasize the importance of more individualized care.

One experiment is evaluating the outcomes of such efforts. Groark, Muhtemedrahimov, Palmov et al. (2005) have developed interventions in baby homes in St. Petersburg to see if the stability and social responsiveness of caregivers can be improved and whether the developmental progress of the infants can be promoted. The homes prior to the intervention were orderly but impersonal and the physical care sufficient but mechanical. They compared two active interventions with a no-intervention group. In the first experimental group, carers were helped to replace detached caregiving with more warmth and sensitive responsiveness. In the second group, structural changes only were made to increase the stability of caregivers to provide more continuity of relationships. Initial data (see www.education.pitt.edu/ocd/projects/russiaproject.pdf) have shown that significant changes were observed in the carers’ behavior and in children’s development (physical growth, psychological development and positive affect), but the full analysis comparing outcomes across groups is ongoing.

In a Romanian intervention study, Sparling, Dragomir, Ramey et al. (2005) established small groups with a familiar adult, stressing enriched educational activities. Significant developmental progress was demonstrated compared with usual institutional care controls. Zeanah, Nelson, Fox et al. (2003) are conducting a randomized controlled trial into foster family care as an alternative to institutionalization in Bucharest. Institutional children are being randomly selected into a newly set up foster care system and compared with those who remained in the institutions.

It is important to consider which features of early institutional care affect outcomes across a range of developmental domains. The specific contributions of inadequate nutrition, physical and sexual abuse, lack of play and stimulation, of opportunity for selective attachments and lack of personalized care need to be investigated. Further research, based on follow-ups from differing early care environments is needed in order to tease apart these influences.

Clearly, those families willing to take on the care of ex-institutional children need good evidence-based information on their likely life course plus relevant preparation and long-term support services (Groze & Ileana, 1996). Those families facing continuing difficulties should be encouraged to seek help from specialist child and adolescent mental health services for the assessment and treatment of complex developmental and social problems. There remains a great amount of institutional care internationally and warnings have been sounded that the AIDS epidemic will produce many more orphans where the family and community are not able to absorb them (Levine, 2000).

**Modern Residential Care and Children’s and Adolescents’ Mental Health**

Residential provision for children and young people, when defined most broadly, can embrace care settings with a variety of titles. In this chapter we deal with non-family settings that aim to provide care, protection and control, variously known as children’s homes, community homes or group homes. We will also deal with residential treatment centers that aim to provide therapeutic care for mental health needs and are specifically staffed and resourced to do so. However, severe problems can be found in each setting, because examples of major mental illness that have been missed can be found in social care settings (McCann, James, Wilson et al., 1996). Child and adolescent psychiatric units (see chapter 69), special residential schools (often for older disabled children; see chapter 74), young offender institutions (see chapter 68) and independent fee-paying boarding schools may all be seen as forms of residential care but are beyond the scope of this review.

Defining types of residential care can be problematic and even services carrying the same name (e.g., “residential group home”) will differ widely within and across countries, especially with regard to the size and characteristics of the resident population, the staffing ratio, typical length of stay, objectives and culture: all of which make for difficulties in making meaningful comparisons of “residential” outcomes. Residential care is clearly not a single entity, as the physical and psychological environment for the child is capable of considerable variation, with the quality of care likely to be the most important aspect. Furthermore, it is hard to judge the validity of classic studies conducted several decades ago when practices and attitudes may have been very different.

Reviews of residential care outcome studies have generally lamented both the small volume and modest quality of evaluative research (Bates, English, & Koudou-Giles, 1997; Foltz, 2004; Whittaker, 2000). Few studies have been conducted at Level One, that is employing experimental evaluation (see the York Centre for Reviews and Dissemination hierarchy of research designs), and most research is at Level 3, that is cohort studies without controls. The research requirements to answer “what works” questions are similar to those for other psychosocial interventions; namely, adequate sample size, random allocation to the intervention, appropriate and
CHAPTER 32

reliable multiple outcome measures across time, detailed identification of the intervention and fidelity in its application, appropriate statistical analysis and economic costing. The fact that such studies are rare is partly because of the ethical and logistical obstacles to be surmounted in randomly allocating children in “real world” settings to residential care or to alternatives. Most studies are therefore of single children’s homes, or study samples combining children from several homes, and employing within-group analysis of outcomes. Single sample designs do not, of course, permit conclusions about the effectiveness of residential care, but can be used to see which factors predict differential outcomes. However, even where controlled studies have been conducted in related areas, namely on young offenders and child and adolescent psychiatric inpatients, few differences in outcome have been shown on key measures. When benefits have been shown, the effect sizes have been small (Lyman & Campbell, 1996).

Unfortunately, experimental studies comparing different models of residential care would necessitate large cluster randomized trials and the cost may not fall within the budgets of the child welfare research funding agencies. In the near-absence of randomized controlled comparisons, the residential field has had to rely on culling the best information from existing studies, despite their limitations. The following studies have been selected because they have been conducted recently, thus reflecting current practice, and on relatively large samples.

### Group Homes for Children Designed to Offer Care, Protection and Control

This section deals with the population of children in countries where residential care is no longer used for younger children, but continues to be used for young people without available families or those who cannot live with, or be managed within, their own or a foster family. In the UK, the residential care population constitutes a relatively small, but high-risk and resource-consuming aspect of child welfare.

In the UK, most residents will be young adolescents showing very raised levels of social and emotional problems, and dysfunctional coping strategies (Meltzer, 2003). They are likely to have experienced abuse and/or neglect, to have been in previous failed placements, to have an ethnic minority background and may have been placed by virtue of being unaccompanied asylum seekers or refugees. Young people in residential care are also more likely to have physical or intellectual disabilities that may raise the risk for attendant mental health problems (Sinclair, 2005).

Given these problematic backgrounds, the staff of children’s homes are therefore confronted with numerous problems in managing the young people in their care. The home must carefully judge its protective response to the young people in relation to sexual exploitation, bullying, drug-taking and exposure to health risks. Conflicts are likely to arise in controlling disruptive behavior or threats against staff and in the application of restrictions, forms of punishment and physical restraint. Sometimes, these “care” and “control” principles are in conflict (e.g., when the “right” of a young person to abscond conflicts with the aims of the home to protect the young person from risk).

The heavy criticism of the quality of residential child care evidenced both by abuse inquiries (Utting, 1997; Waterhouse, 2000) and studies of the psychological needs and problems of residents has led many to the conclusion that residential care is ineffective, or at worst positively harmful, and resulted in a swing to a “family is best” ideology. This, combined with the cost, has made residential care a disfavored option and in many countries has led to the rapid run down of residential care places. However, the current literature reveals a spectrum of views on the future of residential care including advocates of high-quality selectively used facilities (Hellinkk, 2002; Pecora, Whittaker, Maluccio et al., 2000). Arguments in favor of residential care are that it is often the young person’s preference, that it can provide better support for educational progress for some and may remove the residents from the influence of delinquent peers in the community. Countries that have tried to do without residential care have had to pull back and recognize that family-based care can have its limits, may similarly result in abuse and that specialized and selective residential facilities are still needed (Ainsworth & Hansen, 2005). Further efforts need to be made to ensure that residential care provides a good quality, safe environment (Stein, 2006). This will include improving the vetting, selection, training and support of residential staff, guidelines on best practices and effective complaints procedures to expose institutional abuse.

Two recent studies have examined the outcomes of group home care. Sinclair and Gibbs (1998), in their study of 48 children’s homes in the UK, assessed the outcome of former residents against the effect of having been in what was characterized as a “good home.” This rating was an attempt to develop an overall measure of the social climate or culture by which the homes could be differentiated. Reports by staff and residents of high morale, friendliness and resident involvement were defined as a “good home.” However, having been in a “good home” was found to be unrelated to the outcome measures, particularly when the residents had moved from the home. They concluded that the beneficial experience was true only for their time as residents and did not relate to subsequent outcome. The lack of impact may have been because of the negative effect of the new environment they then entered and may argue for greater continuity of support and mental health intervention.

Scholte and van der Ploeg (2000) monitored the outcomes of 200 young people 2 years after admission to residential care. This was a social care setting in the Netherlands that employed some use of specialist psychological interventions. Those who left as planned had reasonable outcomes, whereas those who left prematurely had further developmental difficulties including problems of aggression and antisocial behavior as severe as before their admission. Factors predicting good outcome included the therapeutic climate of the home, use of cognitive–behavioral therapy, emotional support and “home
centeredness.” Subsequent negative post-care factors may undo the benefits of good quality residential care while a longer period in good quality care may lead to greater benefit. Better post-care support may help to sustain the positive changes.

Residential Treatment Centers
Several recent studies have examined the post-residential outcomes of specialized treatment programs for children. A US study (Connor, Miller, Cunningham et al., 2002) examined a psycho-educational program using individual and group therapy and medication for seriously emotionally disturbed children. One-third of the children showed improvement or stayed the same, but the remainder showed deterioration. Children with a high level of psychopathology at admission and children with abuse histories were more likely to be in the deteriorating group. Gorske, Sreabus, and Walls (2003) investigated the outcomes for 150 adolescents in residential treatment centers in Pennsylvania which employed a combination of psychological interventions. Most cases resulted in successful discharge. Those more likely to succeed exhibited less antisocial behavior, lived with family members prior to placement and were given a combination of treatments. Another psycho-educational program (Hooper, Murphy, Devaney et al., 2000), with a longer prospective design than most, found that 6 months after discharge, performance was rated as satisfactory for 68% but reduced to 29% by 24 months. This implies that, in future studies, the effect of the post-care environment will need to be evaluated.

Only limited conclusions can be drawn from follow-up from single settings. Studies that show positive outcomes may at first appear encouraging, but leave open the possibility of several explanations. The improvements could have occurred simply through maturation and development. Children in settings that were not studied could have benefited from other more cost-effective interventions. However, it can reasonably be concluded from within-group analysis that those with more adverse histories and more severe problems generally do worse; that continued involvement with a reasonably well-functioning birth family is a positive factor and that the post-discharge period is critical for positive development or for the re-emergence of problems. Where the outcomes were poor, it is possible that the residential care environment was not specialized enough to meet their needs.

Interest has recently turned to German and Scandinavian models in the search for improved quality of residential care (Cameron, 2004). The “social pedagogy” model, which emphasizes careworkers sharing the everyday lives of young people in residential services, placing educational aims more centrally and working with their families and the community in order to achieve effective integration into society, is likely to become more influential in the UK (Boddy, Cameron, & Petrie, 2005). This model is not directly comparable with UK services, however, as it has much better staffed and trained workers with higher remuneration. Rigorous evaluations of its effectiveness do not seem to have been conducted, or planned.

What is the Quality of the Evidence on Residential Care Environments?
Several points need to be made about conceptualization and methodological concerns in residential care research. First, it is evident that the terms institutional and residential care cover a broad range of environments in terms of severity and types of deprivation. It is misleading therefore to refer to the effects of residential care per se. The environment needs to be clearly examined as to the potentially negative and beneficial physical and psychological elements. Second, reliable data are often lacking about events and circumstances prior to admission to residential care. In building a comprehensive model of the factors leading to outcomes subsequent to residential care it is necessary to take into account not simply the degree of exposure to an institutional experience, but genetic inheritance, risk exposure during the pregnancy, perinatal and other pre-residential factors. These may all contribute, in combination with the residential care experience, to long-term development.

In addition to these prior factors, it is important to consider how long-term outcomes are mediated by subsequent events and how residential care experiences may have different types of adverse effect depending on the developmental age of the child. If the negative effects are reversible, or at least reducible, what is the capacity for adaptability of the individual, or constraints on making flexible responses to a changed environment?

Finally, is it possible to have a form of residential care that comes without the usual disadvantages? If resources allowed for the quality of the physical environment, nutrition and medical care to be raised to the highest standard, could paid non-related carers replicate, or approximate, the level of investment and involvement provided by most birth parents? The key test would be whether the quality of staff would be such as to provide consistent individualized care capable of promoting selective attachments.

Guidance for Practitioners on the Use of Residential Care
Evidence is often lacking to support clear-cut placement choices. However, children with repeated failed foster placements, high-risk behavior or strong opposition to family placement might well be better placed in appropriate residential care. Contact with attachment figures should be maintained where possible, while bearing in mind that children can have very powerful attachments to parents who are abusive and that further rejection, or re-involvement in the negative circumstances that led to care, might result from contact. Careful assessment of risk factors, and of the quality of current relationships with attachment figures, is necessary to counterbalance the presumption that contact is beneficial.

Providing Foster Family Care
Many children spend only a matter of weeks in public care. Such short-stay foster care placements are known to be a
helpful response at times of crisis or to provide a valuable short break during family hardship and stress. These placements commonly meet their aims, may prevent family breakdown and need not lead to serious distress for the children depending, of course, on how well the move and return are handled and the quality of the alternative care (Aldgate & Bradley, 1999). However, when a safe return home then becomes hard to achieve, the children may drift into becoming part of the longer-stay group.

Foster care is considered to be the preferred placement for children who have experienced family breakdown or maltreatment (Roy, Rutter, & Pickles, 2000), but of those so placed a significant proportion disrupts; that is, the child has to leave the placement in a manner that is not in accordance with the plans of the foster care agency or department. This is seen as one of the major flaws of foster family care. Rates of breakdown range from 20% to 50% and differ considerably according to the national context and placing agency (Minty, 1999). Ward and Skuse (2001) found that in the first year of care less than half of the children remained in the same placement although half of these moves were regarded as "planned transitions." We know virtually nothing about the effect of these planned moves on children's mental health. A recent meta-analysis suggests that the first 6 months of placement pose the greatest risk of breakdown (Oosterman, Schuengel, Slot et al., 2007). For all concerned, a precipitate placement ending is traumatic, not least for the child who then faces changes of school, community and friendships and is left with an uncertain future. When a child has experienced a series of placement disruptions, residential care may be seen as either the "end of the road" or as a relief from the pain of forming relationships that may fail again. Alternatively, the child may drift back to the birth family in the late teenage years, often with unsatisfactory results.

Efforts are currently being made to convert stable foster placements into adoption, but little is known about the proportion for whom this legal change is being achieved and with what outcome. It is likely that these placements will be more stable than stranger adoptive placements as positive relationships will largely have been established when the application to adopt is made (Barth, Berry, Yoshikami et al., 1988).

What are the factors associated with foster care stability? These are difficult to collate as studies use different samples, definitions of placement endings and different follow-up periods, but meta-analysis has demonstrated significant associations with behavior problems in the child, older age of the child at placement and a history of residential care (Oosterman, Schuengel, Slot et al., 2007). It has been alleged that transracial foster placements have negative effects on the children, especially in relation to identity and self-esteem. However, in the 1990s, Tizard and Phoenix's (1995) UK study of mixed parentage adolescents suggested that social class, school and peer groups exerted greater effects on racial identity than the ethnicity of their parents. Rushton and Minnis (1997) reviewed the comparative outcome literature on transracial placement and, although they did not find worse outcomes on standard measures, they did highlight the difficulties that may arise for the children of being separated from the community of origin. In the UK, ethnically matched placements are sought as far as this is feasible and within reasonable time limits.

Sinclair and Wilson (2003) found significant associations with outcome for the child wanting to stay in the placement, having high prosocial scores and low disturbance scores. Foster carer characteristics such as warmth and child-oriented foster carers were significantly associated with success. Further multivariate analysis attempted to examine the interactions between child and foster carer characteristics. They found that where foster carers are committed to the child, despite child disturbance, outcomes can be good, at least in the short term. In placements where the foster carers are less committed and the child has a high level of difficulties, outcomes are likely to be less successful. Reinforcing commitment as well as promoting parenting skills should both, in the light of this, be targets for support services. Clearly, policy needs to be directed towards greater recruitment of carefully selected foster families permitting more placement choice, more effective training, more intensive support for foster carers, promoting a skilled and committed children’s social care workforce. Increased financial rewards for foster parents have been shown to be related to retention rates and outcomes for the children and campaigns have been mounted to increase remuneration for foster carers (Chamberlain, Moreland, & Reid, 1992). The impact of such changes has not been subject to recent evaluation.

**What do we Know About the Mental Health of Children in Residential and Foster Family Care in Modern Child Welfare Systems?**

All studies have consistently demonstrated a high level of mental health problems in children in public care (Blower, Addo, Hodgson et al., 2004; Curtis McMillen, Zima, Scott et al., 2005; Dimigen, Del Priore, Butler et al., 1999; Halfon, Mendonca, & Berkowitz, 1995; McCann et al., 1996; Meltzer, 2003; Meltzer, Gatward, Goodman et al., 1999). Recent estimates suggest an approximately five-fold prevalence compared to the general population (Meltzer, 2003). These problems include some previously unrecognized major psychiatric disorders (McCann et al., 1996) and a high prevalence of both disruptive behavioral and emotional problems (Meltzer, 2003).

Recent work in the USA has demonstrated that nearly 90% of young children entering an episode of care, regardless of placement type, have physical, developmental or mental health needs, with more than half demonstrating more than one problem (Leslie, Gordon, Meneken et al., 2005). A key question here is whether the mental health difficulties of children in public care are a cause or consequence of that care. Harsh parenting and a tendency toward emotional overarousal (which may be inherited) interact in very early life to increase the risk of conduct disorder (Scaramella & Leve, 2004). Disruptive behavioral disorders are particularly linked with foster family breakdown (James, 2004; Leathers, 2002, 2006) and these disorders may test carers beyond their capabilities.
Adults need to guard against having lower feelings of self-worth and ambition. Securing the stability of engagement with the child’s education and the young person’s placement changes and breakdown, foster carers’ level of with peers and adults in the school setting associated with experiences on cognitive development, broken relationships ing in influencing poor progress are the effects of adverse carers for education support. Other factors worth consider- with 56% for the non-looked after population (DfES, 2005). It is not clear why this is so. One possibility is to do with the educational environment. However, studies in Europe and the USA indicate similar educational problems. A high-quality French study of young adults who had spent at least 5 years in foster care showed that two-thirds obtained no general educational diploma (a rate more than double the national norm). Poor educational outcome was particularly associated with learning difficulties before going into care (Dumaret, Coppel-Batsch, & Couraud, 1997). It may be that the stability of these long-term placements was important for children to achieve better educational outcomes, which suggests that poor educational outcomes may be associated with frequent changes of placement. One US study compared educational outcomes of high school and post-high school foster care youth matched with those living with their birth families (Blome, 1997). More educational disruption was evident for the foster care youth, a higher rate of school dropout, behavioral problems in school and less financial assistance from their carers for education support. Other factors worth consider- ing in influencing poor progress are the effects of adverse experiences on cognitive development, broken relationships with peers and adults in the school setting associated with placement changes and breakdown, foster carers’ level of engagement with the child’s education and the young person’s feelings of self-worth and ambition. Securing the stability of the foster care placement should therefore be a major aim, as well as striving for better collaboration between education and social services. Adults need to guard against having lower expectations of young people in foster care and to promote opportunities to remain in education. Research is needed to identify promising socio-educational interventions and to evaluate their impact. Improving academic achievement will be central to future employment prospects, to economic status, to life satisfaction and indeed to the mental health of the ex-care population.

**Comprehensive Assessment of Psychosocial Problems of Children in Public Care**

The current agenda is to understand how to achieve comprehensive assessments leading to effective interventions. No generally accepted, evidence-based model exists for assessing these children. Recent US research has shown that nearly 90% of children newly entering care placements have complex difficulties including mental health, academic and language problems (Evans, Scott, & Schultz, 2004) and other US evidence suggests that specialists are more successful than community practitioners at recognizing these multiple problems (Horwitz, Owens, & Simms, 2000). Despite this evidence, a recent US survey of national guidelines for the assessment of children entering foster care found that, in less than half of the areas studied, was there a requirement for comprehensive physical, mental health and developmental examinations of all children (Leslie, Hurlbur, Landsverk et al., 2003).

Achieving comprehensive assessment of children entering foster family and residential care is complex. Full assessment of child psychopathology usually depends both on current symptomatology and on developmental history and acquiring this information can be difficult, especially for a child who has recently been placed in a new foster or residential placement (Garwood & Close, 2001). Foster carers or residential workers may be able to report on current symptoms, if they have had time to get to know the child, but may have little information on early developmental milestones. Timing of assessment is also important. Many commonly used measures of psychosocial functioning have been normed in the general population and are designed neither to detect problems in recently traumatized children nor to discriminate between ongoing psychopathology and adjustment reactions.

In addition to the assessment of conventionally recognized mental health problems, the child’s current relationship functioning needs to be considered. In an innovative project in Louisiana, every child coming into foster care under the age of 4 years has a comprehensive assessment by a specialist Infant Mental Health Team (Zeanah, Larrieu, Heller et al., 2001). The assessment consists of face-to-face contact with the child and each important caregiver such as birth parents, foster carers and child care providers. It includes home- and clinic-based observations, interviews and self-report measures designed to identify strengths and weaknesses in children and families. In a quasi-experimental design, this group has shown that the assessment package, plus an intervention designed to

RESIDENTIAL AND FOSTER FAMILY CARE
help parents accept responsibility for their maltreatment, significantly reduces the recurrence of maltreatment of children who return home and significantly reduces maltreatment of subsequent children by the same parent. Interestingly, the rate of freeing for adoption was also increased in the group receiving intensive assessment and treatment, suggesting that the assessment allows a clear decision to be made regarding the viability of the child-birth family relationship.

In the UK, many new specialist mental health teams for children in foster and residential care have been developed over the last few years, but models of assessment and treatment vary from teams that offer mainly consultation, to those that offer detailed assessment of the child in the family context. Although studies comparing different models of assessment are rare in this population, there is evidence that problems are commonly missed in this group (Evans, 2004; Horowitz, Bell, Trybulski et al., 2001; McCann et al., 1996). This, and our clinical experience, would lead us to recommend that there should be a thorough assessment of the child’s strengths, interests and potential protective factors that could be built on, all areas of psychopathology, speech and language functioning and the quality of attachment relationships. Because educational difficulties are so common in this group, we would strongly recommend full cognitive and educational assessment even when problems are not suspected.

### Interventions to Improve the Mental Health of Children in Public Care

#### Interventions in Residential Settings

Long-standing problems exist in recognizing mental health problems in the residents of children’s homes, and despite the call for greater involvement of specialist child mental health services, few projects have been evaluated. Many problems are potentially treatable by a range of psychological interventions. The efficacy of such interventions has been reviewed by Fonagy, Targett, Cottrell et al. (2002) but there is a lack of evidence on the extent to which modifications may be needed when applied in the context of residential care. In considering how to achieve greater access to evidence-based interventions, residential care managers and practitioners will need to assess which staff members with what levels of experience and skill might use these interventions. Many aspects of the children’s and young peoples’ lives will be different in the residential care context so that individual, group- and family-based approaches may need to be thoughtfully adapted.

The quality of the relationship between staff and young people is likely to be a major factor in promoting positive mental health. The rationale is that supportive and containing relationships between young people and staff can contribute to ameliorating past negative relationships (Berridge, 2002; Moses, 2000). The residential careworkers may be the best target for providing training, support and mental health consultation because they are likely to have the greatest influence in helping the young person to develop self-understanding and prospects for change (Wilson, Petrie, & Sinclair, 2003). Careworkers need skills in managing oppositional behavior and aggression, containing the expression of powerful feelings as well as understanding the underlying problems in order to shape their response more appropriately. However, little evidence has so far emerged to show that improving the skills and knowledge of the staff can have a beneficial impact on the resident, both during and after residential care. The external residential consultant will need to respect the stresses that fall on, frequently young, residential staff providing 24-hour care. The mental health consultants can help the staff of a residential home to have a greater understanding of the possible origins of a young person’s current difficulties and to help staff to adopt rational management strategies. They can identify the type and severity of disorders and recommend appropriate treatment, based either in the home or in the clinic.

#### Interventions in Foster Family Care

There has been a sea change, at least in the UK and USA, in attempts to intervene with the psychosocial difficulties of children in public care. The accumulating evidence regarding placements themselves (Sinclair, 2005) and about these children’s difficulties, along with a realization of the need for co-ordination between different agencies (Callaghan, Young, Pace et al., 2004; Racusin, Maerlender, Sengupta et al., 2005), has stimulated the development of teams whose remit is to provide specialist intervention for these children. Interventions tend to fall into two main categories: symptom focused or systemic (Racusin et al., 2005).

However, considerable variation still exists in the provision of child and adolescent mental health services for such children (Callaghan et al., 2004; Leslie, Gordon, Meneken et al., 2005; Minnis & Del Priore, 2001). Some of the most vulnerable children do not access child and adolescent mental health services (CAMHS) because of their mobility through placements, a tendency for social workers and foster carers not to refer on despite recognition of problems or, once referred, their mental health profile not fitting with conventional diagnostic criteria used in CAMHS (Callaghan, Young, Pace et al., 2004).

Because almost all children in public care have suffered disruption of attachments and been maltreated, an obvious focus for intervention is attachment relationships. Maltreatment (Carlson, Cicchetti, Barnett et al., 1989) and institutional care (Vorria et al., 2004) are both strongly associated with disorganized attachment but, in addition, unusual attachment patterns are common in children adopted from institutions (Chisholm, 1998; Marcovitch, Goldberg, Gold et al., 1997; O’Connor & Zeanah, 2003a). Reactive attachment disorder (RAD) describes a constellation of social behavioral abnormalities, including: (i) disinhibition with strangers; or (ii) inhibited, hypervigilant or highly ambivalent reactions (American Psychiatric Association, 2000) and, although the research database is scant, there is now research on both institutionalized (Boris, Zeanah, Larrieu et al., 1998; Boris, Hinshaw-Fuselier, Smyke et al., 2004; Chisholm, 1998; O’Connor &
Zeanah, 2003b; Smyke, Dumitrescu, & Zeanah, 2002) and otherwise maltreated groups of young children (see chapter 55; Boris et al., 2004). RAD and insecure attachment patterns are different entities and it is possible to have RAD yet an apparently secure attachment with the current caregiver.

Placement in a stable family environment is a major intervention in itself (van IJzendoorn & Juffer, 2006) and there is evidence of the development of attachments between children adopted from institutions and their adoptive parents (Chisholm, 1998; O’Connor & Zeanah, 2003a). A study of children placed in foster care in Romania from institutions showed a reduction in RAD symptoms, compared to controls. After around 18 months, there was no difference between foster care and never-institutionalized comparisons for emotionally withdrawn/inhibited symptoms whereas disinhibited symptoms persisted, albeit in a reduced form (Zeanah & Smyke, 2005). Conversely, the development of secure attachment in foster care seems to depend more on the foster carer’s “state of mind” with respect to attachment than on the child’s history (Dozier, Lindhiem, & Ackerman, 2005), so the story is far from simple.

Zeanah’s group in New Orleans (Zeanah & Smyke, 2005), and Dozier’s group in Delaware have developed intervention packages to help children and new foster carers develop attachments. Barriers to attachment in the child can include regulatory, psychosocial and developmental problems, an internal working model of relationships as being inconsistent and conflicting loyalties between birth parents and foster carers (Zeanah & Smyke, 2005). Foster carers may present their own barriers related to their own experience of parenting and child care and to their experience of, and attitudes towards, fostering. Dozier, Lindhiem, & Ackerman (2005) found that foster mothers with dismissing and unresolved states of mind with respect to attachment were likely to have infants with disorganized patterns. They conclude that it is easier for a child in foster care to organize his or her attachment system if the caregiver is nurturing and is autonomous with respect to his or her own attachment history. A key goal of treatment therefore is to assist foster carers to become the person the child goes to when distressed. In order to achieve this, both the New Orleans and Delaware teams aim to support foster families to provide a safe and predictable environment, help the child regulate emotions, understand the child’s (often confusing) signals and provide nurturance even in the face of avoidance from the infant (Dozier, Lindhiem, & Ackerman, 2005; Zeanah & Smyke, 2005).

More intrusive therapies, previously called “holding therapies,” have been used in an attempt to treat RAD and great concern has been raised because of certain particularly coercive forms that resulted in child deaths (O’Connor & Zeanah, 2003a). Some therapists who came from this tradition have now explicitly stated that they no longer use coercive techniques and small-scale research suggests clinical benefits from what is now called dyadic developmental psychotherapy (Becker-Weidman, 2006; Hughes, 2003). These methods require adequate evaluation for both effectiveness and safety.

There have now been a number of randomized controlled trials (RCTs) evaluating training of foster carers to be agents of therapeutic change for the child. For example, two UK studies have used the RCT design to evaluate group-based interventions with foster carers aimed at improving parenting and, hence, children’s emotional and behavioral functioning. One used an attachment-based model (Minnis & Del Priore, 2001) while the other used a cognitive–behavioral model (Macdonald & Turner, 2003). Overall effect sizes were small and non-significant with respect to changes in the children, despite carers reporting benefits from the interventions in both cases. The interventions may not have been intensive enough, or insufficiently targeted on the specific problems or not followed through tenaciously enough with the carers to produce significant change in the children, although all changes were in a positive direction. It seems counterintuitive that group interventions should be effective in vulnerable populations (Scott, Spender, Doolan et al., 2001) yet apparently less effective in foster care. One possible explanation may be that foster carers are already engaging in effective parenting practices so that effect sizes will inevitably be small compared to families in which there is greater scope for change. Furthermore, foster care training, while important, is a minimal intervention when the complexity of children’s lives and difficulties is considered and should be seen as part of a comprehensive package of support to foster families.

A number of promising developments in the UK include the Coram Family adaptation of Webster-Stratton’s Incredible Years program for the fostering population (Henderson & Sargent, 2005), publication of the comprehensive Fostering Changes manual (Pallett, Blackey, Yule et al., 2005) and pre-post study (Pallett, Scott, & Blackey et al., 2002) and Rushton, Monck, Upright et al’s (2006) RCT comparing behavioral and educational parenting interventions with social work support service as usual.

**Treatment Foster Care**

Treatment Foster Care (TFC) is not just a more specialized form of foster care but a treatment in itself and an alternative to psychiatric inpatient treatment or incarceration (Meadowcroft & Thomlison, 1994). Although there are various treatment foster care models, the best known and best evaluated is multidimensional treatment foster care (MTFC; www.mtfc.com). MTFC is a multimodal approach in which foster carers receive extensive pre-service training and ongoing consultation and support from program staff. Children receive individual therapy and birth parents or other permanent placement resources receive parent training.

RCTs from the Oregon Social Learning Center indicate that MTFC, when delivered to antisocial children who then return to their birth families, had a modest positive effect on behavior problems and on other psychological outcomes such as self-esteem and had large positive effects on social skills (Reddy, Hay, Murray et al., 1997). MTFC is currently being evaluated in 20 local authorities in the UK.
Although MTFC initially developed to provide an alternative to secure accommodation/incarceration for delinquent adolescents (Chamberlain, Price, Reid et al., 2006; Clark, Prange, Lee et al., 1994), more recent modifications for preschool children have also demonstrated success, particularly in terms of securing permanent placements (Fisher, Burraston, & Pears, 2005).

In the Oregon MTFC model, for both adolescents and preschoolers, key elements of the program include foster carers having daily telephone contacts in which the child's progress is reviewed systematically, weekly foster parent support group meetings and 24-hour on-call crisis intervention. Children have services of behavioral specialists who work in preschool or daycare and at home, and children attend a weekly therapeutic playgroup. A consulting psychiatrist provides medication management. When the child enters a permanent placement, a family therapist works to train the parents in the same parenting skills as foster carers, whether the birth parent, relative or non-relative adopter. The training, for both foster carers and permanent carers/parents, emphasizes encouragement for pro-social behavior, consistency, non-abusive limit setting and close supervision of the child. The preschool program also follows a developmental framework of helping carers understand delayed maturation and the program attempts to create optimal environmental conditions to facilitate developmental progress including a responsive and consistent caregiver and a predictable daily routine with preparation for transitions between activities (Chamberlain, 1995).

The apparent success of TFC has prompted recent calls, in the USA, for an end to the use of “shelters” or “safe houses” where group care is used for crisis management, assessment and planning for children requiring substitute placements (Barth, 2005). Recent research has shown that ordinary foster care is superior to such group care (DeSena, Murphy, Douglas-Palumberi et al., 2005) and that TFC is superior for the most vulnerable children to ordinary foster care (Chamberlain & Reid, 1998), although this has not yet been proven for maltreated children who do not have serious mental health problems or risky behavior.

Despite the evidence for TFC, its implementation in practice is not always easy, especially if placement goals are unclear. It requires a high level of co-ordination of services and success may depend on the ability of the model to span the multiple systems involved in these children's lives (Meadowcroft & Thomlison, 1994). There has been considerable focus on risk behaviors, such as violence, as an outcome measure of TFC (Chamberlain & Reid, 1998; Hahn, Lowy, Bilukha et al., 2004), but this may not always be in the best interests of the child. In an evaluation of an intensive foster care scheme in Scotland, tensions were evident between social services' desire to use the scheme for the reduction of risk behaviors before moving on to less intensive (and less costly) placements, and the desire by social workers, foster carers and young people themselves to allow young people to develop stable relationships rather than move on quickly (Walker, Hill, & Triseliotis, 2002).

Leaving Residential and Foster Family Care

Although this chapter might strictly concern the period children spend in residential or foster family care, the importance of the transition out of care and into independence must be recognized and will be referred to briefly in relation to recent UK studies. Clearly, the nature of childhood experiences prior to and during care will affect progress after care. As most young people leave care at around 16–17 years, they have to face the challenges of independent living earlier than their peers. Although a proportion of care leavers do well, those with worse outcomes are likely to have unstable living arrangements, difficulties in personal relationships, poor social networks, lack of involvement in education and training opportunities, unemployment and poverty. Coping with early pregnancy and parenthood is a common challenge. Black and mixed heritage children leaving care may have more difficulties in contact with family and community and difficulties are compounded for disabled children. Biehal and Wade (1996) showed that older ex-care young people rarely return to their birth families, at least not in the short term. Good relationships with them are often irretrievable following histories of abuse, neglect and rejection. Some young people, but by no means all, maintain continuing relationships with their foster parents, but this is less so with residential care staff.

Leaving care schemes, mentoring and personal adviser projects designed to help in the transition to adulthood and independence have been developing and are beginning to be researched, but specified interventions to improve post-care life chances have not yet been rigorously evaluated (Dixon, Wade, Byford et al., 2006). Prospective studies are needed comparing matched groups receiving contrasting leaving care services and followed up at multiple time points.

An important part of post-care services should be to attend to mental health needs by more intensive psychological interventions with special concern for problems of identity and self-esteem, establishing and sustaining social relationships, developing interpersonal problem-solving skills, managing emotional problems and controlling drug and alcohol use. Problems in providing accessible, acceptable mental health services to this group have been highlighted (Broad, 2005) and more progress is needed in promoting links between care leaving projects and specialist child and adolescent mental health services.

Comparative Outcomes and Costs and Future Directions

Studies Comparing Residential and Foster Family Care Outcomes

It has not been possible to provide definitive answers as to the differential effectiveness of residential and foster family care. The review of studies by Curtis, Alexander, and Lunghofer (2001) highlighted the methodological weaknesses in studies...
that have attempted to compare out-of-home care outcomes. The study by Chamberlain and Reid (1998) of adolescent delinquent boys is one of the very few to compare TFC with community-based group care using randomized allocation. It was established that the groups were equivalent on key variables, although the foster care group received more therapeutic help. More positive outcomes were recorded for the TFC group, including less criminality a year after discharge.

The study by Roy, Rutter, & Pickles (2000) has helped to tease out the effects of prior problems from the effects of being in care by studying children from similar social environments who experienced contrasting “in care” child rearing environments: either residential or family foster care. Both groups were compared with classroom controls and although both were more prone to hyperactivity/inattention, such a problem was substantially more marked in the group who had experienced residential care. The same applied to scholastic achievement (Roy & Rutter, 2006). A picture is emerging that genetic risk, early environment (both pre-care and state care environments) and poor educational provision may interact to compromise educational progress (Roy, Rutter, & Pickles, 2000). This in turn may have a negative effect on self-esteem and life chances.

The Odyssey Project (Drais-Parillo, 2006) examined a large sample of over 2000 children and young people in either residential group care (RCG) or TFC on assessment, at admission, at discharge and 6, 12 and 24 months post-discharge. The RCG group was found to be older, more likely to be male, more ethnically diverse, with more psychiatric and criminal history. Although fairly good outcomes were reported for both groups, major sample attrition compromised the ability of the study to make valid post-discharge statistical comparisons.

When definitive evidence is lacking, practitioners involved in making placement choices for young people will need to apply flexible decision-making, sensitive to the needs of the individuals. The quality of the care environment and the population residing in each placement type will need to be taken into account in making these choices.

One recent study examined placement alternatives for children orphaned as a consequence of violence in Iraqi Kurdistan (Ahmad, Qahar, Siddiq et al., 2005). Those placed in traditional foster care (n = 94), indicating integration of the child into the family, mostly kin, were compared with orphanage children (n = 48) living in impersonal and regimented group care, but where contact with birth family members could occur. Efforts were made to achieve comparability of the groups on other factors. The mean age of the children was 11 years and 1 and 2 year follow-ups were conducted. Similar outcomes were found on many measures, including some deterioration, but improvement in problem profiles and traumatic stress scores after 2 years were found to be more significant in the foster care than the orphanage sample. The authors concluded that foster care provided more suitable conditions (“a natural family atmosphere”) and that the best policy was to support foster families rather than to build more orphanages.

Cost-Effectiveness

Considering estimates of costs alongside evaluations of effectiveness of psychosocial interventions is becoming more common and will deliver more useful evidence for service providers. (DeSena et al., 2005; Knapp, 1997; Minnis, Everett, Pelosi et al., 2006). In a recent study of costs in foster care, a tiny minority of children were found to be attracting a disproportionately high level of services and costs (Barth, 2005; Minnis et al., 2006). It may therefore be necessary to accept that the few most vulnerable children will require very expensive services.

A recent cost-effectiveness comparison of placing children in group care versus family foster care placements in the USA has shown that family foster care is both more effective in terms of placement stability and considerably cheaper (Barth, 2005; DeSena et al., 2005). Residential care in the UK has been claimed to be seven times more costly than comparable foster care (Polnay, Glaser, & Dewhurst, 1997), but when full comparative costing is undertaken, including education, a smaller, four-fold difference has been reported (Curtis & Netten, 2005). Current average costs for statutory and non-statutory residential care are in the region of £118,000–121,000 per resident per year. TFC has been shown to be expensive, but cost-effective for very disturbed adolescents (Chamberlain & Weinrott, 1990). Foster family care may be cheaper and produce better outcomes in general, but where family-based care is not tenable, high-quality expensive well-targeted residential care may be the best option for some young people (Barber, Delfabbrol, & Cooper, 2001).

Future Directions

The evidence base is often lacking in order to support specific practice guidelines for out-of-home care. As little assessment has been made of the long-term adaptation of children once placed in out-of-home care, this hampers the ability to select the most promising placement according to the characteristics and history of the individual young person. Future studies, rather than simply comparing residential care with foster family care, could be conducted on appropriate sequences of residential and family foster care used flexibly and as required.

However, we have sufficient findings about the mental health problems of this group of children to push forward with high-quality assessment linked to appropriate interventions. In the past, children in public care have had their mental health needs neglected and a major task is to ensure that these children have proportionate access to services. Interventions need to be evaluated using gold standard research techniques. At present, the gold standard is considered to be the RCT with health economic evaluation and, despite the logistical and ethical challenges of such research, attempts must be made to achieve this. Promising practices and service developments need to be defined more precisely and the specific characteristics and intensity of the approaches identified. Without this, effectiveness trials will be uninformative.

In addition to intervention studies, more information is needed on how outcomes of foster and residential care
CHAPTER 32

compare with matched cases living in birth families with similar pre-care backgrounds. More research is needed to reveal the complex interactions of factors that predict placement outcome. More needs to be known about how long it takes, and to what extent, children with disadvantaged or abusive circumstances can catch up with their peers once placed in good quality out-of-home care. Further research is needed to reveal what principles and procedures should be followed for matching carers and children in order to produce the best outcomes.

Despite efforts to keep children out of care, keep their families together, intervene early on when there are signs of poor quality or abusive parenting and conduct a wider search for possible placements with extended family and friends, some children will need to be cared for by the state and looked after by strangers. An expanding research base is needed on what kinds of placements produce what kinds of outcomes and for which children. This should strengthen the capacity for practitioners to make rational placement decisions and service providers and policy makes to extend the range of good quality placements.

CHAPTER 32

Adoption is an increasingly common means of forming a family. Most broadly, it has contributed to a redefinition of the essential features of the nuclear biological family and come to be intertwined with other trends in family formation such as step-parenting, kinship care, parenting by gay and lesbian couples, and use of assisted reproductive technologies. These trends have raised some of the same issues as confronted by adoptive families such as the relative contribution of genetic, biological, social and psychological factors to child development. They also have translated the definition of family from a biological and ethnocultural concept to one that emphasizes family as psychological parenting of a child. Moreover, with the increase in open adoptions and the more rapid movement of children from foster care to adoption, many adoptive families are, in essence, multiple families with birth parents and sometimes extended birth families, maintaining contact with adopted children and their families over time. Searches for birth parents and reunions of adopted adolescents and adults are also increasingly common and represent another way that birth and adoptive families connect.

The chapter begins with an update of these trends in adoption practices and families created with the help of assisted reproductive technologies. It then goes on to discuss the outcomes of domestic and intercountry adoption. Finally, both post-adoption and clinical services are discussed, highlighting the increasing attention paid by the professional community to adoption-related issues.

Contemporary Trends in Adoptive Family Formation

Sources of Children for Adoption

For some time there has been a decline in the number of infants available for adoption domestically, accounted for by greater prevalence of single motherhood and legal avenues to control reproduction through birth control and abortion. This is coupled with a greater demand for children related to infertility associated with delayed childbearing and greater acceptance of non-traditional parents who are single, gay or lesbian.

In comparison with domestic adoption, intercountry adoption continues to grow worldwide. Intercountry adoption originated with efforts to rescue children victimized by epidemics and other calamities such as war. More recently, intercountry adoption includes children abandoned because of poverty and population control policies and is now motivated by preference for adopting infants and/or children without apparent special needs and children who are not observably racially different, and for adoptions that are fully closed.

The most recent estimates indicate that more than 40,000 children are adopted worldwide each year from over 100 countries (Selman, 2002). An important historical event was the establishment of the Hague Convention in 1993, which set out minimum rights and procedures for intercountry adoption. Thus, whereas the earlier years of intercountry adoption were clouded by irregularities in procedures and shady practices such as child abduction and trafficking of infants, procedures have become more regularized and integrated with those of the agencies or governments in countries where adoptive parents reside.

The needs of children being adopted have also changed. Prior to the 1990s, most intercountry adoptees came from Korea, which had a high standard of living and health care, and where children were cared for in foster homes (Johnson & Dole, 1999). Subsequent sending countries have not had such high standards. Typically, children have lived in institutions and experienced some degree of deprivation, which affects all areas of functioning (Gunnar, Bruce, & Grotevant, 2000). Currently, most international adoptions to the USA are from China, Russia, Guatemala, South Korea and Kazakhstan whereas most international adoptions in Europe are from China, Russia, Colombia, Ukraine and Bulgaria. To counteract the effects of deprivation, there has been a move toward increasing opportunities for foster care and implementing programs to improve the caregiving and environmental conditions within orphanages (Groark, Muhamedrahimov, Palmov et al., 2005).

Open Adoption

Up until 35 years ago, severing ties with the birth family was a natural prerequisite for forming an adoptive family. In this way, the genetic and psychological heritage of the adoptee was minimized in favor of adoption kinship. This practice also meant that members of the adoption triad (i.e., the birth parents, adopting parents and adopted child) were protected from the
perceived stigma of adoption by the confidentiality of the adoption process. The intention was to create a situation in which all members of the adoption triad could get on with their lives. The reality proved to be otherwise and since the 1970s a gradual movement toward greater openness emerged, largely spearheaded by birth mothers. Some degree of openness in domestic adoptions is now becoming the norm rather than the exception (Grotevant & McRoy, 1997).

The term “open adoption” typically applies to adoption of infants and refers to a continuum of contact and communication among members of the child’s adoptive and birth families (Grotevant, 2000). Openness became increasingly more possible since fewer infants were available for adoption and birth mothers could have a say in choosing the adoptive parents. Openness has been allowed to take various forms, although laws related to openness vary in different jurisdictions. At one end of the continuum are fully open adoptions that allow contact and communication directly between birth and adopted children and their families. There are also mediated arrangements where contact occurs through a third party, such as an adoption agency, without identifying information. At the other end of the continuum are fully closed adoptions where there is no contact, communication or shared identifying information. Once established, these arrangements are not carved in stone and it may be necessary to change contact arrangements over time (Berry, Cavazos Dylla, Barth et al., 1998). It is important to acknowledge that openness has been a negative experience for some adoptive parents who prefer closed adoption or who are repeatedly not chosen by the birth mother to parent her child.

In order for openness to work, commitment, communication, flexibility and mutual respect on the part of both adoptive and birth parents are necessary (Grotevant, 2000). The best outcomes ensue when adoptive parents demonstrate high levels of empathy and sensitivity towards the child and the birth parent and are motivated to help the child integrate past and present experiences (Neil, Beek, & Schofield, 2003). This seems obvious but may be more difficult to keep in mind if rough spots in the relationship emerge. Ultimately, the arrangements must benefit and support the child. Mediated open adoption remains the most predominant arrangement (Henney, McRoy, Ayers-Lopez et al., 2003). There are practical implications for adoption agencies in that supports for educating birth and adoptive parents, mediating openness arrangements (e.g., amount and schedule of contact), and providing ongoing services to both birth and adoptive parents must be established (Maynard, 2005).

It is still not clear what factors need to be taken into account and how to decide the best level of openness for a particular triad (Fralvel, McRoy, & Grotevant, 2000). In a follow-up study of adolescents, Mendenhall, Berge, Wrobel et al. (2004) found that adolescents involved in adoptive arrangements in which there was contact with birth parents maintained higher satisfaction with contact status than those who did not have contact. Moreover, although many adolescents did not have contact with their birth fathers, when they did it was a positive experience. The benefits of openness, however, have not been fully established. Much of the research on openness has been carried out with infants who are relinquished voluntarily and there is little information on contact among groups of children and adoptive parents who were involuntarily removed because of abuse or neglect. Openness can be detrimental when birth parents make unrealistic promises or continue to perpetrate the physical and psychological abuse that led to the child’s removal in the first place. Although not specific to adoption, it has been shown that outcomes are worse when children continue having contact with violent fathers (Jaffee, Moffitt, Caspi et al., 2003).

In a recent review, Rushton (2004) summarized the limited studies indicating that contact can be managed by adoptive families if they feel that they have control over the situation. Research on openness in older children in foster care who are adopted also suggests some benefits in promoting the child’s ability to accept the adoptive family and resolve the child’s loyalty conflicts. Given the increasing move from foster care to adoption, which is discussed next, more research is clearly needed.

It is also important to acknowledge that there are many children for whom openness is not possible, most obviously, children adopted from other countries, and domestically adopted children whose birth parents have chosen closed adoption or where contact has been lost because the birth parent has died or disappeared (Sullivan & Lathrop, 2004). Brodzinsky (2005) has suggested that, in these cases, openness can be conceptualized in a different way as a state of mind rather than a concrete event. It is important to all adopted children to know that there is an openness in their adoptive families to actively consider the impact of adoption in their lives and on their emotions and affective attunement (Brodzinsky, 2005; Leon, 2002).

**Moving from Foster Care to Adoption: Adoption with Contact**

Current trends show an increase in the number of both infants and older children entering the foster care system and the length of time they spend there (see chapter 32; Shapiro, Shapiro, & Paret, 2001). These children often have been abused, neglected or otherwise stressed and traumatized. Some children are in and out of foster care and their birth family home numerous times before permanent plans are made. The numbers of children in foster care are of tremendous concern because they are more likely to exhibit behavioral and emotional problems (Simmel, Brooks, Barth et al., 2001). Historically, the policy for permanency planning was to return children to their family after steps were taken to ensure the child’s safety. Often this means that children remained in the limbo of foster care for years, sometimes growing to maturity in that environment or making repeated moves from their birth family to foster care. More recently, at least in the USA, the best interests of the child have begun to take priority such that permanency planning has been hastened toward adoption. About two-thirds of children are adopted by their unrelated...
CHAPTER 33

foster parents, which means that they experience continuity in relationships, 15% by relatives and 23% by families they have never known (Shapiro, Shapiro, & Paret, 2001).

Because openness in adoption is generally more accepted, older children may have some limited contact with birth parents or information that can flow both ways. Approximately 15 years ago, Triseliotis (1991) made a strong case for adoption with contact with birth parents, drawing a parallel with findings indicating that children’s adjustment following divorce is related to consistent and ongoing relationships with both parents who are able to cooperate. When children lack contact, they also may continue to worry about their birth family. Opposing arguments usually claim that continuing contact will interfere with the child’s bonding to the new family. Where children have suffered severe abuse within the birth family, the question remains as to whether contact eases or is disruptive to adjustment in the adoptive home (Freundlich, 2002). There is some evidence that the time in foster care is shortened and the number of different placements reduced when a child advocate or caseworker oversees the child until permanency planning is achieved (Calkins & Millar, 1999).

Kinship Care

Care by family members is a long-standing tradition for children whose parents have died or could not meet their children’s needs. Use of kinship care has increased and is now used more frequently to reduce or eliminate a child’s stay in foster care. It has become part of the formal child welfare system associated with permanency planning (Brooks, 2002; O’Brien, Massat, & Gleeson, 2001). Kinship care has come about with changes in laws that permit family members to become foster parents and thereby gain financial support for care, the push toward rapid permanency planning, and the desire to keep children within their extended family and in the same ethnic and cultural community. For all of these reasons, on the surface, kinship care seems like an optimal solution. In the USA, children of color are most likely to be taken into public care, especially in ethnic or poor families. There are potential problems, however. For instance, children’s physical health and mental health are at risk if early experiences have been traumatic. Sometimes, family members have contributed to abuse directly or as part of an intergenerational pattern that may be repeated. There also is a risk that standards for placement are lower for kinship placements and that monitoring and services are not as complete as for foster care (Farmer, 2006). Furthermore, kin carers may have multiple stresses of their own that will impact directly on the child, and especially the capacity to cope with grieving and vulnerable children who may have a history of mistrust. Some kin carers do not even know the children who are suddenly thrust into their lives.

Intervention with intergenerational families is often complex because individual, family and societal factors are at play. Both professional and financial supports are frequently necessary to stabilize the household (Burnette, 1999). Just as in any adoptive or foster situation, the quality of earlier experiences influences those that follow. The kin carers and the child must deal with loss while taking into account that the relationship with the birth parent may continue in some way and be an ongoing source of distress and disruption. Establishing an alliance with kin carers can be difficult for professionals because of issues of trust related to fears about loss of children into public care, especially in ethnic or poor families. Research has identified poverty, isolation, mental and physical health problems and high stress to be related to the degree of kin caregiving burden (Burnette, 1999). Generally, there is less support for kinship carers than for foster and adoptive families so that development of outreach services is an important undertaking.

Transracial Adoption

Transracial adoption is a long-standing controversial issue that remains salient in the public eye, and within some racial groups, despite research showing little reason for concern from the child’s or family’s perspective. Earlier research on this topic was largely focused on White family adoption of Black children but the racial mix in most countries has expanded, partly as a result of intercountry adoption. In a review of the literature, Lee (2003) noted that ethnic minority adoptees are portrayed as passive rather than active participants. Research typically asks about the impact of racial and ethnic experiences rather than the more important question of how adoptees act on their environment to negotiate identities and their place in society which, in the long run, is more important. Four patterns or strategies emerged from the literature that adopted children and their families pursue:

1 Cultural assimilation, in which adoptive parents reject or downplay differences;
2 Enculturation, which involves adoptive parents acknowledging differences within the family which promote children’s learning about their birth culture and heritage;
3 Racial inculcation, which involves adoptive parents teaching coping skills to facilitate their children’s capacity to deal effectively with racism and discrimination; and
4 Child choice, wherein adoptive parents provide their children with cultural opportunities but ultimately abide by their children’s interests (Lee, 2003).

Longitudinal research has shown that, based on parent report, adjustment problems are no more common in adulthood among transracial than in racial adoptees (Burrow & Finley, 2004; Tizard & Phoenix, 1995). In the USA, a 19-year follow-up study of transracial adoptees as young adults indicated that females were better adjusted than males, and individuals adopted from Asia adjusted better than either African-Americans or Caucasian domestic adoptees. When international and domestic adoptions were combined, African-American males were most prone to adjustment problems but inracial adopted Caucasian males had the worst outcomes (Brooks & Barth, 1999). Meta-analytic studies of intercountry adoption indicate that most transracial adoptees, domestic
or international, do not have serious behavioral or emotional problems (Bimmel, Juffer, van IJzendoorn et al., 2003; Juffer & van IJzendoorn, 2005). Bimmel et al. wisely point out that there is heterogeneity across samples and differences in conditions in various countries, adoption procedures and age at arrival. Thus, there may be subgroups of youngsters at greater or lesser risk for development of adjustment problems, making report of overall percentages unhelpful.

Racial and ethnic identity development also varies according to children’s age and social and emotional development. Transracially adopted pre-adolescents tend to identify with birth cultures. For adolescents and adults, sense of race and ethnicity generally diminish but may become more ambivalent in some cases and more salient in others (Lee, 2003). When racial and ethnic experiences are positive, they contribute to good psychosocial adjustment (DeBerry, Scarr, & Weinberg, 1996). This is especially so when adoptive parents actively promote their children’s ethnic culture (Yoon, 2001). Some benefits also accrue to adoptive families living in racially heterogeneous communities (Feigelman, 2000).

Contrasting results have been reported by Cederblad, Hook, Irhammar et al. (1999), who found that self-perceived negative racial and ethnic experiences were related to behavior problems, emotional distress and low self-esteem among transracially adopted youth in Sweden when family functioning and structure and support from friends were taken into account. Consistent with this, Hjern, Lindblad, and Vinnerljung (2002) found that rates of psychiatric disorder and social maladjustment were higher among transracial adoptees and immigrants than domestic adoptees and the general population. In Holland, Juffer, Stams, and van IJzendoorn (2004) found that adopted children’s wish to be White uniquely predicted mother-reported behavior problems. Such findings raise the question of whether there are national differences dependent not only on a history of racism, but also attitudes toward immigrants.

From a clinical perspective, the takeaway message is that there is considerable variability in the psychological experiences and psychological adjustment of transracial adoptees which are dependent on the child, family and social milieu. In other words, it is prudent not to make assumptions but to ask questions; that is, to understand adoptive identity through narrative in both research and clinical practice (Grotevant, Dunbar, Kohler et al., 2000).

Adoption by Non-Traditional Families

Assisted Reproductive Technology

Almost 30 years ago, science opened the door to a new opportunity for family formation through application of various forms of assisted reproductive technology (ART). The separation of conception from intimate sexuality, and the possibility of collaborative parenthood, have raised many questions similar to those regarding open adoption. There are some issues that differ between families who adopt and those who use ART although, in both cases, parents must confront feelings of loss and grief.

The forms of ART have different implications for parents and children. Both in vitro fertilization (IVF) and intracytoplasmic sperm injection (ICSI) involve fertilization of an egg with the father’s sperm so that both parents are genetically related to the child. Donor insemination (DI) has been used in couples with an infertile male partner and by single or lesbian women or couples and involves insemination of banked sperm from an anonymous donor.

Citing statistics from the Institute for Science, Law, and Technology Working Group (1998), Shapiro, Shapiro, & Paret, (2001) reported that as of that date approximately 75,000 babies were born annually through the use of ART, with 60,000 of these births resulting from DI and 15,000 resulting from the use of IVF in the laboratory. A further 1000 births per year occur through surrogate or gestational parenthood. According to these authors, twice the number of infants are born using ART than there are infants available for adoption at birth. The number has likely increased since these statistics were published.

In these latter forms of ART, only the mother is related. In egg donation, there is a genetic tie with the father and not the mother. However, unlike DI where the donor is typically anonymous, egg donors are often relatives or friends of the parents and thus may have contact with the child over time. The final form of ART, artificial insemination surrogacy, also involves a situation where the father but not the mother is genetically related to the child. Again, the surrogate may be someone in the family or a friend who will have ongoing contact with the child.

Both adoption and some forms of ART give a chance for parents to be selective about preferred child traits by reading physical descriptions and the donor’s family health history. In general, birth mothers pursue donors they believe to have positive inheritable characteristics such as good health, desirable physical and personal attributes, and intellectual abilities. Character also is thought to be important but birth mothers tend to believe that character is more a product of environment than genetics (Scheib, Kristiansen, & Wara, 1997), an assumption that genetic research would suggest is naive.

To date, there is no evidence of problematic cognitive or socioemotional outcomes or that parent–child relationships are affected based on research on any of these forms of ART (Golombok, 2006; Golombok & MacCallum, 2003). However, a recent review concluded that there is heightened risk of birth defects following IVF or ICSI compared with spontaneously conceived infants (Hansen, Bower, Milne et al., 2005).

A basic difference between adoption and ART is that in some forms of ART there is a genetic link with the child (with the exception of DI). Although the child is biologically linked with one parent, there may be some tension and feelings of loss within the marriage or between partners. There is an assumption that the emotional connection to the child will diminish any feelings of loss that may emerge. Couples do not only have to confront issues that arise between them, but also...
must decide how to tell their children. In fact, one of the main concerns is that parents using DI tend to keep the means of conception secret from their child (Golombok & MacCallum, 2003). This is very much the opposite of common practice with adopted children, where the benefits of open discussion with children about their origins and feelings are widely acknowledged (Feast, 2003).

**Single, Gay and Lesbian Families**

Single women are choosing parenthood to an increasing extent. Some have an agreement with a known partner to conceive a child, others use ART and others adopt. A number of factors contribute to the choice including feelings about having a genetically related child, attitudes about an unknown sperm donor, comfort in undertaking infertility treatment if needed, carrying a child to term without the support of a partner, and a host of financial, religious and cultural issues. Research has shown that single-parent adoptions are successful and should not be compared critically to two-parent homes (Shireman, 1996). Brooks and Goldberg (2001) outlined strengths that facilitate adoption success, such as having support from family and friends, psychological stability, resourcefulness, sensitivity, educational success and financial security. Organizations such as Single Mothers by Choice also provide information and support. A small but growing number of single men are also choosing to adopt.

Gay and lesbian adoption has expanded but is not universally accepted and varies even within regions of countries. Brodzinsky, Patterson, and Vaziri (2003) estimated that 2.9% of public and private adoptions in the USA involve children placed with self-identified gay and lesbian individuals and couples. However, this is likely to be an underestimate because not all individuals and couples identify themselves as gay or lesbian in their applications. For both single and gay or lesbian parents, establishing a close supportive relationship with their child or children will help the children cope with the special nature of their family and the questions and issues that emerge as they mature.

There are a number of routes to gay and lesbian adoption. In some jurisdictions only older and other special needs children are available for adoption by gay and lesbian families. While international adoption from some countries is open to single parents, it is not consistently open to gay and lesbian parents, meaning that one parent often adopts as a single parent. This places the co-parent at a disadvantage in terms of legal parental status and accompanying practical matters in relation to health benefits and inheritance. Should the couple separate, the co-parent is also at a disadvantage in terms of custody, visitation rights and continuation of a relationship with the child (Horowitz & Maruyama, 1995).

Similarly, when a child is born using ART, a decision must be made as to who carries the child, which may stimulate reactions in the couple and their extended families. As in heterosexual families, changes arising from pregnancy and childbirth may also upset the relationship. Particularly in lesbian relationships, both partners may feel equal in the mothering role but physiological changes in the mother giving birth, and the child’s possible preferential reaction to her, can disturb this sense of equality. Thus, parents in lesbian families may need guidance and support in negotiating their early relationship with their child at different developmental turning points.

There are more lesbian than gay parents. Some gay couples also choose to form their families through adopting older and other special needs children or through ART with the use of surrogate birth mothers. Much the same as for lesbian mothers, gay fathers’ parenting compares well with that of single heterosexual fathers (Patterson, 2002). In this context, parenting includes encouraging children’s sexual identity as well as sharing child care and engaging in cohesive and affectionate family interactions. Again, a complicating factor is prejudice in the broader community. Gay and lesbian families likely benefit from becoming part of their community and known as individuals and as a couple before bringing a child into their home. In urban areas there are also likely to be support networks for gay and lesbian parents.

Research on single and gay and lesbian families has focused on the impact of growing up in these non-traditional families on the children’s development and on the nature of the relationship between parents and children. There are often important psychosocial factors to take into account outside of the family constellation in such studies. These include the acceptance of neighbors, schools and religious institutions in the community where children can potentially encounter bias toward themselves or their parent(s), which complicates the developmental process. By and large, however, studies indicate that there are no significant differences in gender identity or gender role behavior, self-esteem or health of social relationships of children raised by gay or lesbian parents compared to children raised in heterosexual families. Moreover, they have not found the children to be vulnerable to psychopathology (Patterson, 2002). Furthermore, findings from a longitudinal study have shown that mental health and work status of adults raised by lesbian parents compared well with adults from heterosexual families (Tasker & Golombok, 1997).

While these are generally positive findings, clinicians must be sensitive to the psychological health of parents and to the prejudice that single, gay and lesbian families may experience and support the family’s strengths. Clinicians also must become aware of their own biases.

**Opening the Birth Records: Search for Birth Parents and Birth Children**

Just as openness in infant adoption has become more normative, so too has the search for birth parents by adolescent and adult adoptees. Factors motivating a search include curiosity, looking for a sense of belonging, seeking medical information, developing a sense of personal identity, wanting more information about physical similarities, having an interest in what happened
to a birth relative (Howe & Feast, 2000) and being at a life cycle transition point (Campbell, Silverman, & Patti, 1991). In some cases, only non-identifying information is exchanged while in other cases there is ongoing personal contact. Interviews with adoptees who reunited with birth parents indicate that various types of relationships evolve following reunion (Gladstone & Westhues, 1998). However, in general, early contact usually diminishes in frequency and intensity over time and continues through letters or by telephone.

A number of factors predict the outcome of reunions. Howe and Feast (2001) found that the emotional stability and security of either the adopted or the birth relative are paramount. While feelings of emotional closeness are important, other factors mediate the outcome of reunion including geography, perceived response of birth relatives or adoptive family members, sexual attraction and expectations that each party has of the others (Gladstone & Westhues, 1998). In a follow-up of adult adoptees 5 and 8 years post-reunion, regardless of the outcome of the reunion, most adult adoptees say that the search and contact experience was satisfying and worthwhile and that it helped to answer questions about their origins, background and the reason for being placed (Howe & Feast, 2001; Triseliotis, Feast, & Kyle, 2005; Wrobel, Grotevant, & McRoy, 2004). Of those who met their birth mother, 63% were still in some form of contact 8 years or more after their reunion (Howe & Feast, 2001). From the perspective of the birth mother, 94% were pleased that the adopted adult had contacted them (Howe & Feast, 2001). When asked to identify the hardest parts of the reunion process, all parties indicated that the waiting period prior to reunion and the adjustment period that accompanied the negotiation of the relationships afterward were the most difficult (Sullivan & Lathrop, 2004). For adoptive parents, fear of the potential loss associated with sharing their child with someone who they did not know was most threatening. It is also important to realize that choosing not to search can be positive (Wrobel, Grotevant, & McRoy, 2004).

A widely held belief has been that only individuals who have an unsatisfactory relationship with adoptive parents want to reunite with a birth parent. Although a negative evaluation of adoption made it more likely that an individual would remain in contact with their birth mother, a positive evaluation of the adoption had no effect. Howe and Feast (2001) concluded that whereas many adopted people feel a need to know their genetic and genealogical background in and of itself, this does not imply a need, or even wish, for a relational connection. Help may be needed to resolve conflicts associated with expectations, inappropriate behavior, role ambiguity and differences in attitudes or values. There are few social guidelines indicating the ways that these family members should behave towards one another and clinicians may be requested to help in negotiating the relationship. Finally, clinicians can help the adoptee to deal with the reality of post-reunion relationships and their outcomes.

Children born through ART will likely be interested in their heritage for the same reasons adoptees are (Feast, 2003; Howe & Feast, 2000). There is no legislation at this time to protect children’s right to search in the way that adoptees can (Golombok, 2006). There are also legal issues with ART, with the donor legally absolved of all parental responsibility and assured that identity is safeguarded. The rights of donor-conceived individuals to access to information regarding their genealogical heritage is increasingly being voiced and some donors do agree to be contacted when the child reaches 18 years of age. In England, the Human Fertilization and Embryology Act, 1990 allows inquiry regarding whether an individual is genetically related to the person they plan to marry but information on heritage or genetic history is not available. However, there are websites designed to unite children who share a donor and therefore a genetic link (http://www.donorsiblingregistry.com). This has also become the practice in families adopting internationally, some of whom search for siblings of abandoned children through DNA matching (e.g., http://www.kinsearchregistry.com/index.html). Thus, although a direct link with parents may not be possible, families are looking at alternative ways of acknowledging other biological connections for their child.

**Outcomes of Adoption: Factors Contributing to Risk and Resilience**

It is recognized that there are various pathways to development and adjustment. These are determined by an ongoing transaction between genetically influenced strengths and vulnerabilities, prenatal factors, premature birth and associated complications, and early growth promoting and traumatic experiences such as abuse or neglect. These are critical, especially in children adopted late (Hauggaard, 1998; Howe, 1997).

Studies of adopted children have been used to understand that genetic factors are important but do not fully explain heightened risk. For instance, although children born to parents with psychiatric and antisocial disorders are at higher risk for psychopathology, this is most likely if such disorders and/or associated psychosocial adversity are also present in the adoptive family (Peters, Atkins, Marc et al., 1999), a situation that is relatively uncommon (because of the screening of people wishing to adopt). A more plausible explanation is that adopted children who are at genetic risk for antisocial behavior exhibit some characteristics that draw more negative control from parents than those children not at risk (O’Connor, Deater-Deckard, Fulker et al., 1998). Furthermore,
CHAPTER 33

Longitudinal research suggests that genetic influences increase
and shared environmental influences decrease in terms of cog-
nitive ability. More specifically, although the cognitive and
behavioral style of young adopted children is congruent with
that of adoptive parents, by adolescence these styles diverge
(O’Connor et al., 1998) and children make choices and select
opportunities that may suit their genetic disposition (Scarr
& McCartney, 1983). Adoptive parents typically put high
value on achievement and the power of the environment and
of their capacity to shape their children’s future. This may
lead to frustration and conflict later in development as it has
been a long-standing finding that one of the most important
predictors of adjustment of adopted children is the capacity
of parents to set realistic expectations for their child (Barth
& Berry, 1988).

Biological factors such as nutrition, limited medical care
for the child and birth parent, and prenatal exposure to drugs
and alcohol are documented risks (Barth & Brooks, 2000;
Moe, 2000). Even if children experience adequate caregiving,
biomedical risks associated with prenatal drug exposure are
still a potential determinant of specific developmental prob-
lems (Moe, 2000). Early disruptive life experiences, including
a history of multiple placements prior to adoption, and a
history of abuse or neglect also have serious consequences for
developing adjustment problems (Dance & Rushton, 2005;
Howe & Fearnley, 2003). Findings regarding the specific
prevalence of adjustment problems vary across studies but, for
instance, Dance and Rushton (2005) report that of domestically
late placed adoptees, 49% had a positive outcome, 28% were
difficult but continuing and 23% disrupted.

We now know that some children facing negative life cir-
cumstances are more resilient than others. Genetically shaped
characteristics such as intelligence and easy temperament are
protective factors as well as having a sense of curiosity, a feel-
ing of personal control and prior experience in establishing
a close interpersonal relationship (Masten, 2001). Another
protective factor, of course, is adoption into a positive fam-
ily environment.

Outcomes of Domestic Adoption

The positive outcomes for domestically adopted infants have
been well documented in relation to both development and
attachment security (e.g., Singer, Brodzinsky, Ramsay et al.,
1985). However, there is a shortage of healthy infants for adop-
tion. Older children coming into care continue to be available
for adoption in large numbers. These children have been
identified as “special needs” adoptions, not only because they
are older but because they often have cognitive, physical, emo-
tional or behavioral problems that can make adoptive parenting
more challenging. The preponderance of research indicates
that, despite inauspicious beginnings, the majority of adopted
children with special needs and their families have a positive
outcome. For instance, analysis of data from the National
Longitudinal Study of Adolescent Health indicated that back-
ground characteristics, early maltreatment, peer and family
relations were associated with antisocial behavior but that
adoption status contributed little or no additional predictive
power (Grovevant, van Dulmen, Dunbar et al., 2006). There
is also accumulating evidence that satisfying attachment rela-
tionships do develop among late placed children and their
adoptive parents within the first years of adoption, which
supports the resilience of children when offered experiences
that promote social–emotional growth (Rushton & Mayes,
1997).

Two meta-analytic reviews of both domestically and inter-
nationally adopted children’s cognitive, behavioral and emo-
tional outcomes put these findings into clearer perspective.
Van IJzendoorn, Juffer, and Poelhuis (2005) concluded that
adopted children performed better than left-behind non-
adopted siblings and peers but lagged behind non-adopted
environmental peers and siblings. Although adopted children’s
cognitive skills were in the average range and similar to
current peers, there was a two-fold increase in special educa-
tion referrals for learning problems for the adopted children.
In a meta-analysis of emotional and behavioral problems,
Juffer and van IJzendoorn (2005) showed that adoptees ex-
hibited more behavioral and emotional problems. For both
cognitive development and behavioral and emotional problems
the effect sizes were small. However, adoptees were overrepre-
sented in mental health referrals. Thus, adoption is an
effective intervention that improves behavioral, emotional
cognitive development. Adoptive families likely seek help
because they have a lower threshold for referral for mental
health services both because of their expectations of their
children and because they tend to be people who utilize ser-
ices (van IJzendoorn, Juffer, & Poelhuis, 2005).

At the extreme, disruption of adoptive placements has been
associated with the child’s age at placement, length of time
in care, the number of moves and returns to the birth home,
the child’s level of behavior problems and inattention/
overactivity, preferential rejection by birth parents, and the
child’s ability to show signs of attachment to their new fam-
ily (Dance & Rushton, 2005; Rushton & Dance, 2003). In
contrast, children with identifiable developmental or physical
disabilities have fared well (Glidden, 1991).

Haugaard (1998) strongly advised clinicians not to gener-
alyze the risk of adjustment problems to the entire adopted
population, as it is applicable only to a small subset of
adopted children. Similarly, Hodges, Steele, Hillman et al.
(2003) found that, during their first year of adoption, chil-
dren who had been maltreated showed an increase in mental
representations of adults helping and limit-setting and being
aware when children needed them. When older children do
have behavioral and emotional problems, it is important to
recognize the unique histories that they bring to their adopt-
tive families. When raised in environments of abuse, neglect
and rejection, children develop strategies to ensure survival that
make them ill-equipped for loving and responsive care. Many
of these children are unable either to elicit sensitive care or
to respond to it, which raises the risk that the adoptive fam-

508
ily will feel rejected or punished by the child. Such findings reinforce the need for parents adopting older children to receive help to set realistic expectations, to understand their children’s needs, and to appraise both their own and their child’s contribution to the relationship (Stovall & Dozier, 1998). Rushton, Mayes, Dance et al. (2003) followed the development of new relationships and the presence of behavioral and emotional problems in domestically adopted 5- to 9-year-old children placed with adoptive families. A relatively small proportion failed to form an attachment relationship with one or both parents by the end of their first year in placement (27%) but they were more likely to exhibit behavioral problems. Some of the ways that these children interact and show their emotions (e.g., false affection, superficiality and distancing behavior) may be misperceived by parents, who take the behavior at face value rather than as defensive actions.

Outcomes of Intercountry Adoption

Reports from a number of countries confirm the positive outcome of intercountry adoption. Most intercountry adoptees have lived in institutions of varying quality prior to adoption, deprived of health care, optimal cognitive and social stimulation, and individualized attention which may have observable effects for months or years following adoption (Kreppner, Rutter, Beckett, et al., 2007; Rutter, 2005).

Intercountry adoptees are at risk for infectious diseases and other health and neurological problems, often not diagnosed until parents bring their child home (Johnson, 2000). Malnutrition and inadequate stimulation are also common, leading to children weighing less, being shorter and having a smaller head circumference than children raised in birth families or adopted domestically (Mason & Narad, 2005). Fortunately, most of these problems can be managed with appropriate medical and dietary intervention (Johnson, 2002; Mason & Narad, 2005). The rate of catch-up growth depends on the quality of early experience and the age at adoption. Thus, children adopted younger, and from presumably less depriving conditions, such as those in institutions in East Asia and China, grow rapidly within the first 6 months after adoption (Cohen, Lojkasek, Yaghoub Zadeh et al., in press; Miller & Hendrie, 2000; Pomerleau, Malcuit, Chicoine et al., 2005) whereas for children adopted later from more depriving environments catch-up growth takes longer (Rutter, O’Connor, & the ERA Study Team, 2004). It is important to note, however, that two years after adoption, at approximately 3 years of age, the physical measurements of children adopted from China were still lower than those of non-adopted comparison children (Cohen et al., in press).

Problems with cognitive, motor and language development are common in children who have experienced institutional care and are dependent on the length of institutionalization (Ames, 1997; Cohen et al., in press; Marcovitch, Goldberg, Gold et al., 1997; Miller & Hendrie, 2000; Pomerleau et al., 2005; Rutter, O’Connor and the ERA, 2004). At one extreme are children adopted from Romania at the fall of the Ceausescu regime in 1989. Whereas some children adopted later than 6 months of age made remarkable gains, most showed marked delays that persisted, even up to 7.5 years post-adoption (Beckett, Maughan, Rutter et al., 2006; Croft, Beckett, Rutter et al., 2007). In fact, by the age of 11 years, outcomes for children deprived for 6–12 months were similar to those who had been deprived longer. These findings for children who had been profoundly deprived suggest both a sensitive period for development and limits on the effects of exposure to a stimulating environment as there were no differences in adoptive family characteristics.

At the other end of the continuum are children adopted from China and other East Asian countries who experienced less severe deprivation. For instance, when Cohen et al. (in press) followed children who were, on average, 13 months of age at adoption, from the time of their arrival to Canada and then 6, 12 and 24 months later, rapid gains were made within 6 months. By this time children were functioning within the average range in cognitive, motor and language development, a pattern also observed at 6-month follow-up by Pomerleau, Malcuit, Chicoine et al. (2005) in children adopted between 6 and 18 months from China, East Asia and Russia. Although there were rapid changes, Cohen et al. (in press) found that the children adopted from China did not catch up to non-adopted peers from similar family backgrounds until 2 years post-adoption.

Taking a broad view of the literature on intercountry adoption, the meta-analysis carried out by van IJzendoorn, Juffer, & Poellhuis (2005) on cognitive development and achievement of adopted children also included intercountry adoptees. That review showed positive outcomes for children adopted younger than 1 year of age.

The importance of establishing secure attachment relationships is widely recognized. Similar to infants adopted domestically, intercountry infants adopted before focused attachment occurs do not exhibit difficulties (Juffer & Rosenboom, 1997; Stams, Juffer, & van IJzendoorn, 2002). Moreover, even children previously institutionalized in Romania were able to form a secure or insecure attachment relationship with adoptive parents within a few years after adoption, and there was no evidence of children being unattached (Chisholm, 1998; O’Connor, Marvin, Rutter et al., 2003).

At the same time, there is agreement that in institutional settings children rarely have the sort of individualized positive interactions with caregivers required to meet emotional needs. Some older placed children who were adopted from Romanian institutions were at increased risk for atypical maladaptive behaviors such as indiscriminate social behavior, characterized by affectionate or friendly behavior towards all new adults, including strangers, with lack of the caution exhibited by non-adopted family reared children (Gunnar, Bruce, & Grotevant, 2000; MacLean, 2003; Rutter, Colvert, Kreppner et al., 2007). Surprisingly, neither age at adoption nor the length of time in institutional care was related to the quality of attachment insecurity (Chisholm, 1998; Judge, 2004).
CHAPTER 33

Rather, insecure attachment was associated with lower child IQ scores (Chisholm, 1998; Judge, 2004), a higher degree of behavioral problems (Chisholm, 1998; Marcovitch et al., 1997), adopting more than one child at a time (Ames & Chisholm, 2001) and high levels of parenting stress (Chisholm, 1998).

The few studies of attachment in intercountry adoptees have considered outcomes 1 year or more after adoption. One study has examined the process of attachment formation from arrival among infants adopted from China. Among the children who were, on average, 13 months of age at the time of adoption, Pugliese (2006) found that within weeks of being adopted there were signs of forming an attachment, based on mother-completed questionnaires, interviews and mother-infant observation. Interviews at bi-weekly intervals showed a gradual increase in attachment behaviors over time. Although in the first month with their adoptive parents, some infants showed atypical or extreme patterns of behavior (e.g., showing attachment behavior in nonstressful situations), for the most part these disappeared by 6 months post-adoption.

Like their domestically adopted counterparts, intercountry adoptees who experienced poor institutional care are at greater risk for behavioral and emotional problems than those who experienced less extreme early care (Ellis, Fisher, & Zaharie, 2004; Hoksbergen, Rijk, van Diijkum et al., 2004; Verhulst, 2000a,b). Some different patterns of symptoms were observed among children adopted from Romania, a form of inattentiveness/overactivity and autistic-like symptoms (6%), which were qualitatively different from attention deficit/hyperactivity disorder (ADHD) or autism observed in western clinical settings and which might have been an outcome of institutional care (Kreppner, O’Connor, Rutter & the ERA Study Team Group, 2001). The latter symptoms, along with disinhibited attachment and cognitive impairment, were associated with social and emotional difficulties at the age of 11 years only in children who had experienced institutional deprivation for longer than their first 6 months of life. There was also an increase in emotional, but not behavioral, problems when children were followed from age 6 to age 11 years with evidence that difficulties with emotion recognition might have a role in the emergence of these problems (Colvert, Rutter, Beckett et al., in press), something that would not have been easily observed when the children were younger.

Again, using meta-analysis to examine intercountry adoptees, whereas adoptees from a wide range of countries had more behavioral and emotional problems compared to domestically adopted children, the effect sizes were small (Bimmel et al., 2003; Juffer & van IJzendoorn, 2005). Thus, most children were well adjusted despite many having experienced poor institutional care. Moreover, intercountry adoptees had less severe emotional and behavioral problems and were less likely to be referred for mental health services than domestic adoptees. Juffer and van IJzendoorn (2005) speculate that the sources of emotional and behavioral disturbance among intercountry adoptees may be different than for domestic adoptees.

Intercountry adoption comes about because children are given over to institutions for economic or political reasons rather than genetic or prenatally determined risk factors or removal from birth parents because of abuse or neglect.

Intercountry adoptees also exhibit other types of behavior problems such as problems with eating (Ames, 1997; Beckett, Bredenkamp, Castle et al., 2002; Johnson, 2002), stereotyped and self-stimulating behaviors, pain agnosia and tactile defensiveness with hyper- or hyposensitivity to touch, light, sound, smell and taste (Ames, 1997; Beckett et al., 2002; Fisher, Ames, Chisholm et al., 1997; Groze & Ileana, 1996). It has been presumed that these atypical behaviors arose as a response to experiencing a depriving environment in institutional care and were adaptive within that context (e.g., self-soothing in times of distress). Such problems tend to be transitional and decline during the post-adoption period (Ames, 1997; Fisher et al., 1997; Johnson, 2002). Nevertheless, 40% of previously institutionalized Romanian children continued to display some of the stereotyped behaviors 3 years post-adoption, 18% continued to rock at 6 years of age (Ames, 1997; Beckett et al., 2002) and 15% still had difficulties with eating solid foods at 6 years of age (Beckett et al., 2002). Moreover, among adoptees who had experienced institutional deprivation, about 1 in 10 show a pattern of autistic-like behavior in the British study of adoptees from Romania (Rutter, Anderson-Wood, Beckett et al., 1999; Rutter, Kreppner, Croft et al., 2007).

There is little known about adjustment in intercountry adoptees in adulthood. In a survey of a mixed group of intercountry adoptees, Tieman, van der Ende, and Verhulst (2005) found that although the majority of adults, ranging in age from 22 to 32 years, did not show serious mental health problems, there was increased risk among children raised in high socioeconomic class families, possibly because of the unrealistic demands and expectations set by these parents. They also noted that those adoptees who could not be contacted or who dropped out of the study earlier had initially higher problem behavior scores. Thus, the study may have underestimated the risk for mental health problems in adult intercountry adoptees.

Selection, Preparation and Assessment of Adopted Children and Adoptive Families

Whether a child is adopted from a public, private or independent agency, attention is paid to assessing adopters to ensure that children will be safe and that relational support and educational opportunities will be provided. In parents, personal qualities such as warmth, mental health and parenting capacity and style are taken into account. Parents’ own attachment histories are not systematically assessed but Steele, Hodges, Kaniuk et al. (2003) found that 3 months after adoption, children whose adoptive mothers showed signs of insecure attachment exhibited aggressiveness in their themes to a story
completion task relative to children adopted by mothers with secure attachment responses. In older children, a rather ill-defined criterion regarding whether a child wants and feels ready to be adopted is also considered.

The process of adoption is especially complex for children who are older at adoption, have a history of abuse, and birth parent history of drug and alcohol use. In domestic adoption, the needs of both child and family are addressed through arranging multiple visits of increasing length so that the prospective parents and children can get to know one another, gain comfort and make a gradual transition to adoptive family life. Group meetings for prospective adoptive parents are arranged to provide information, talk with experienced adoptive parents and air potential risks in the adoption process. These have gone some way to challenge unrealistic expectations. Moreover, in some cases information is targeted for particular subgroups, something that is common in agencies arranging special needs and intercountry adoptions.

Families of both domestic and intercountry adoptees are generally dissatisfied with the amount of information provided prior to adoption and some feel that they were not fully aware of the difficulties they would face. Showing parents of domestically adopted children videos of children available for adoption is becoming a common practice. Some internationally adopted children also have a pre-adoption video for prospective adoptive parents to review with a physician before making their commitment to adoption (Boone, Hostetter, & Weitzman, 2003). The value of this review is that the clinician can help parents to understand the consequences of prolonged institutional care and other risk factors. For instance, a video can help to identify dysmorphic features associated with fetal alcohol syndrome and genetic or neurological disorders. Boone, Hostetter, & Weitzman (2003) found that estimates of development from the video were correlated with direct assessment of child development post-adoption. However, this procedure cannot estimate relational differences between children.

It is important to highlight that assessment of some critically important adoptive parent qualities may be difficult prior to adoption. These qualities include flexibility in setting realistic expectations and understanding not only the importance of attachment relationships but also that some of the children’s behavior problems may actually be an indirect way of getting closer. Dance, Rushton, and Quinton (2002) found that adoptive parent characteristics such as warmth, the ability to deal with both the facts and the effects of children’s early experiences, and the competence to manage child behaviors, assessed immediately after placement, were related to outcome one year post-adoption. Even more important was the nature of the relationship that emerged over this period. Among children aged 5–11 years who had been preferentially rejected by their birth parents, an important predictor of maladjustment in the first year post-adoption was false display of affection by the child early in placement and not the level of behavioral difficulties. Moreover, lack of warmth and sensitivity in parent interactions was heightened when the adoptee had problems with attention and affect regulation (Rushton, Dance, & Quinton, 2000). It was recommended that these children should be flagged for more intensive work in the preparation of parents and in post-adoption services. Mistrust of relationships, low self-esteem, anger and fear of abandonment all contribute to the likelihood of significant child psychopathology during the transition to adoption and unresponsiveness to parents’ bids for closeness. Parents may need guidance in evaluating their child’s behavior and finding the right level of interaction to sensitively read their child’s signals and to pace their efforts in forming a relationship. This is notable because in their sample Rushton and Dance (2006) found that more than one-third of children had ongoing difficulties 6 years later. Such findings heighten the need for post-adoption services as a routine part of the adoption process.

**Post-adoption Services**

It is not possible to prepare parents for everything that they will encounter once a child joins their family. Parents often minimize genetic and prenatal physiological conditions in favor of a family systems explanation for maladaptive behaviors and do not acknowledge the potential limitations of the post-adoption environment (Barth, 2002). Funderhughes (1996) has described four stages through which families move in the process of including a child with special needs: anticipation when the family looks forward to the child’s placement with the accompanying expectations and fantasies; accommodation to a child who may test limits and, in doing so, disappoint parents’ expectations; resistance when family members experience ambivalence; and restabilization when the family achieves a new equilibrium where expectations and reality are more closely matched. Parents adopting children internationally, although prepared by adoption agencies, may not be fully aware of the long-term effects of institutional rearing and go through their own adjustment stages. Moreover, parents need to be made aware that they should limit contact with other adults in favor of maximizing opportunities for parent–child interaction and generally avoid overstimulating the child with too many toys and outings. As well, toys should be purchased that fit the child’s developmental level rather than age.

For both domestic and intercountry adoptions, a comprehensive assessment should be carried out once children join their adoptive families, and include a thorough medical examination, a developmental assessment of cognitive, motor and language ability, and observation of the child in structured and unstructured situations. Observations should consider the child’s predominant affective tone, curiosity, involvement in particular situations, sharing of activities with others and reaction to transitions (Weitzman, 2003). Functional rather than standardized evaluations are preferred, and interpreters should be available for children over the age of 3 years in order to evaluate language competence. Behavior problems, including unusual behaviors (e.g., rocking and other self-stimulating
CHAPTER 33

behaviors) and, for older children, aggressive behavior and inattention should be recorded. Parents should be encouraged to seek help when it is needed (Johnson & Dole, 1999).

There is a long-standing awareness of the need to provide health focused post-adoption services early in the adoption process with a view toward easing the transition and preventing difficulties down the road, especially in families adopting children with special needs. It is not possible to talk about post-adoption services in a unitary fashion. The expanding variety and needs of adoptive families call for multiple forms of support and co-ordination of services. In the UK, a survey of local authority adoption services in the year 2000 led to the development of new adoption support services (Rushton & Dance, 2003). In the USA, this happened as a result of the President’s Adoption 2000 initiative (cited by Shapiro, Shapiro, & Paret, 2001).

For example, Juffer, Hoksbergen, Riksen-Walraven et al. (1997) compared two short-term programs directed at promoting maternal sensitive responsiveness in international infant adoptions. One involved giving participants a book that focused on sensitive parenting and a second that involved using the book in conjunction with three video-feedback sessions. Intervention effects were observed in relation to an untreated comparison group in maternal sensitive responsiveness, infant competence and infant–mother attachment in the group receiving both the book and video feedback (Juffer et al., 1997) and a lower rate of disorganized attachment in infancy (Juffer, Bakermans-Kranenburg, & van IJzendoorn, 2005). When the children were followed at the age of 7 years, both boys and girls who had received the intervention showed less internalizing behavior problems and girls showed greater ego-resiliency (Stams, Juffer, van IJzendoorn et al., 2001).

Other programs have been directed at dealing with the transition to adoption (Cohen & Duvall, 1996) and with behavior problems in older adopted children, especially those who have experienced trauma associated with an early family history of abuse, neglect and multiple moves (e.g., Dozier, Albus, Fisher et al., 2002; Rushton, Monck, Upright et al., 2006).

Some systematic post-adoption services for these children are currently being tested. For instance, Rushton et al. (2006) are comparing two manualized interventions for parents adopting older children in relation to routine support services. One is based on cognitive behavior modification that focuses on dealing with the understanding the current meaning of challenging behaviors and ways of dealing with these. The second is an educational model based on understanding the meaning of children’s behavior from a historical point of view, focusing on broken or distorted attachments and the child’s coping mechanisms. Unfortunately, there are not yet empirical data on the outcome of these services.

In a survey of post-adoption service use, Brooks, Allen, and Barth (2002) found that less than 30% of adoptive families used post-adoption services although a higher percentage read books and articles on adoption (82%) and attended lectures or seminars (43%). These latter activities were the most accessible as families could pursue them on their own, something that may be most appealing to the educated parents likely to adopt. Although books and lectures can be helpful, they are neither geared to the families’ individual needs nor are they experiential. Independent adopters made the least use of post-adoption services, most likely because they involve fewer children with special needs. Nevertheless, given findings that adoptive parents are more likely to use services, a potential need for specialized post-adoption consultation and intervention continues to be valid.

Families involved in kinship adoptions and in various open adoption arrangements have different post-adoption needs to those involved in extrafamilial adoptions. Moreover, the increase in open adoptions and various other forms of adoption with ongoing contact with the birth family has accelerated a need for continued mediation between adoptive and birth parents. This raises a need for systematic study of programs for these families.

Picking up the thread of openness in adoption as a state of mind as well as a set of actions, an important health focused post-adoption activity that contributes to promoting mental health for all adopted children, but is often overlooked, is preparation of a Life Book. This provides children with a sense of their own personal histories and an acknowledgement of the positive value that adoptive parents place on that history. Optimally, child protection workers who take domestically adopted children into care collect background information and mementoes for children from birth or foster families, but this is sometimes overlooked. One might assume that children adopted as infants or adopted internationally, some of whom were abandoned with no clues as to birth parenthood or history, cannot have a Life Book. However, there are creative suggestions in both books and websites that provide ideas of how to construct a history for the child. For instance, information about the town where the child was born, where the institution was located, current events on the day of the child’s birth obtained from a newspaper archive, photos, a narrative about the transition to adoptive family life, and older children’s drawings of what they imagine about their birth family are examples of what can be included (http://www.lifebooks@earthlink.net).

There is also need for health focused post-adoption services at later points in the post-adoption life cycle. Brodzinsky (1987) has suggested that for children adopted as infants there are key turning points related to shifts in cognitive development and consequent understanding of the meaning and implications of adoption. One turning point comes in the early school years, around the ages of 6–7, when children first truly understand the meaning of adoption. Another turning point is in adolescence when thoughts about their own reproductive future and life choices give rise to adolescents’ questions about their identity. Sometimes they decide to meet or know more about the birth family or, in the case of ART, the donor. Changing needs with respect to provision of and discussion about different types of information (Wrobel,
Kohler, Grosvant et al., 2003), response to emotions evoked at life transition points (Brodzinsky, 2005) and styles of coping with birth parent loss (Smith & Brodzinsky, 2002) are important content for post-adoption services for these children and youths. It is impossible to prepare parents for these possible reactions when children are very young or at the beginning of the adoption process. Consequently, it is essential that mental health professionals be aware of these turning points so that they can provide resources to meet the changing needs of adoptive families.

Clinical Services
Adoptive parents are more likely to seek services some time after adoption has occurred when they encounter difficulties within their families, in relation to their children’s behavior or in attachment relationships. These problems have been conceptualized in different ways relating to behavior management, family systems and attachment theory, and parenting style, which have been used to shape clinical as well as post-adoption services (Cohen & Duvall, 1996; Juffer et al., 1997; Rushton et al., 2006).

Attachment research has been influential in providing advice to parents about how attachment behaviors can sometimes be displayed in unexpected ways. For instance, from reviewing 83 clinical referrals of parents and their adopted foster care children, Lieberman (2003) found that parents often missed subtle attachment cues and misinterpreted defiance and temper tantrums as signs that the child did not care for them. It is a difficult task for parents both to acknowledge their children’s displays of attachment behavior and provide appropriate warmth and support while, at the same time, being able to set limits in a non-rejecting firm way. Thus, the adoptive parent must consciously teach attachment skills to the child, as the feeling of being wanted does not come automatically to a child who has never known love and care. Clinical services need to educate adoptive parents on the psychological and emotional challenges of children deprived of a consistent and reliable attachment figure during their formative years. They also need to provide guidance and experience with interpreting and appropriately responding to children’s emotional needs.

For the most part, post-adoption and clinical services are focused on helping children to develop selective attachment relationships. This is achieved by facilitating sensitive responsive and pleasurable interactions between parent and child and increasing parents’ ability to be good observers of their child’s behavior. However, these services have not been specific to adoption (e.g., Cohen, Muir, Lojkaske et al., 1999; Juffer et al., 1997; Lanyado, 2003; Lieberman, Silverman, & Pawl, 2000). It is also important to note that these interventions were developed for young children. It remains a challenge to devise parallel interventions for older children and adolescents (Cohen & Duvall, 1996). Moreover, in any intervention, some individuals are likely to benefit more than others. Thus, it is notable that outside of the adoption literature it has been observed that mothers’ own attachment style is related to their response to particular forms of therapy; something that should be taken into consideration in therapy with adoptive families and in research (Bakermans-Kranenburg, Juffer, & van IJzendoorn, 1998).

Even when children develop attachment relationships with parents, they continue to have problems in peer relationships that extend into the school years (Hodges & Tizard, 1989; LeMare, 2004). O’Connor and Zeanah (2003) suggest that symptoms of attachment disorder that extend beyond primary caregivers to peer relationships should be a focus of treatment. For instance, group therapy for adopted children is becoming more common (Nickman, Rosenberg, Fine et al., 2005). For children with severe attachment problems (e.g., reactive attachment disorder) there is little by way of systematic study of treatment outcomes. A dual focus on attachment promoting and behavioral management interventions may be needed over a long period of time, recognizing that such attachments may not form at all or that they may not be achieved until adulthood (Howe, 1996). For children with severe attachment disorder, support groups for adoptive parents may be of benefit (O’Connor & Zeanah, 2003).

Unfortunately, untested and potentially damaging forms of therapy continue to be used, many of which are touted on the Internet as providing certain cure. The most contentious of these is holding therapy, an intervention that involves close physical contact of a child with a therapist and/or parent. The rationale behind this is that it provides the child with the experience of touching and holding that is essential in the normative attachment process and helps to contain children prone to extreme distress or rage. Tragically, there have been at least six deaths from various forms of holding therapy. According to Hughes (1999), most therapists have now modified holding therapies by seeking the child’s consent to being touched or held and always including the parent in therapy. In any event, there are no empirical data suggesting that any form of holding therapy is effective. While parents need help in controlling children’s uncontrollable outbursts, this should not be confused with attachment and can be addressed with more conventional treatments for behavioral and emotional problems (Webster-Stratton, 2005).

There is not a “one size fits all” intervention. As in any clinical service, it is essential to make a thorough assessment of factors within the child, parents and environment before proceeding. For the most part, the kinds of interventions that have been applied to birth families have been used with adoptive families, hopefully with sensitivity to particular issues that adoptive families may bring to the fore. Moreover, while helping parents set realistic expectations may be important in any therapy, this may be an especially salient issue with adoptive families. Finally, it must be recognized that in some cases therapeutic interventions need to be long-term and multimodal without promise of a desired outcome. Adoptive parents who are used to finding effective solutions to problems may be frustrated with the apparently impervious nature of their children’s problems.
CHAPTER 33

Adoption and the Professional Community

In the past, the professional community was criticized for being insensitive to the needs of post-adoptive families (Nickman & Lewis, 1994). There has been a welcome growth in the private sector in attending to the specialized needs of post-adoptive families. Professionals working in the adoption field also are increasingly involved in setting a curriculum and developing training models, and training a range of other professionals engaging with adopted children (American Academy of Child and Adolescent Psychiatry, 2005; Chamberlin, 2005; Dozier et al., 2002; Palacios & Sanchez-Sandoval, 2005). Some specialized medical clinics for intercountry adoptees have been established that provide thorough medical and developmental examination, review records to identify potential risk factors, and observe the child to determine affective tone, involvement in testing, quality of relationship with the examiner and adoptive parents, and atypical behaviors. It is important to follow closely intercountry adoptees on all of these fronts. While these clinics assess and monitor children, they typically do not offer mental health services.

Conclusions and Future Challenges

Adoption has come to have an increasingly prominent role in the fabric of family life worldwide. The research base for many adoption-specific issues accordingly has broadened. Moreover, since the last edition of this book, there has been significant growth in the understanding of specific issues relevant to adoptive families by professionals. It is heartening to know that many prejudices surrounding adoption have been overcome although some remain around gay and lesbian adoption, for instance. Moreover, while there is greater acceptance of openness in adoption, for the most part, this has applied to children adopted as infants. One of the challenges in years to come will be to test forms of openness for children adopted under less benign conditions to determine whether there is value in contact with birth families who, for one reason or another, have not been able to provide proper direct care for their children. Furthermore, new issues will come to the fore as children conceived through ART (and especially DI) mature into adolescence and adulthood and consider searching for a biological parent. Given the large number of children available for domestic adoption who are older and have other special needs, there is a continuing challenge in moving children into a permanent arrangement and providing supports that will facilitate positive adjustment. There is also a challenge in testing the effectiveness of various practices.

More research on the impact of intercountry adoption on children is also needed. There have been active efforts to improve the early lives of children in institutional care and there is now a fuller range of pre-adoption experiences to consider. Longitudinal studies are especially important to track the progress of children and families over time. It is essential not only to describe the outcomes for children adopted internationally, but also to provide information about the process of development and adjustment that will contribute to better preparation of families and establishment of post-adoption services. Finally, the systematic implementation and study of both post-adoption and clinical services tailored to the needs of adoptive families have been a long time in coming. There are now signs that these important tasks are under way. Until there is solid ground for recommending post-adoption and clinical services, the lure of a quick cure will continue to appeal to some families who are experiencing serious problems in their relationships with their adopted children.

CHAPTER 33

LeMare, L. (2004). Development of children adopted to Canada from Romanian orphans ten years later. Paper presented to the Intercountry Adoption Policy Roundtable, organized by Intercountry Adoption Services, Social Development Canada.

Clinical Syndromes
Many children show a persistent style of behaving in an impulsive, inattentive and restless fashion. The style can endure for many years, but tends to manifest in somewhat different ways at different ages. When the behaviors are severe they carry considerable importance for clinicians; most importantly, because extreme levels put children at risk for later antisocial adjustment, educational failure and aspects of personality dysfunction in later adolescence and adult life. Impulsiveness, inattentiveness and restlessness can also be very unpleasant for the caregivers, and for this reason constitute some of the most common reasons for clinical referral during the school years.

This chapter treats these behaviors as a lifespan condition rather than one restricted to middle childhood and early adolescence.

**Clinical Presentations**

**Inattentiveness** refers to a style of behavior, involving disorganization and lack of persistence, rather than to the psychological processes that are indexed by tests of attention. The presentation is naturally in different forms at different ages, as summarized in Table 34.1, and the impact varies with the demands for attention that the environment makes. The behaviors can be seen by direct observation (at least in childhood) if the setting is appropriate (Taylor, 1998). Motivation improves attention, as for everybody else; and some children’s activities (such as playing computer games with very frequent and insistent rewards) provide so many and so rapid incentives that they are not good ways of assessing function in the ordinary world. As people enter adult life, poor attention often becomes the most salient aspect of the condition (Kessler, Adler, Barkley et al., 2006; Millstein, Wilens, Biederman et al., 1998).

**Overactivity** refers simply to an excess of movements; it is often the most salient problem in early childhood but the least important in adult life. Its features are statistically closely allied to impulsiveness and they are often combined into one construct of “hyperactivity.”

**Impulsiveness** means acting without reflecting. This is often the aspect that gets young people into trouble, or irritates other people. However, in early childhood, and to some extent later, these features of impulsiveness can be difficult to distinguish from other types of oppositional behavior. Lack of clarity about social rules or angry resistance to adults can be other causes of rule-breaking, so it is important, but often difficult, to go beyond the description of unacceptable conduct to determine whether thoughtless impulsiveness underlies it (see chapter 35).

Subjectively, adults often come to recognize these problems in themselves, and either describe themselves as confused or overreactive, with their thoughts in a whirl and their actions often half-considered and unwise. Children do not often do so, but some will describe the subjective difference when medication is effective, and say that they are now able to think things through more clearly without the intrusion of other thoughts. The subjective experience of children with hyperactivity is more often one of being unfairly punished or discriminated against: they experience the reactions of others to the condition rather than the condition itself.

Some degrees of inattentiveness, high activity and impulsiveness are of course shown by ordinary children. Diagnostic identification needs to be based on the extent, severity and consistency of the behaviors and on their impact on social adjustment. It is quite possible for inexperienced parents or teachers to regard ordinary childish high spirits as evidence of hyperactive behavior. The tolerance of parents varies a good deal, and in community surveys it, and the degree of financial loss suffered because of the child’s problems, are strong predictors of which hyperactive children will be referred for professional attention (Sayal, Taylor, Beecham et al., 2002).

**Diagnostic Definitions**

There are two main approaches to defining disorders of inattentiveness, hyperactivity and impulsiveness: DSM-IV-TR (American Psychiatric Association, 2000), which recognizes “Attention Deficit/Hyperactivity Disorder” (ADHD), and ICD-10 (World Health Organization, 1992), which uses the category of “Hyperkinetic Disorder.” They are based on essentially the same descriptions of behavior, but weight the different items differently (Swanson, Sergeant, Taylor et al., 1998). In brief, hyperkinetic disorder requires all three components to be present, while ADHD is divided into cases where this is so (“Combined type”) and those where only inattentiveness, or only overactivity and impulsiveness, are present.

However, hyperkinetic disorder cannot be simply identified as the combined type of ADHD; the definition is even more exacting. The diagnostic criteria must be met in more than one situation (e.g., both home and school), while ADHD requires only that there should be some impairment in more than one setting. Hyperkinetic disorder is excluded by the presence of other disorders such as autism and anxiety states, while ADHD is only excluded if its signs are better explained by a coexistent disorder. Both schemes require that the level of behaviors should be out of keeping with the person’s developmental age, and that they should be impairing to social adjustment.

The practical consequence of these differences in definitions is that the ICD-10 category of hyperkinetic disorder is a subgroup of ADHD (Santosh, Taylor, Swanson et al., 2005). Evidence on which definition is more useful does not give clear answers. Researchers often do not make very clear distinctions. Indeed, research papers on ADHD very often require convergent identification by parents and schoolteachers, often focus on the combined type (or contain a predominance of combined type cases) and usually exclude cases with coexistent autism or affective disorders – although anxiety is not necessarily an exclusion. This not only achieves a refined phenotype of ADHD, but also entails that hyperkinetic disorder criteria are usually met. Much of the neurodevelopmental validation of ADHD, reviewed below, therefore leaves open the possibility that findings are confined to the hyperkinetic subgroup. When the hyperkinetic subgroup has been systematically compared with other forms of ADHD, it appears that it is particularly likely to be associated with a marked response to stimulant medication and a poor response to behavioral treatment alone (Santosh et al., 2005), and a high clustering of other neurodevelopmental anomalies such as delays in language and motor development (Taylor, Sandberg, Thorley et al., 1991).

Some latent class analyses of family and twin data suggest that one of the classes that breed true is a severe and pervasive form of hyperactivity and inattentiveness (e.g., Rasmussen, Neuman, Heath et al., 2004).

On the other hand, the genetic evidence of large twin studies has suggested that the degree of heritability is very similar at all levels of hyperactive behavior (Gjone, Stevenson, & Sundet, 1996), so that genetic findings would validate a dimension of hyperactivity rather than either diagnostic category. No separate etiological pathway has yet been established at any level of severity. Membership of the hyperkinetic disorder subtype does not seem to determine the course over time: persistence is not greater than in a wider ADHD phenotype (Lahey, Pelham, Chronis et al., 2006). Responsiveness to stimulant medication is not confined to a subgroup (although it differs in degree); indeed, ordinary people without ADHD show some enhancement in attention when they receive stimulants (Elliot, Sahakian, Matthews et al., 1997; Mehta, Owen, Sahakian et al., 2000; Rapoport, Buchsbaum, Weingartner et al., 1980).

Clinicians may find it useful to use the concepts of both schemes, recognizing their strengths and weaknesses. A broad notion of ADHD is helpful in the screening and initial detection of cases, and marks a group at risk. However, it may encourage an inappropriately wide identification of cases, and blur some important differences of presentation within the category. The narrower concept of hyperkinetic disorder may mark a group where medication is particularly useful and neurobiological changes particularly relevant, but if it were the only category it would exclude children in need of intervention. Furthermore, the exclusion criteria in ICD-10 would, if applied too literally, rule out the diagnosis for children who deserve it in all respects except that they have other problems too.

Subtypes of Disorder

Apart from the distinction between “broad” ADHD and “narrow” hyperkinetic disorder, other subtypes have been suggested within the broad grouping of ADHD, even though current scientific evidence does not allow for clear conclusions about whether biologically valid subtypes are present or whether the clinical heterogeneity should be conceptualized as variation of expression within a single broader disorder.

Attention deficit without hyperactivity can be identified as a separate group in community surveys (Taylor et al., 1991). It is not often seen in psychiatric clinics, but often presents as a failure of academic progress. Children are not disruptive or overactive; they may be dreamy and even somewhat inert, but
they are often muddled and disorganized in the classroom and find it hard to persist. Cognitive deficits are usually present, but they are both wider and less specific than in children who also show impulsiveness. They include working memory problems, poor spatial skills and delays of language development; motor coordination is often poor; and the IQ is often lowered (Warner-Rogers, Taylor, Taylor et al., 2000; Weiss, Worling, & Wasdell, 2003).

Evidence on the scientific validity of the inattentive subtype is inconclusive so far. On the one hand, it has emerged from some latent class analyses as a distinct group (Todd, Sridharaksa, Reich et al., 2002; Stawicki, Nigg, & von Eye (2006) have provided a meta-analysis of six studies that included informative family history information, with the conclusion that there is indeed evidence for specific subtype transmission in families. On the other hand, Geurts, Verte, Oosterlaan (2005) argued against the validity of an inattentive subtype on the basis that executive dysfunction was similarly impaired in that and the combined subtype. Perhaps one should conclude that inattentiveness is a separable component from hyperactivity-impulsivity, and that it is responsible for much of the cognitive impairment (but little of the oppositionality) of the combined subtype. The DSM-IV definition may be responsible for some confusion: the inattentive subtype (ADHD-I) requires only that the diagnostic criteria for hyperactivity-impulsivity are not met, so many apparent cases of ADHD-I may be better considered as showing mild ADHD-C. Furthermore, the behavioral descriptions of inattentiveness are not necessarily factorially pure; they include descriptions, such as failing to follow through on instructions that are very easy to confuse with non-compliance.

For clinical practice we suggest that “pure” inattentiveness deserves recognition, and distinction from other subtypes. It is particularly important to detect whether the inattentive behaviors are secondary to intellectual disability or specific academic disability; and to expect the absence of hyperactive-impulsive behaviors and not just a subdiagnostic level. The risk it carries is for educational and occupational underachievement rather than for psychiatric disorders.

An overactive/impulsive type without inattentiveness has been harder to identify, and is decidedly uncommon in clinical series. In epidemiological studies it is probably less common than the other forms of ADHD (Taylor et al., 1991). It can be hard to distinguish from oppositional disorder. A recent population survey of teacher ratings of children did not identify an attentive-but-hyperactive subgroup (de Nijs, Ferdinand, & Verhulst, 2007); and indeed it is ordinarily a feature of parental rather than teacher descriptions. In our developmental perspective, it is consistent with a notion that the relevant problems in the first 3 years of life are a rather diffuse set of difficulties in emotional, cognitive and behavioral self-regulation, and that at school entry the attentional component becomes particularly significant because of the scholastic difficulties it brings (see p. 532). In this account, a subtype without inattentiveness persists in problems at home rather than at school.

Situationality (i.e., children whose hyperactivity presents only at home or only at school) may also be worth distinguishing. Some evidence from twin studies suggests that this is not caused only by misidentification by one or the other party, but that to some extent there may be different genetic influences on behavior in the two settings (Nadder, Rutter, Silberg et al., 2002). Ho, Luk, Leung et al. (1996) surveyed a Chinese school population in Hong Kong with parent and teacher questionnaires, and selected those who showed hyperactive behavior at home only, at school only, or pervasively across both situations. The home-specific group showed less evidence of cognitive problems and more evidence of family conflict and adversity; perhaps they reacted with misbehavior that in turn was poorly controlled. The school-specific group showed more evidence of academic learning difficulties; perhaps some of their off-task behavior was a result of inability to cope with the lessons. In keeping with this, a cluster analytic study of subgroups in a clinically referred population in the UK found that the behavior problems in a school-situational group tended to appear later, only after school entry (Taylor, Everitt, Thorley et al., 1986).

The diagnostic and assessment work should not stop at the point where ADHD is recognized, but go on to a wider range of strengths and weaknesses.

Overactivity with stereotyped movements is a rather different pattern seen in clinical practice, especially in young people with severe intellectual disability. The activity can be extreme, but its repetitive quality distinguishes it from the disorganized and unpredictable activity of ADHD. ICD-10 recognizes it as a distinct category – “Overactive disorder associated with intellectual disability and stereotyped movements” – and places it as a type of pervasive developmental disorder, distinct from autism. The ICD-10 description includes the comment that stimulant medication is often unhelpful.

Such a disorder has not been validated – in fact, the idea has led to virtually no research. A key question is whether it is useful to separate it from autism and other brain disorders. Several predictions could test this: the pattern of activity and attention will not be the same as that of ADHD when it coexists with autism (see p. 524); it will not be brought about only by akithisia and dyskinesias caused by neuroleptic medication; it will be a persistent trait (rather than the episodes of cata-tonic overactivity sometimes seen in complex brain disorders); and it will not be accompanied by the characteristic social impairments of autism. All these can be tested; in the meantime the concept is of uncertain validity.

There are two useful current implications: the first is to emphasize a subgroup of overactive and handicapped children whose condition may actually be worsened by stimulants. The second is more theoretical: the idea relates to a distinction that can be made in animal experiments between hyper- and hypodopaminergic states. Some experiments can cause reduced dopamine transport activity in the brains of animals such as mice, and these lead to overactivity and changes in learning (Gainetdinov, Wetsel, Jones et al., 1999). Some forms of environmental stress on animals can also lead to overactivity
and cognitive alterations, and these are mediated by excess of dopamine (Arnsten & Goldman-Rakic, 1998). These states are probably not identical to that of the overactivity associated with hypodopaminergic states (see p. 529): they are often accompanied by stereotypic behaviors, made worse by novelty and improved by serotonin reuptake inhibitors or dopamine blockers rather than by stimulants (Gainetdinov et al., 1999). It is not impossible that such a heterogeneity might exist also in humans.

**Coexistent Disorders**

Clinical cases are often dominated by the coexistence of other problems alongside ADHD. The reasons for these associations need to be understood in the formulation of individual cases. There are three main sorts of associated psychiatric condition: neurodevelopmental disorders, disorders of childhood onset and adult type mental illnesses.

**Neurodevelopmental Disorders**

ADHD behaves in many ways like other neurodevelopmental disorders (see chapter 49). The male sex predominance, the course of persisting disability, research findings about altered brain structure and function, and associations with motor and language delays all parallel the findings in other conditions such as autism and other pervasive developmental disorders, learning disability, and Tourette disorder. Each of these conditions raises the probability of others being found in the same person. The likely reasons are that enhanced assessment leads to the discovery of other conditions, that the risk factors overlap and are of diffuse effect upon brain development and that the associated conditions all represent different aspects of neurological compromise with a range of expression.

In the case of *autism and allied disorders*, there is a clear clinical distinction to be made, and ADHD does not by itself produce the characteristic behaviors of autism (see chapter 46). The brain changes and neuropsychological alterations of autism are so different from those of ADHD that it seems unhelpful to regard them as a single condition. The small size of the brain in hyperkinetic disorder contrasts with the increased size in some cases of autism; the family histories do not overlap much; at the neuropsychological level both show difficulties in executive function, but inhibitory dysfunction is characteristic of ADHD while the more autistic problems of central coherence and theory of mind deficits are not (Banaschewski, Hollis, Oosterlaan et al., 2005). The comorbid state tends to have the associations of both conditions. It seems likely therefore that the two disorders are independent but often associated.

It is too soon to be clear about genetic similarities or differences. It is noteworthy that genome scans for autism and those for ADHD have both identified chromosomal loci that appear to be similar (Faraone, Perlis, Doyle et al., 2005). It is possible that there will prove to be both genetic influences of general effect, acting as susceptibility for a range of neuro-developmental problems, and others of more specific influence on individual disorders. At present, however, the results of molecular mapping of the chromosomes are too unstable for firm conclusions to be drawn. Some conditions known to have diffuse brain effects – notably congenital rubella and tuberous sclerosis – also raise the probability of showing both hyperkinetic disorder and autism.

It is sometimes possible for autism and hyperactivity to be associated in a different way: autism can produce a different sort of motor restlessness, to be distinguished from ADHD by its stereotyped nature and the perseveration upon idiosyncratic concerns. The distinction is made by the type of overactivity, which contrasts with the impulsive and frequently changing behaviors seen in hyperkinetic disorder. Conversely, children with ADHD may become very unpopular. Their social isolation and unreserved approaches to other children can then be mistaken for the social obliviousness of young people in the spectrum of autism. These conditions can often be distinguished on the basis of: (i) the presence of good social understanding that is shown by children with ADHD only, when they are given time to reflect about their social relationships; and (ii) direct observation of children interacting with their peers for the nature of the difficulties that they are showing.

When both problems are present together, detailed assessment is often needed. Sometimes the specific features of autism can be masked by the chaotic presentation of ADHD, so persistent observation over time is needed and the diagnosis should be reviewed when overactivity and impulsiveness have been reduced (e.g., by medication). It can be important to recognize the presence of ADHD in children with autism, even though the diagnostic schemes of ICD-10 and DSM-IV regard them as exclusive categories. Stimulant medication can be valuable for the control of overactive impulsiveness even in people who have clear autistic syndromes (Aman, Smelt, Derivan et al., 2002; Research Units on Pediatric Psychopharmacology Autism Network, 2005).

*Intellectual disability* can also both simulate and coexist with hyperactive syndromes (Willcutt, Pennington, & DeFries, 2000). For this reason, assessment of generalized and specific learning difficulties should be included in the evaluation of children presenting with hyperactivity and inattention syndromes. Attention problems can be secondary to cognitive impairment, and this may contribute to the finding of a late-onset and school-specific version in some cases (see p. 523). Problems in learning, however, can be secondary to poor attention and it is wise to re-evaluate the severity of academic difficulties after medication has been given. The widespread difficulties of children with intellectual disability (see chapter 49) usually include poor concentration, but it is only sensible to make the additional diagnosis of ADHD when the impairment of attention and activity control is out of proportion to developmental level. The way to allow for developmental delay has not been rigorously established, and it would be helpful to develop norms for different levels of disability. Until that is done, a useful clinical rule of thumb is to judge the patient’s attentiveness with reference to that which would
be expected in a child of chronological age equivalent to the
patient’s mental age.

**Tourette disorder** can either simulate ADHD or be an asso-
ciation of it. Evidence at this time is not conclusive about the
reasons for the association of the two disorders. Some
analyses of whether other family members are affected have
indicated that the two are unlikely to be related genetically
(Pauls, Hurst, Kruger et al., 1986), others that there is a
genetic link (Comings, 2001). Occasionally, the presentation
of overactivity proves on close analysis to be attributable to
a large quantity of different tics, making it difficult to appreci-
ate the repetitiveness involved unless and until prolonged
observation is undertaken, perhaps with videotaping for detailed
analysis. More commonly, ADHD and Tourette symptoms pur-
sue different courses in the same individual, with the waxing
and waning of tics being in some contrast to the persisting
difficulties imposed by the ADHD. Stimulants will sometimes
(but not necessarily) make the tics worse and improve the
ADHD. Careful delineation of the target problems in the
individual child and monitoring of treatment effects are then
required.

**Associations with Childhood Onset Problems**
The most common overlap of symptomatology is between
ADHD and oppositional/defiant or conduct disorders. Statisti-
cal analysis of symptoms, such as the latent dimension model-
ing by Ferguson and Horwood (1995), have suggested that
they can be seen as independent dimensions, but that they are
highly intercorrelated. A major diagnostic trap is to regard
ADHD as present when the evidence is only that of opposi-
tional misbehavior. It is also possible to make the opposite
error and attribute uncontrolled and impulsive behavior to
deliberate defiance. There is considerable scope for misunder-
standing among parents, teachers and health professionals.

In general, studies of children with both hyperactive and
defiant behavior have suggested that they show the associ-
atations of both conditions. Associations with other neurode-
velopmental delays are present as strongly in the combined
group as in those with hyperactivity alone; indeed, family
histories may be even more likely in the comorbid group
(Thapar, Harrington, & McGuffin, 2001). The group with both
problems is also more likely than those with ADHD alone to
show adverse factors in family life, including high levels of
critical expressed emotion (Taylor et al., 1991). Cross-twin
cross-trait analyses have suggested that a good deal of the
genetic influence on oppositional and conduct disorders is
the same as that influencing hyperactivity. When both prob-
lems are present, the history usually suggests that hyperac-
tivity came first; and follow-up of community ascertained
children who showed hyperactivity but not oppositionality
indicated that oppositionality could develop in people who
had originally shown hyperactivity only, but that the reverse
pathway was uncommon and that children with opposi-
tional disorders did not develop hyperactivity later (Taylor,
Chadwick, Heptinstall et al., 1996). The drug treatment of
hyperactivity is no less effective in those who have conduct
problems too than in those who do not (MTA Cooperative
Group, 1999).

Putting all these sources of evidence together, the sugges-
tion is that hyperactivity represents either a risk factor for later
oppositional and conduct disorders, or that it is an early-
onset form of conduct problem, with the longitudinal evidence
favoring the former hypothesis. The clinical implications are
important; it is worth detecting and treating hyperactivity
even before conduct problems have appeared. When conduct
problems do appear, the most useful diagnostic approach is
not whether they or hyperactivity predominate in the picture,
but whether hyperactivity and inattention are in fact present
– in which case a mixed disorder is recognized.

There is also an association with anxiety disorders: about
25% of children with ADHD also have an anxiety disorder
(Pliszka, 2000). These cases may represent a separate con-
dition, as implied by the ICD-10 rules in which anxiety
excludes the diagnosis of hyperkinetic disorder; may represent
an independent problem, as in DSM-IV’s conceptualization of
multiple diagnoses; or could represent a developmental change
in which some children with ADHD are at risk for the devel-
opment of anxiety as a complication. Research has not yet
distinguished these possibilities securely.

**Adult Type Mental Disorders**
In adolescence and adult life, ADHD starts to show an asso-
ciation with other diagnoses that are seldom made in child-
hood. Adolescent substance misuse, in particular, seems to be
much more common in people with the diagnosis of ADHD
(Wilens, Faraone, Biederman et al., 2003), although it is not
yet clear whether it is the ADHD per se that generates the
risk or the coexistent presence of antisocial activities and
peer groups. ADHD is common in personality-disordered
offenders (Young, Gudjonsson, Ball et al., 2003). Surveys in
prison populations have suggested that many incarcerated
young adults also show both previous histories and currently
high levels of hyperactive behaviors (45% in a survey by Rosler,
Retz, Retz-Junginger et al., 2004).

It has become increasingly popular to diagnose bipolar
disorder, even in prepubertal children (see chapter 38). Traditi-
onally, the distinction has been fairly easy to make. Bipolar
disorder has been associated with euphoria, grandiosity and
a cycling course, with each episode lasting for at least several
days. ADHD, by contrast, has been regarded as a persisting
disability in which euphoria is not particularly a feature.
The goal-directed overactivity of mania is usually seen as in
some contrast with the disorganized and off-task activity of
ADHD. However, there has been a broadening of the con-
cept of bipolar disorder to include cases where the mood change
is not euphoria but irritability, and where the cyclical nature
consists of many changes within a single day. This leads to a
very considerable similarity in formal definitions between this
so-called ultradian version of bipolar disorder and ADHD. An
unstable and overreactive mood is very common in ADHD,
even though it is not part of the diagnostic definitions, and
the development of an oppositional disorder, in which frequent
tantrums are common, can be described as an “irritable” state and therefore contribute to a bipolar diagnosis. For this chapter, it is important chiefly to note that the assessment of ADHD needs to include the recognition of rapid and volatile mood changes when they are present, and that they sometimes deserve intervention in their own right and monitoring as an outcome measure. Many assessment measures, such as the Conners’ scales, do indeed include such symptoms.

Possible associations with schizophrenia are raised because both groups can show erratic behavior and inattentiveness in childhood. Follow-up studies of ADHD into adult life (summarized below) have not shown an increased rate of psychosis, but the numbers involved have not yet been large enough to detect a modest increase in the rate. The clinical question sometimes arises of whether stimulant medication is unacceptably hazardous for the children of a schizophrenic parent. The strongest concern is usually to promote the best possible social adjustment for the child, so stimulants should not be ruled out lightly.

### Etiology and Pathophysiology

#### A Complex and Multifaceted Condition

Metaphors are often used in science to communicate complex and subtle ideas with clarity, coherence and power (Bradie, 1999). There are three metaphors commonly used in relation to ADHD: a genetic disorder (Comings, Chen, Blum et al., 2005), a frontostriatal executive dysfunction disorder (Loge, Staton, & Beatty, 1990; Wasserman & Lynn, 2001) and a catecholamine disorder (Levy & Swanson, 2001). In contrast to these simple metaphors, research suggests that ADHD is a heterogeneous and multifaceted condition involving interplay between diverse systems across multiple levels within the individual (Asherson, Kuntsi, & Taylor, 2005; Nigg, Willcutt, Doyle et al., 2005). In what follows, to help convey this complexity and sharpen the focus, existing empirical evidence will be set against the three simple metaphors mentioned.

#### Is ADHD a Genetic Disorder?

**Heritability**

Genetic factors are clearly important in ADHD (Thapar, Harrington, & McGuffin, 2005a) but little is known about the mechanisms by which their influence is exerted (Asherson, Kuntsi, & Taylor, 2005). Family, adoption and twin studies suggest ADHD is familial and largely inheritable (Rietveld, Hudziak, Bartels et al., 2003). Parents and siblings of cases display up to an eight-fold increased risk for ADHD (Faraone & Biederman, 2000) and biological relatives are more at risk than adoptive family members (Sprich, Biederman, Crawford et al., 2000). According to twin studies, ADHD is amongst the most heritable conditions with estimates between 60 and 90% (Thapar, Harrington, Ross et al., 2000).

**Specific Genes**

Candidate gene studies have produced a number of replicated associations (Faraone et al., 2005). The monoamines (especially dopamine, norepinephrine and serotonin) have been a major focus because of their hypothesized role in ADHD pathophysiology. In meta-analysis, significant pooled effects have been reported for three polymorphisms of dopamine genes; the D4 and D5 receptors (DRD4 and DRD5) and the dopamine transporter (DAT1; e.g., Faraone et al., 2005; Thapar, O'Donovan, & Owen, 2005a). Of these, the DRD4 and DAT1 are most likely to have functional significance. However, the DAT1 association has been challenged in recent meta-analysis (Wohl, Purper-Ouakil, Mourén et al., 2005). Given its claimed role in ADHD pathophysiology, it is surprising that there is as yet no evidence that norepinephrine gene variants are associated with ADHD (although it may be forthcoming). Based on animal knockout models, tests of potentially functional polymorphisms of the serotonin transporter and receptor genes (SLC6A4 and HTR1B) suggest an association with ADHD (Faraone et al., 2005). Genes coding for other neurotransmitter systems are actively being pursued.

**Interpreting Genetic Effects**

In contrast to the high heritability estimates, the effects of specific genes are small. When aggregated, they account for only a fraction of variance in symptom expression. How can this gap be explained? First, twin studies, although a potentially powerful tool for dissecting genetic and environmental effects, need to be interpreted with caution for a number of reasons, as they may overestimate genetic main effects (Rutter, 2002). For instance, heritability estimates subsume the effects of gene x environment interactions so that subtler environmental effects can be missed.

Second, it remains possible that a large number of genes, some of at least moderate effect, exist but have yet to be identified. The results from linkage studies, if further replicated, provide support for this although genes of major effect are unlikely (Arcos-Burgos, Castellanos, Pineda et al., 2004; Bakker, van der Meulen, Buitelaar et al., 2003; Hebebrand, Dempfle, Saar et al., 2006; Smalley, Kustanovich, Minassian et al., 2002).

Third, genes may interact with each other (Carrasco, Rothhammer, Moraga et al., 2006) and with environmental risk factors (see below) to increase the risk of ADHD in a non-linear manner so that genes of small main effect have disproportionate power when acting together or with environmental factors (Rutter, Moffitt, & Caspi, 2006).

Fourth, ADHD may be an etiologically heterogeneous condition with different combinations of genes (and environments) producing ADHD in different groups of ADHD children (Buitelaar, 2005; Todd, 2000). To combat this, researchers are attempting to create genetically more homogenous groupings by partitioning heterogeneity using clinical phenotypes (Faraone, Chen, Warburton et al., 1995) or by identifying pathophysiological intermediates that are more likely to be linked to specific genes than is the clinical disorder: so-called endophenotypes (Doyle, Faraone, Seidman et al., 2005).
Candidate Environments

The growing realization of the limitations of the study of the genes in isolation from environments has led to renewed interest in environmental risk in ADHD.

Prenatal Factors

Maternal lifestyle during pregnancy (e.g., smoking and drinking) has been linked to ADHD (Linnet, Dalsgaard, Obel et al., 2003). The evidence is strongest for maternal smoking, for which a dose–response relationship with ADHD appears to exist (Thapar, Fowler, Rice et al., 2003). The findings for alcohol consumption are less clear-cut if fetal alcohol syndrome is not implicated (Linnet et al., 2003). Exposure to cocaine has a range of harmful effects in utero, of which an increased risk of ADHD might be one (Linares, Singer, Kirchner et al., 2006). Maternal stress during pregnancy and associated over-secretion of cortisol have been implicated in ADHD (Kapoor, Dunn, Kostaki et al., 2006; O’Connor, Heron, Golding et al., 2003; Rodriguez & Bohlin, 2005). Exposure to medication (e.g., benzodiazepines; anticonvulsants) may represent a risk although these effects are difficult to disentangle from the effects of the maternal mental illness (Steinhausen, Losche, Koch et al., 1994).

Perinatal Factors

Bhutta, Cleves, Casey et al. (2002) reported a two-fold increase in ADHD in children born with a very low birth weight; an effect possibly mediated by small and subtle lesions in fronto-striatal brain circuits (Carmody, Bendersky, Dunn et al., 2006). ADHD children are more likely to have experienced pregnancy and birth complications (Ben Amor, Grizenko, Schwartz et al., 2005) but these effects are difficult to disentangle from low birth weight and the increased risk that vulnerable children may be at for a difficult birth.

Postnatal Physical Factors

Social and biological factors appear to have a role in the postnatal period. The role of artificial food additives remains controversial but a randomized controlled trial (McCann, Barrett, Cooper et al., 2007) showed important effects. Idiosyncratic allergies and intolerances of specific food stuffs are often identified by parents (Aardoom, Hirasing, Rona et al., 1997), and a recent meta-analysis and a large well-designed trial both suggested small but significant effects in exclusion and challenge trials (Bateman, Warner, Hutchinson et al., 2004; Schab & Trinh, 2004). Exposure to lead and related neurotoxins may be associated with a substantially increased risk of inattentive and hyperactive behavior – but these exposures are both linked to social disadvantage and cause other non-specific neurodevelopmental difficulties (Levit, 1999). Animal models implicate exposure to insecticides, such as DDT, although a clinical link has yet to be confirmed (Mariussen & Fonnum, 2006). Suggestions of the role of dietary deficiencies (e.g., omega-3 fatty acids, Richardson & Montgomery, 2005; iron, Konofal, Lecendreux, Arnulf et al., 2004) require further examination in large-scale trials.

Postnatal Social Environment

Chronic exposure to exceptional social environments early on during development can increase the risk for ADHD-like patterns. In the English and Romanian Adoptees study, for example, children who experienced extreme physical, cognitive and social deprivation in infancy were at an increased risk of pervasive and persistent overactivity and inattention (Kreppner, O’Connor, & Rutter, 2001; Stevens, Sonuga-Barke, Kreppner et al., in press) despite being adopted into well-resourced and committed homes before the age of 4 years. Claims that parenting is implicated in the causes of ADHD are controversial. Whereas children suffering extreme neglect and abuse may be at increased risk for ADHD (Glad & Teicher, 1996), variation in parenting style within the normal range has been assumed not to play a part (but see Morrell & Murray, 2003). Child ADHD can evoke negative and hostile responses from parents (Scipp & Johnston, 2005), while parental characteristics (including adult ADHD symptoms) can moderate these responses and exacerbate co-ercive cycles (Murray & Johnston, 2006). However, the very limited evidence from good longitudinal studies does not support the idea that this increases the likelihood of ADHD onset or persistence; rather, it predicts the onset of later comorbid conduct disorder (Taylor, 1999) and depression (Ostrander & Herman, 2006). However, the fact that parent training can significantly reduce core ADHD symptoms in preschoolers highlights the potential power of the social environment to influence the course of ADHD (Sonuga-Barke, Daley, Thompson et al., 2001).

Interpreting Environmental Effects

As with genetic effects, the literature suggests a role for multiple environmental influences of small effect. However, one must be cautious when interpreting these findings because specific environmental risks are embedded in a network of other factors relating to lifestyle, social class/economic adversity and maternal personality (Taylor & Warner Rogers, 2005). Furthermore, interpreting these associations is complicated by the fact that environmental risks may be markers of genetic risk (Dick, Viken, Kaprio et al., 2005). These sorts of effects can be because environments experienced by the child are correlated with genes shared with parents (passive gene–environment correlation; Kendler & Baker, 2007). Knopik, Heath, Jacob et al. (2006) found evidence in support of this by exploring levels of ADHD in the children of identical twins with or without a history of alcohol abuse: ADHD was common both in the children of twins with a history of alcohol abuse and of the monozygotic cotwins who had no such history themselves. Environmental associations could also be evoked by genetically based characteristics in the child – as when ADHD symptoms elicit maternal hostility (active gene–environment correlations). Although these gene–environment correlations are assumed to exist and account for a proportion of environmental risk in ADHD, little evidence exists for their role.

Because of the limited size of effects of genes and environments when each is considered in isolation, attention has turned
to gene–environment interactions. A gene–environment inter-action occurs when the phenotypic effects of a gene vary as a function of the physical or social environment (Caspí, Sugden, Moffitt et al., 2003) and the two risks are combined in a non-linear way to account for a disproportionate amount of variance in ADHD. Gene–environment interactions have been reported for ADHD involving both maternal smoking (Kahn, Khoury, Nichols et al., 2003) and alcohol consumption during pregnancy (Brookes, Mill, Guindalini et al., 2006) and DAT1 as well as for DRD4 and season of birth (Seeger, Schloss, Schmidt et al., 2004). These findings, although potentially important, require replication before their ultimate significance can be assessed.

In summary, ADHD is not a genetic disorder in a simple sense. A reasonable working hypothesis is that genetic and environmental influences of small effect, while correlated to some extent, likely act together (both additively and multiplicatively) to create a spectrum of neurobiological risk.

Is ADHD a Fronto-striatal/Executive Function Disorder?

The Fronto-striatal/Executive Function Disorder Hypothesis

Evidence for the role of alterations in brain structure and function in ADHD is compelling. Debate continues as to which specific brain circuits are most important. The search for the biological basis of ADHD has been motivated by the assumption that a common core of neurobiological dysfunction is responsible for the condition (Sonuga-Barke, 1998). Following the reconceptualization of hyperactivity disorders in DSM-III-R, the role of attention was highlighted, placing neurocognitive deficits at the core of the disorder (Castellanos, Sonuga-Barke, Tannock et al., 2006). Subsequent attempts to “fine-map” deficits in terms of more refined attentional concepts from cognitive psychology have mostly been unsuccessful (Huang-Pollack, Nigg, & Carr, 2005).

The fronto-striatal/executive function disorder (FS/ED) hypothesis involves a broader conception of cognitive deficits based on the observation of similarities between people with ADHD and those with disorders caused by frontal lobe lesion or disease (Denckla, 2002). The publication of Barkley’s model, in which early established inhibitory processes are a developmental precursor to the emergence of executive competence, has been extremely influential (Barkley, 1997). FS/ED focuses on higher order intentional cognitive processes including response inhibition, planning, working memory, attentional flexibility and speech fluency: constructs grouped loosely under the umbrella of executive function; a concept, although criticized for its lack of specificity, that continues to be used widely in the psychological literature. Neuroanatomically, these functions are linked to activity within the “cognitive” thalamo-cortico-striatal loop (Alexander & Crutcher, 1990). Projections from the prefrontal cortex (specifically the dorsolateral region) to the neostriatum (specifically the caudate nucleus) pass via a complex set of direct and indirect basal ganglia pathways through the thalamus and back to the prefrontal cortex. Although anatomically and functionally segregated, this network has strong connections to other more posterior regions including the frontal motor cortices, the parietal cortex and the cerebellum (Timmann, Richter, Schoch et al., 2006). Activity within this circuit is mediated by GABA and glutamate and modulated by the catecholamines – dopamine and norepinephrine.

Evidence Supporting the FS/ED Hypothesis

Neuropsychology

Recent quantitative reviews support the association between ADHD and executive dysfunction across a wide range of domains and measures within domains (Huang-Pollack & Nigg, 2003; Lijffijt, Kenemans, Verbaten et al., 2005; Oosterlaan, Logan, & Sergeant, 1998; Willcutt, Doyle, Nigg et al., 2005). A comprehensive review is outside the scope of this chapter but a brief survey provides robust and convincing evidence that children with ADHD perform worse than controls in domains such as response inhibition and interference control, planning and working memory. Pooled effect sizes from a meta-analysis of nearly 7000 children are only in the moderate range (0.4–0.6; Willcutt et al., 2005). Furthermore, in a very large study using an extensive battery of tasks only about half of the children with ADHD displayed a deficit on any one executive task and very few subjects showed a pervasive pattern of EF deficits (Nigg et al., 2005). This is in keeping with the idea that neuropsychological tests are of limited value diagnostically, in and of themselves.

Structural Neuroanatomy

Total brain volumes of children with ADHD are reduced by up to 5% with effects on both gray and white matter and larger reductions apparent in the right hemisphere (Seidman, Valera, & Makris, 2005). Reductions in intracranial volume have been reported (Durston, Pol, Schnack et al., 2004). Unsurprisingly, given the dominance of the FS/ED hypothesis, work has concentrated on two regions in particular – the prefrontal cortex and the striatum, especially the caudate nucleus. Region of interest (ROI) analyses provide good evidence of alterations within the dorsolateral prefrontal cortex and the neostriatum (caudate/putamen; Castellanos, Lee, Sharp et al., 2002). Cortical thinning may be especially marked in prefrontal regions implicated in executive control (Shaw, Lerch, Greenstein et al., 2006). While these effects persist after controlling for medication status and comorbidity, most are lost if total brain volume is taken into account (Castellanos et al., 2002).

Functional Neuroanatomy

Functional magnetic resonance imaging (fMRI) case–control studies report reduced activation within both the ventrolateral and dorso-lateral prefrontal cortex (Durston, Tottenham, Thomas et al., 2003; Rubia, Overmeyer, Taylor et al., 1999, 2005) as well as the neostriatum (i.e., caudate and putamen; Rubia et al., 1999; Vaidya, Bunge, Dudukovic et al., 2005), with the most consistent findings relating to the caudate nucleus. Positron emission tomography (PET) and single photon emission computed tomography (SPECT) report reduced
glucose metabolism in frontal regions (Ernst, Kimes, London et al., 2003; Schweitzer, Lee, Hanford et al., 2003). Studies using event-related potentials (ERPs) and other electrophysiological paradigms provide further evidence for the FS/ED hypothesis (Fallgatter, Ehls, Rosler et al., 2005).

Beyond Fronto-striatal/Executive Dysfunction

Despite this focus on the FS/ED circuit there is strong evidence for the involvement of other brain circuits and related psychological functions. At the neuropsychological level, a very broad range of extra-executive domains has been implicated, including timing and temporal synchrony (likely implicating thalamo-cerebellar circuits; Toplak, Dockstader, & Tannock, 2006); reward and motivation (likely implicating orbito-frontal-ventral-striatal circuitry; Sagvolden, Johansen, Aase et al., 2005; Sonuga-Barke, 2005); attentional orienting and alerting (likely implicating posterior parietal networks; Banaschewski, Brandeis, Heinrich et al., 2004) and more broadly based difficulties in the regulation of arousal and alertness (Sergeant, 2005) and heightened stimulation seeking (Antrop, Roeyers, Van Oost et al., 2004). In these studies, effect sizes are in the range reported for executive deficits; again suggesting that only a subgroup of ADHD children are affected by each pattern of difficulty. Structural alterations are also widespread affecting temporal, occipital and parietal lobes, the corpus callosum and cingulum (for a review see Seidman, Valera, & Makris, 2005). Effects in relation to the cerebellum are perhaps most striking (Castellanos et al., 2002). There is emerging evidence of alterations in key foci such as the amygdala (Plessen, Bansal, Zhu et al., 2006). In terms of functional imaging studies, two types of evidence for extra-executive circuitry involvement come from imaging studies. First, there are those studies that have specifically probed executive circuits but found evidence for the role of other brain regions. For instance, response conflict studies using Stroop-like tasks have reported reduced activation in widely distributed networks with loci not normally conceptualized within the executive loops (i.e., anterior cingulate cortex; Bush, Frazier, Rauch et al., 1999; Rubia et al., 1999; Tamm, Menon, Ringel et al., 2004), the parietal and temporal lobes and cerebellum (Tian, Jiang, Wang et al., 2006; Vaidya et al., 2005). There are also those studies that have purposefully probed other regions and processes in an attempt to explore the neurobiological basis of the diverse neuropsychological processes implicated in ADHD. Although currently less common these studies have started to delineate the functional neuroanatomy of alerting and reorienting and reward anticipation (Scheres, Dijkstra, Ainslie et al., 2006).

Interpreting the Neuroscience Evidence

Although, at the group level, FS/ED is associated with ADHD, a closer examination of the evidence does not support a strong version of the FS/ED hypothesis – that FS/ED is the common core dysfunction of ADHD. In fact, FS/ED may be sufficient for ADHD but it is not necessary. It seems increasingly clear that: (i) at the group level, ADHD is associated with a diverse range of non-executive deficits; and (ii) at an individual level, many children with ADHD appear not be affected by executive dysfunction to any significant degree. Recent models have emphasized this psychopathophysiological heterogeneity (Sonuga-Barke, 2005) and developed the idea that ADHD is an umbrella construct which, while clinically useful, subsumes multiple groups of patients with distinctive etiological and pathophysiological profiles. Studies with measures from multiple domains and large samples sufficient to test this multiple pathway hypothesis are currently rare and limited to the neuropsychological domain. Solanto, Abikoff, Sonuga-Barke et al. (2001) found that executive dysfunction (measured using the stop signal paradigm – a measure of the ability to inhibit an already initiated response when requested) and delay aversion (measured using the choice delay task – a preference between a small immediate and a large delayed reward) were both deficient in ADHD, despite being uncorrelated with each other – suggesting two dissociable bases for the disorder. Similar results were found in samples of preschoolers (Dalen, Sonuga-Barke, Hall et al., 2004) and children with hydrocephalus and spina bifida (Stevenson & Cate, 2004). Research extending this account to other areas of deficit and levels of analysis is currently under way.

In summary, ADHD is not an FS/ED disorder in any simple sense. A reasonable working hypothesis is that ADHD is an umbrella construct that subsumes multiple subgroups of patients each with their own distinctive psychopathophysiological signature, of which fronto-striatal/executive dysfunction is just one.

Is ADHD a Catecholamine Disorder?

Four observations provide indirect evidence for the role of catecholamine dysregulation in ADHD. First, ADHD symptoms are reduced by dopamine (DA) and norepinephrine (NE) agonists such as methylphenidate, amphetamine and atomoxetine, which act via different mechanisms to increase extracellular DA and NE but have similar clinical effects (Pliszka, 2005). Second, as reported above, there are a number of associated polymorphisms in genes affecting catecholamines, especially DA (Faraone et al., 2005). Third, within animal models pharmacological lesions and gene knockout of catecholamines produce behaviors that mimic ADHD (Arsten & Li, 2005; Madras, Miller, & Fischman, 2005). Fourth, NE and DA, although widely distributed within the brain, have core branches that heavily innervate regions implicated in the neuropsychological underpinnings of ADHD. There are two main dopamine branches: the meso-cortico-limbic branch with cells projecting from the midbrain ventral tegmental area to the limbic regions including the amygdala, the ventral striatum and the frontal cortex and the nigro-striatal branch projecting from the substantia nigra to the striatum. The norepinephrine system has major projections from the locus ceruleus throughout the cortex (anterior and posterior) and into the cerebellum.

More direct evidence for the role of catecholamines in ADHD comes from several sources, with the literature being
largely limited to DA. SPECT and PET studies have found increased dopamine binding in the striatum in ADHD (reviewed by Spencer, Biederman, Madras et al., 2005), a finding that fits well with the clinical action of methylphenidate (Volkow, Wang, Fowler et al., 2005). Methylphenidate (MPH) has remedial effects on neuropsychological deficits in the domains of inhibition (Boonstra, Kooij, Oosterlaan et al., 2005; Klein, Fischer, Fischer, et al., 2002; Turner, Blackwell, Dowson et al., 2005), sustained attention (Boonstra et al., 2005), working memory (Mehta, Goodyer, & Sahakian, 2004; Turner et al., 2005), set shifting and planning (Kempton, Vance, Maruff et al., 1999). MPH appears to have beneficial effects on other areas of functioning not traditionally linked to the fronto-striatal cognitive loop, such as visual memory (Rhodes, Coghill, & Matthews, 2004), timing (Baldwin, Chelonis, Flake et al., 2004) and the motivational salience of a task (Volkow, Wang, Fowler et al., 2004), but whether these effects are related to the treatment of ADHD is not known.

Interpreting Neuropsychopharmacology of ADHD

Although the evidence implicating the catecholamines is persuasive, much of it is circumstantial and indirect in nature and therefore difficult to interpret. Even if one can demonstrate that dopamine agonists reduce symptoms and improve functioning, and that this varies as a function of genotype, it does not necessarily implicate DA in the pathophysiology of the disorder. There are a number of reasons for caution. Case-control studies suggest that the effects of MPH are similar in nature for both clinical cases and controls. In keeping with this, recent reports have suggested that MPH has a broad-based generic effect on arousal and the motivational salience of tasks rather than specific effects on the neural circuits shown to be affected in ADHD (Volkow et al., 2005). Interpreting these effects vis-à-vis the role of DA in ADHD is further complicated by observation that MPH can have effects on both the phasic and tonic aspect of the DA response. Volkow and Swanson (2003) have argued that the therapeutic effects of DA occur following slow and stable increases in DA (i.e., increased DA tone), while its abuse potential is related to short and rapid changes that mimic phasic firing. The significance of these effects for understanding the specificity of the “dopamine deficit” (in phase or tone) in ADHD is as yet unclear. The most direct evidence for DA deficits comes from those PET imaging studies showing increased dopamine transporter (DAT) density in ADHD (although there have been a number of non-replications of this effect). However, the adaptive quality of neural systems means that DAT up-regulation is likely to be a consequence of a complex set of neuroanatomic alterations (Russell, 2002). While lower densities could represent a relatively permanent trait closely linked to the fundamental neurobiological causes of ADHD, they could equally be a consequence of the condition or a marker of some more fundamental neurobiological process (Madras, Miller, & Fischman, 2002). Animal models suggest that DA and NE systems interact (Liprando, Miner, Blakely et al., 2004) with each other and with other neurotransmitters such as serotonin and acetylcholine (Olijslagers, Werkman, McCreary et al., 2006), and future models of both the pathophysiology of the disorder and its treatment need to take account of this.

In summary, a sensible working hypothesis is that catecholamine function appears to be implicated in ADHD but the issues of cause and effect are difficult to disentangle and the particular mechanisms are likely to be complex and involve interactions between NE and DA as well as other neurotransmitters.

An Integrative Framework for ADHD

Etiology and Pathophysiology

Figure 34.1 illustrates a framework that integrates the working hypotheses set out above with the aim of communicating the key themes set out in this section. Multiple early genetic and environmental influences of small effect act together to create a spectrum of neurobiological risk by altering brain structure and function and associated cognitive processes that mediate the emergence of ADHD. The postnatal environment also has an important role within the model, both as secondary direct influences on brain processes (e.g., diet, environmental toxins) and as mediators/moderators of outcome through reciprocal coercive cycles of interaction (e.g., negative parenting). The framework also makes explicit the heterogeneity in ADHD by including multiple pathways to ADHD, each potentially associated with a different set of primary influences, and mediating and moderating processes. In this particular model, three different pathways are hypothesized but this is for illustrative purposes only. Exploring these different pathways by examining the way that neuroanatomic and neuro-functional and psychological processes mediate the effects of genes and environments on ADHD represents a major research priority (Castellanos & Tannock, 2002). From a clinical point of view, this sort of model highlights the need for broad-based assessments of multiple impairments across diverse regions of functioning as well as tailoring of treatment to a child’s particular areas of difficulty rather than generic or formulaic approaches.

The assumption behind most of the research on pathophysiology has been that the basis for ADHD is similar during all developmental periods. This means that there are few comparative data across different stages. Studying developmental changes in the pathophysiology of ADHD is an important priority for future studies.

Epidemiology

Several studies converge on a point prevalence for hyperkinetic disorder of about 1.5% in the primary school age population, and about 5% for ADHD (Swanson et al., 1998).
A recent National Morbidity Survey in the UK was based on a nationally representative sample of more than 10,000 children studied with rating scales and structured interviews given by non-clinical researchers, after which clinicians made diagnoses on the basis of the information gathered (Meltzer & Gatward, 2000). The rate for hyperkinetic disorder was about 14 per 1000 children, with the rate substantially lower for girls than for boys (the usual ratio in the population being around 1 : 3; Heptinstall & Taylor, 2002).

The use of health services was quite high in the hyperkinetic group, with nearly half of the children receiving some sort of intervention – but this did not necessarily imply that their hyperactivity had been identified as a problem. Indeed, an epidemiological study in a London borough found that only about 1 child in 10, out of those identified by high scores on rating scales from teacher and parent, were in practice receiving a diagnosis of ADHD (Sayal et al., 2002). National UK figures suggest that stimulant medication is given for only about 3 children per 1000 (NICE, 2005), and most other European nations are lower still. By contrast, surveys in the USA indicate about 3% of all school-age children being diagnosed and treated (Olfson, Gameroff, Marcus et al., 2003; Safer & Zito, 2000) – although with considerable variation in different parts of the nation.

A child whose behavior is hyperactive has a complex journey to becoming a diagnosed case. The knowledge, tolerance and attitudes of parents, teachers and health practitioners will all affect the apparent prevalence. The great international differences in the prevalence of diagnosed conditions appear to reflect the criteria used more than the behavior of children (Swanson et al., 1998). ADHD point prevalence estimates internationally cluster around 5–10%; hyperkinetic disorder around 1–2%; screening questionnaire ratings of those at risk around 10–20%. Attention deficit without hyperactivity has received less research attention, but is troublesome for something like another 1% of the school-age population.

In countries where there is a large difference between population rates and the numbers diagnosed in practice, there can be considerable fluctuations over time in the apparent prevalence. The numbers treated in the UK appear to have risen some five-fold in a 10-year period (NICE, 2005), but the point prevalence in the UK’s National Morbidity Survey was very similar to that of estimates made more than 10 years previously (Meltzer & Gatward, 2000; Taylor et al., 1991).
CHAPTER 34

Hyperactive behavior seems to have been relatively stable over decades at a time when other types of mental health problem in young people have been rising (Collishaw, Maughan, Goodman et al., 2004). One implication is that changes in society – such as the rise of television viewing and eating processed food – are unlikely to be critical factors, but that recognition of problems can change dramatically in a short time.

**Longitudinal course**

The course from early childhood into the school years is variable. From infancy to the age of about 3 years there is a great deal of variation, and indeed the early stage may be a rather wide set of temperamental problems in self-regulation, but by the age of 4 years a diagnosis of ADHD is very likely to persist into school age (Lahey, Pelham, Loney et al., 2004). A population study comparing monozygotic with dizygotic twins has concluded that there are genetic influences on the course of hyperactive behavior over the early years, not only on the initial appearance of the problem (Asherson, 2005). The transitions into nursery and school life bring different kinds of challenge to children with less well-developed control of impulse and attention than their peers.

From childhood into adolescence, there is a risk for the core behaviors to continue and about half of previously diagnosed cases will still meet diagnostic criteria (Klein & Mannuzza, 1991). Indeed, unreferral cases in the community, and those with high levels of behavior problems that fall short of the diagnosis, continue to show impaired social development: impulsiveness declines in absolute terms, but remains deviant relative to age-matched peers (Taylor et al., 1996). Lack of friends, work and constructive leisure activities are prominent in adolescence, motor accidents become a considerable risk, and there is academic underachievement. A major possible outcome for those who show impulsiveness and overactivity (as opposed to inattentiveness alone) is the development of aggressive and antisocial behavior and delinquency (Farrington, 1995).

Substance misuse deserves particular mention because of its importance in young people’s development (see chapter 36). A review and meta-analysis by Wilens et al. (2003) has indicated both that ADHD is associated with (and precedes) substance misuse, and that the association is not caused by prescribed medication, for those taking stimulants show lower rates of substance misuse. There is some evidence from longitudinal research (Taylor et al., 1996) that the pathway from ADHD into misuse is dependent upon the appearance of conduct disorder.

Several prospective studies have followed patients through adolescence into adulthood (Barkley, Fischer, Edelbrock et al., 1990; Biederman, Faraone, Milberger et al., 1996a,b; Faraone, Biederman, Mennin et al., 1996; Faraone, Biederman, & Mick, 2006; Hechtman & Weiss, 1983; Mannuzza, Klein, Bessler et al., 1998; Mick, Faraone, & Biederman, 2004; Weiss & Hechtman, 1993). These studies taken together suggest that a majority of diagnosed young people no longer meet criteria for ADHD in adult life, but that nevertheless many will still show above-average levels of inattentiveness and impulsivity (estimated variously at 10–40%: Barkley, 2002; Biederman, Mick, & Faraone, 2000; Faraone et al., 1996; Faraone, Biederman, & Mick, 2006; Hill & Schoener, 1996; Spencer, Biederman, Wilens et al., 1996). There is something of a puzzle in that ADHD diagnosed using strict DSM-IV criteria ought to be substantially less common in adults according to the longitudinal studies, yet cross-sectional surveys in adult life come up with surprisingly high prevalence rates of about 4% (Kessler et al., 2006). Adult surveys also indicate a very high degree of comorbidity, so it may be that ADHD criteria can be met because of the presence of adult mental disorders or that persistence of ADHD is a strong cause of other adult disorders.

The functional importance in adults is variable. Antisocial behavior tends to persist (Hechtman & Weiss, 1986), and sometimes the overall impact may worsen because of the increased demands of an adult environment and manifest as: educational, organizational or occupational failures; substance use disorders and other dependent, risky, antisocial or illegal behaviors; or emotional and relationship difficulties (Millstein et al., 1998). Nevertheless, for some, adult life can also bring opportunities for better social adjustment. People can choose occupational niches, such as sales and trading, in which good skills in immediate problem-solving are more important than longer drawn out planning and foresight.

It is also quite possible for ADHD to present for the first time in adult life. There will then be a story of symptoms having been present in childhood but having been unrecognized, or misattributed or not impairing. Protective factors, such as high intelligence or capable upbringing, may have meant that there was in effect no problem. Some of these protections may have been left behind, or more difficult challenges may have appeared. Sometimes, life changes, such as embarking on higher education or promotion to increasingly responsible positions, may be the first occasions for ADHD to cause failure and presentation to a health service.

The influences determining persistence or remission of ADHD into adolescence and adult life should be very important: they ought to be key targets for intervention. More research is needed to determine this. Environmental childhood factors did not turn out to influence the persistence of inattention and impulsivity into early adult life in a prospective longitudinal study of untreated and non-comorbid hyperactivity (Taylor et al., 1996). However, factors such as hostile attitudes from parents and non-acceptance by peers did predict whether aggressive and other antisocial complications would develop (Rutter, Maughan, Meyer et al., 1997); and a val-val genotype in a COMT gene polymorphism together with a low birth weight predicted the development of antisocial symptoms in those with ADHD (Caspi, Langley, Milne et al., in press; Thapar, Langley, Fowler et al., 2005b). Polymorphisms in the dopamine genes (DAT1 and DRD4) have predicted persistence to poor social outcome later (Mill, Caspi, Williams et al., 2006). Persistent cases of ADHD tend
to have stronger histories of ADHD in other family members (Faraone, 2004), suggesting that genetic factors influence course at this stage of development too; that family relationships help to determine the course; or that one family member’s behavior makes others act in the same way. The implications for practice are that from childhood to early adult life, and perhaps longer, severe levels of hyperactivity and inattentiveness should be seen as potentially chronic disability, and that intervention should target not only the core symptoms but also the surrounding tangle of adverse personal relationships and educational failure.

**Clinical Assessment**

At all ages there is a need for information from multiple sources. Clinical recognition needs to be based upon experience of what is expected of children at different ages and at different developmental levels.

In preschool, observational approaches are often required. There is a wide range of variation of parental tolerance, and considerable overlap with other aspects of a “difficult” temperament. It may be possible to witness directly the overactivity, the disinclination to wait and the choice of immediate rather than delayed gratification – for example, by setting up a waiting situation in which the children will have a larger reward if they refrain from grabbing an immediate one. Parental interview accounts are especially useful if they are based on observable behaviors rather than global descriptions such as “irritable.”

By school age, a wide variety of parent and teacher rating scales are available and have been reviewed (Stein & Perrin, 2003; Taylor, Dopner, Sergeant et al., 2004) with conclusions that instruments developed for the specific purpose of assessing ADHD are usually more accurate than general purpose psychopathological instruments (Miller, Lee, & Raina, 1998). The sensitivity and specificity of such instruments often appear to be very good, yet even then the classification obtained can be inadequate. Measures such as Conners’ rating scales show an effect size for children with ADHD, compared to normal controls, of around 3 standard deviations (SD), and this level of discrimination should correspond roughly to 80% levels of sensitivity and specificity, or even better.

While this sounds very impressive, the difference in base rates implies that non-hyperactive children will still be wrongly identified as ADHD so often that they may outnumber the true cases. (In the above example, and assuming a 5% prevalence, the 20% wrongly identified come from about 95% of the children, resulting in 18% false positives; while correctly detected true cases will be about 4% of the population.) Causes of false positives include raters without sufficient appreciation of the developmental norms for that age, raters who bring qualities of their relationship with the child to bear on making their rating of behavior, and contrast effects in which children are implicitly rated against other members of the family or other members of the subculture.

Detailed clinical interview with the parent (or other caregiver) is usually the most valuable single measure. In this context it is possible to go beyond the request for a rating of whether a child’s impulsiveness is abnormal, to a description of the behavior on which that rating was based. The interviewer can then apply a clinically informed judgment as to whether that level of behavior is in fact abnormal for the child. Every effort should be made to obtain and discuss ratings by schoolteachers.

Observations of the child’s behavior are also valuable, especially when there is diagnostic doubt. By the time of school entry, however, much of the overt behavior will be modified – at least in the artificial circumstances of clinic assessment. The novelty of the situation, the focused adult attention and the structured nature of the situation all militate against hyperactivity being readily observable. The diagnosis should therefore not be dismissed for the sole reason that the child appears well controlled during assessment. Nevertheless, when abnormality is seen, then direct observation is invaluable for detecting its pattern, its antecedents and its consequences.

For adults who seek services for the first time, their own account of themselves is often the main presentation. However, self-report is of limited value by itself. There was less continuity between childhood hyperactivity at age 7 and self-reports at age 17 than there was for ratings made by people who knew the young person well (Danckaerts, Heptinstall, Chadwick et al., 2000). Genetic influences are less strong for self-report than for ratings by others. Whenever possible, diagnostic assessments should include the accounts of parents, partners or other good informants, and the differential needs to include hypomania and personality disorder.

Various rating scales have been developed for adults. The Wender Utah Rating Scale focuses on retrospective symptoms in childhood plus current hyperactivity, inattention and other symptoms: the recall of childhood has been validated against parent report and found to be reasonably reliable (Ward, Wender, & Reimherr, 1993). The Adult Self Report Scale (Adler, Kessler, & Spencer, 2004; Kessler, Adler, Ames et al., 2005), Conners’ Adult ADHD Rating Scale (Conners, Erhardt, Sparrow et al., 1998) and Brown Adult Attention Deficit Disorder Scale (Brown, 1996) are also available.

Assessment should not stop at the recognition (or exclusion) of a syndrome of hyperactivity and inattentiveness, but go on to consider the subtypes, any coexistent disorder and the likely causal pathways as sketched in this chapter. The strengths and weaknesses of the family and school are important for their ability to cope and for what kinds of intervention will be most appropriate.

Physical examination should be close enough to uncover any evidence of neurological disease and assess coordination; to exclude hearing impairment; and to note any evidence of underlying chromosomal disorder or thyroid disease. Physical investigations are not routinely needed, but should be guided by history and examination. Psychological testing does not normally give the diagnosis (which is behavioral) but is valuable for several other purposes: analyzing reasons for poor
learning, providing suggestions for classroom education, detecting coexistent cognitive impairments, and establishing an approximate estimation of mental age, against which the specificity of attention impairment should be measured. The research tests reviewed earlier in the chapter have not in general been developed to the point that their test–retest reliability is known and they have not been standardized to the point where normal values are known, so they are not yet recommended for clinical practice. There are several commercial versions of Continuous Performance Tests (which are not necessary for following the response to medication but can be useful in cases where the response is unclear), and a convenient set of tests of sustaining, focusing and dividing attention and inhibition is available as the TEACH (Test of Everyday Attention for Children; Manly, Anderson, Nimmo-Smith et al., 2001).

**Treatment**

Intervention begins with an explanation of the disorder and its nature, directed to the child, family and teachers. Sometimes this is enough in itself. The alleviation of adult guilt and irritation with the child may benefit the child considerably. Advice and assessment should try to ensure that the parenting context includes positive contacts between parent(s) and child together with clear expectations for appropriate, and sanctions for inappropriate, behavior. Simple advice to schools on managing hyperactivity was helpful in reducing hyperactivity ratings of the children in a large-scale randomized non-blind trial (Tymms & Merrell, 2005).

Trial evidence has appeared for some more specific interventions – especially medication, behavior therapy and dietary treatments.

Stimulant medication – usually methylphenidate or dexamphetamine – is widely given and licensed for children in many countries. Atomoxetine has a license in the USA for children and adults and is licensed in Europe for children and for adults if their treatment has started in childhood. These three medicines have received extensive trials and systematic reviews (that by NICE, 2005, is particularly comprehensive). All three are efficacious in comparisons with placebo: effect sizes of MPH on hyperactivity symptoms in randomized controlled trials are between 0.8 and 1.1 SD; and those of atomoxetine around 0.6 SD (Banaschewski, Coghill, Santosh et al., 2006).

Behavior therapy has received several trials, but no very satisfactory systematic review. Miller, Lee, & Raina (1998) excluded most trials on methodological grounds, and from the two trials remaining thought there was no evidence of superiority to standard clinical care. One large-scale random allocation non-blind trial in the USA focused on the comparison between careful medication management, intensive behaviorally oriented psychosocial therapy, a combination of the two, or a simple referral back to community agencies (which usually resulted in medication) (MTA Cooperative Group, 1999). The main conclusions after 14 months’ treatment were that careful medication was more powerful than behavior treatment, and considerably more effective than routine medication in the community. There were many advantages in adding medication to behavior therapy, but relatively few to adding behavior therapy to medication. The superiority of careful medication to behavior therapy was all the more striking in that the behavior therapy provision was much more intensive and prolonged than could be achieved by a community service. The combination of behavior therapy and medication did have some benefits: better control of aggressive behavior at home; improving the overall sense of satisfaction of parents; possibly reducing the medication dosage; and increasing the rate of achieving “normalization” (the reduction of problems to a level where none was rated as more than minor). These improvements were real but modest, and would probably not justify the very high costs of the full treatment package in this research-based form. Follow-up 2 years after the end of the trial suggested that the differences between therapies had lessened or disappeared.

It does not follow from the power of medication that it is always the first choice treatment. Behavioral therapy may be less effective, but it is still helpful for many children. The costs of a short course of parent training are comparable to those of medication; the outcome may be somewhat less favorable in terms of symptom reduction, but it has the advantage of carrying very little physical hazard.

A re-analysis of the MTA study has found that the superiority of medication to behavior therapy is greater in hyperkinetic disorder than in other types of ADHD (Santosh et al., 2005). The trial suggests that most children whose problems are severe enough to get a diagnosis of hyperkinetic disorder will need medication. Family attitudes should of course be respected, and often a trial of psychological treatment will be attempted, but medication should be advised if there has been no substantial improvement after a few weeks.

For children at lesser degrees of severity – those who show ADHD but not hyperkinetic disorder – the choice of initial therapy is more evenly balanced. In these milder cases there are options about which treatment to start with. Decisions will depend on the analysis of the individual child, the strengths and weaknesses of their school and classroom environment, the severity of disturbance of peer relationships, and the preferences of the families. It is quite reasonable to start with either therapy, in the knowledge that one will proceed to the other should the response be suboptimal.

The details of treatments have been spelled out in guidelines (e.g., Taylor et al., 2004) and textbooks (e.g., Barkley, 2000). The principles of behavioral intervention do not differ greatly from those used in therapy of other behavioral problems in childhood. Specifically and operationally described problems should be identified, the contingencies that affect them established, and a monitored approach taken to enhancement of adult attention to the child and effective instruction (see chapters 62 & 64). Particular attention should be paid to speed in the delivery of rewards or response cost; explaining to the child which of their behaviors has earned the reward, or loss of reward; varying rewards frequently; and ensuring that there is variety and novelty in the management system. These aspects
of therapy have particular relevance to overcoming the attention problems that often compromise the response to behavior therapy. Novel non-pharmacological approaches that target core ADHD deficits (e.g., working memory training; Klingberg, Fernell, Olesen et al., 2005) have been developed but lack sufficient empirical support to recommend them at present.

Medication usually starts with immediate-release MPH given three times a day in doses starting with 5–5–2.5 mg or 10–10–5 mg (depending on the size of the child), and should be monitored by parents and teachers (and if possible by the child) using a simple scale such as the abbreviated Conners. The initial monitoring scale focuses on the key target of hyperactivity and a checklist of possible adverse effects; it can be helpful to add to the scale other items that are of particular relevance to the individual child. In the first stage of titrating dosage, monitoring should be frequent – ideally daily but, more realistically, weekly. The dose is then titrated upwards – often weekly, but a daily variation in dosage can also be reliable – until there is a good response, adverse effects become troublesome or the ceiling of 0.7 mg/kg/dose is reached – whichever comes first. Monitoring should include growth in height and weight plotted on developmental charts, pulse and blood pressure, and observation of mental state in case adverse effects such as depression, lack of spontaneity, or perseveration should appear. Blood tests are not routinely required (but the manufacturer recommends them, for unknown reasons).

Treatment with a long-acting medicine is helpful for some children, and can be considered from the start. The advantages over repeated doses of immediate-release medication are for the child, whose treatment can be more private if not delivered in school; and for the school, which does not have to store and administer controlled drugs. Preparations of MPH vary in the physics of their delivery system and the proportion of immediate-release to extended-release that is present. Concerta XL has an action lasting about 12 hours, Equasym XL and Ritalin LA about 8 hours, and a skin patch is also available in the USA. Surveillance of millions of children treated has led to a few reports of sudden death, epileptic seizures, liver failure and electrocardiogram (ECG) abnormality – especially, prolongation of Q-Tc interval. They are too rare to know whether they are in fact associated with the medication or represent coincident disease, or whether they are more common in one drug than another. We suggest that a pre-existing heart problem – structural, or suggested by a history of breathlessness or exercise syncope or a history of sudden death in youthful family members – should be a signal for a cardiological examination before therapy, including ECG.

Stimulants are not contraindicated in coexistent disorders, but caution is needed in the presence of autism or Tourette disorder, both of which can be worsened by stimulants and need careful monitoring. There is some contradiction about the effect of stimulant drugs on those who show high anxiety as well as ADHD. Placebo-controlled trials have indicated that stimulants are of less effect on hyperactivity in children where there is anxiety too (Buitelaar, Van der Gaag, Swaab-Barneveld et al., 1995; Taylor, Schachar, Thorley et al., 1987).

By contrast, the MTA study found that the general superiority of medication to behavior therapy was not affected by the coexistent presence of high anxiety (MTA Cooperative Group, 1999). Inspection of the MTA data suggests that medication was substantially less effective in the group that received stimulants as part of community treatment; the benefits of stimulants were essentially in the group treated with the careful monitoring of the research group. It may be that particularly close attention to monitoring and dosage is required for successful treatment of comorbid states.

Atomoxetine has been introduced more recently; it is an inhibitor of the norepinephrine transporter, and raises synaptic levels of both norepinephrine and (at least in frontal cortex) dopamine. The action will usually last throughout the day if it is given in the morning. Onset of clinical effectiveness is slower than for stimulants; some action is often seen after 2 weeks of administration, but may still be increasing at the 6-week point. There have been case reports of suicidal ideation, liver failure and epileptic seizures. These adverse effects are so rare that it is hard to know whether they are more common in those who take the drug than those who do not, but they deserve vigilance in monitoring and parents should therefore be informed of what to watch for. The choice between atomoxetine and an extended-release stimulant will be made on the basis of effect size and speed of action (favoring MPH or dexamfetamine), freedom from risk of abuse (favoring atomoxetine), balance of adverse effects (insomnia, growth retardation and tics being more common with stimulants, nausea and sedation with atomoxetine), user preferences, and cost. If stimulants are ineffective, atomoxetine may nevertheless be helpful.

Medication is usually effective. If it is not, then the reasons should be sought. Is it being swallowed? If not, careful and sympathetic exploration of the reasons for refusal may help. Has the dose been titrated carefully to the child? The range of effective doses is great, and attention both to this and the timing of doses can correct non-response. Have adverse effects appeared? If so, they can often be managed symptomatically – e.g., with dose adjustment and sleep hygiene measures for insomnia, or rescheduled meals for loss of appetite. If one of the licensed medications has failed, has another one been tried? Has the diagnosis been reviewed (refractoriness to therapy may be associated with an underlying disorder such as autism)? Only after such a process should the disorder be seen as refractory and an unlicensed therapy attempted. Second-line drugs include some with reasonable controlled trial evidence for superiority to placebo (clonidine, modafinil, imipramine, pemoline) and some with limited trial evidence or anecdotal tributes or randomized controlled trial evidence in specific groups (e.g., tiapride, nicotine patches, guanfacine). They should all be used with specialist guidance.

If medication has been effective, then a review of the case should be conducted. What coexistent problems still need intervention, and of what kind? What is the child’s and family’s attitude to the success of treatment? Will they rely on it to the exclusion of educational adjustment or other kinds of help?
Will they now attribute all the child’s successes to the drug rather than their efforts? Do they have an understanding of the limits within which dosage can be varied in response to changing circumstances? A good response to medication is sometimes taken as a proof that the diagnosis of ADHD was correct: this is not logical, because of the evidence that ordinary people respond in qualitatively similar ways (see p. 522). At most, a substantial reduction in hyperactive behavior can be partially helpful in making inferences about how much functional impairment was attributable to that problem.

The question of the length of time for which medication should be continued has not been answered scientifically. Accordingly, an individual approach needs to be taken. At agreed intervals (e.g., once a year) the medicine should be discontinued for a trial period, preferably lasting 2 weeks, to determine whether it is still required.

For preschool children, there has been a beginning of randomized controlled trials of psychological and pharmacological therapies. The most promising intervention is parent training – but this recommendation is based on practice, for there have been few comparative trials. Sonuga-Barke et al. (2001) made a comparison between this, a program of parent counseling and support, and a waiting list control. Parent training was more effective than the other interventions in reducing the symptoms of ADHD and of oppositional defiant disorder, and it also increased the mother’s sense of general well-being. The gains in the parent training group were not entirely transient: they were still present at a 15-week follow-up. The investigators in another trial compared behavioral family intervention (in both standard and enhanced forms) with a waiting list control and again found that the experimental groups showed reduced levels of behavior problems and greater competence by the parents (Bor, Sanders, & Markie-Dodds, 2002). In this study also, gains were maintained at follow-up, and this time the follow-up period was 1 year.

Compared with the school-aged years there has been little published systematic research about drug treatment in preschool children. The few studies of the stimulants in this age group suggest that they can indeed reduce impulsiveness and improve general social adjustment more effectively than a group suggest that they can indeed reduce impulsiveness and school children. The few studies of the stimulants in this age published systematic research about drug treatment in preschool children. This time the follow-up period was 1 year.

DISORDERS OF ATTENTION AND ACTIVITY
CHAPTER 34

Children with conduct disorders (persistent disruptive, deceptive and aggressive behaviors) are highly likely to require clinical intervention. Furthermore, such children constitute an important opportunity to prevent a future burden of poor adult health and social maladjustment. During childhood, conduct problems cause considerable distress for children, their families and their schools, and conduct problems are associated with consequential social and educational impairments for the child (Lahey, Loeber, Quay et al., 1997).

Later, during adolescence and adulthood, children with conduct problems are at substantially increased risk of poor prognosis. This increased risk involves adulthood antisocial outcomes such as antisocial personality disorder, criminal and violent offending, and potential incarceration. Moreover, childhood conduct problems further predict adulthood risk for serious difficulties in education, work and finances, homelessness, abuse and dependence on tobacco, alcohol and drugs, and even compromised physical health including injuries, sexually transmitted infections, compromised immune function, dental health and respiratory health, as well as a variety of mental disorders and suicide attempts (Moffitt, Caspi, Harrington et al., 2002; Odgers, Caspi, Poulton et al., 2007a; Robins 1991). An excess of conduct disorders characterizes the juvenile psychiatric histories of adult patients with substance, affective, anxiety and eating disorders, and even patients with schizophrenia spectrum disorders and mania (Kim-Cohen, Caspi, Moffitt et al., 2003).

As adolescents and young adults, children with conduct problems are more likely to enter and contribute to cohabitations and marriages with domestic violence, and to engage in early childbearing and poor parenting practices, hence putting the next generation at risk (Jaffee, Belsky, Sligo et al., 2006; Moffitt & Caspi, 1998). This breadth of compromised long-term outcomes highlights the prevention opportunity afforded when children with conduct problems are successfully treated.

The conduct disorders are distinctive among mental disorders in that they are embedded in the patient’s social context and have consequences for victims, apart from conferring harm on the individual patient. Many of the features are seen in social interactions, notably verbal and physical aggression, bullying, oppositional behavior and lying. This means that the symptoms of the disorders are also social behaviors that arise in the context of family, peer, educational and wider social relationships, and which in turn have a detrimental impact on these relationships. The origins, maintenance and cessation of the symptoms cannot be understood independently of these contexts. Equally, the symptoms are not simply the product of social processes, in that individual vulnerabilities are known to play a prominent part. Biological, psychological and social processes are all implicated in the etiology and treatment of the conduct disorders, through additive and interactive effects (Hill, 2002; Rutter, Giller, & Hagell, 1998).

This chapter aims to introduce clinicians and researchers to major issues involved in conduct disorders of childhood and adolescence. It covers classification, prevalence, subtypes, associated co-occurring disorders and complicating conditions. Risk factors are examined at the levels of the individual child, the family and the extra-familial social context. Issues in clinical assessment and diagnosis are covered, as are intervention approaches. An exhaustive citation bibliography of all studies of conduct problems is far beyond the scope of this chapter. Thus, only key individual studies with strong methods are cited as examples, and the reader is directed to reviews of the literature when those are available.

**Classification of Juvenile Antisocial Disorders**

**Conduct Disorder and Oppositional Defiant Disorder in DSM-IV and ICD-10**

Two principal classification systems, DSM-IV (American Psychiatric Association, 2000) and ICD-10 (World Health Organization, 1996) are quite similar in that both specify behaviors required for diagnosis. Both emphasize the persistent duration of the symptom behaviors for some months. The principal difference is that, in DSM-IV, Oppositional Defiant Disorder (ODD) and Conduct Disorder (CD) are separated, whereas in ICD-10 the criterion set of items required for CD is very close to what would be obtained by combining the DSM-IV ODD and CD items (Angold & Costello, 2001). ODD is defined as a recurrent pattern of negativistic, defiant, disobedient and hostile behaviors leading to impairment of day to day activities,
and CD as the repetitive and persistent violation of the basic rights of others and societal norms.

Are ODD and CD distinct conditions? It is not clear how valid the distinction is between ODD and CD, because the items in each are clearly age-related (Angold & Costello, 2001). Although some studies have found evidence that CD and ODD symptoms have independent associations with certain clinical correlates, it is commonly accepted that ODD and CD may differ in age-related manifestations of the same condition, in which early ODD often develops into eventual CD (Lahey et al., 1997; Loeber, Burke, Lahey et al., 2000; Maughan, Rowe, Messer et al., 2004).

**Category, or Continuum?**

Although the principal classification systems, DSM-IV and ICD-10, take a categorical approach, this has disadvantages. Unless there is good evidence that the problems operate in a categorical fashion, the cut-off point will inevitably be arbitrary; studies searching for such evidence have not found it (e.g., Moffitt, Caspi, Rutter et al., 2001). One study has systematically examined the predictive validity of categorical diagnoses versus dimensional measures of ODD and CD (Fergusson & Horwood, 1995). The dimensional variables were better predictors of outcome, and there appeared to be a dose-response relationship of increasing risk for juvenile offending and school dropout associated with increasing severity of disruptive behaviors. Genetic influences appear to operate in a similar manner in relation to conduct problems whether they are assessed as dimensions or categories (Eaves, Silver, Meyer et al., 1997). Although diagnoses are expected in clinical settings, using a categorical approach entails the risk that important differences of severity or type of dysfunction below and above the cut-off will be lost (Hinshaw, Lahey, & Hart, 1993).

**Other Conceptualizations**

There has been immense variation in the ways that conduct problems have been conceptualized and measured in the research consulted for this chapter. Many studies have used the DSM diagnoses, but a range of measures such as aggressive personality traits, antisocial behaviors, psychopathic traits and juvenile delinquent offending have also been employed. The terms “conduct problems” and “antisocial behaviors” will be used here to refer broadly to children’s aggressive and disruptive behaviors, measured in a range of ways.

**Descriptive Epidemiology**

**Overall Prevalence**

Estimates of the prevalence of conduct problems vary according to the criteria used (Angold & Costello, 2001; Green, McGinnity, Meltzer et al., 2005). However, on the basis of the majority of epidemiological studies from the industrialized west, 5–10% of children and adolescents have significant persistent oppositional, disruptive or aggressive behavior problems.

**Prevalence by Historical Period, Social Class and Ethnicity**

With respect to historical period, both short-term changes and longer-term changes in youth antisocial behavior have been examined. One example of short-term change was observed in the USA during the 1990s when rates of youth violence, particularly homicide, increased dramatically and then decreased again, a change attributable to short-term alterations in local drug and firearm markets, and to altered policies in policing and sentencing (Blumstein & Wallman, 2005). A longer-term modest rise in diagnosable conduct disorder over the second half of the 20th century has also been observed in a study comparing assessments of three successive birth cohorts in Britain (Collishaw, Maughan, Goodman et al., 2004). Presumably, this increase arises from some societal level factor that has also been characterized by gradual change during the same time period, such as changing family structure.

With respect to socioeconomic class, measured class differences in juvenile antisocial behavior are not as wide as might be expected. Research has consistently failed to find the expected relationship between low family social class and individual youth’s conduct problems or offending, particularly when this behavior is assessed through youth self-reports (Tittle & Meier, 1990). One study found that among low social class adolescents, offending was associated with attitudes of alienation, whereas among high social class, offending was associated with attitudes of unconventionality, suggesting that social class may condition motivation for antisocial conduct (Wright, Caspi, Moffitt et al., 1999).

With respect to ethnicity, the over-representation of offenders of Black African ancestry in US and UK jails and prisons has focused much debate, and some research, on the thorny question of ethnic group differences in antisocial behavior (Morenoff, 2005; Smith, 2005). Research into ethnic differences has not really studied childhood conduct problems, but rather is limited to studies of adolescent and adult offending. Recognizing that the over-representation of Black African-ancestry offenders in official statistics could arise from race bias among police and courts, researchers also consult sources of data such as youth self-reports of antisocial behaviors and crime victim survey reports of perpetrators’ ethnicity. These data, although influenced by their own serious sources of ethnicity-related bias, also tend to show an excess of offenders of Black African ancestry, although the Black–White difference is generally somewhat narrower than in official data. Importantly, Hispanic Americans in the USA and British Asians in the UK do not tend to show an excess of offending when compared to their white counterparts. Hypothesized explanations for a Black–White difference in offending include poverty, prejudice, family structure, subculture, neighborhood context and individual characteristics such as intelligence, but research is insufficient to support conclusions (Morenoff, 2005; Smith, 2005).

**Sex Differences in Prevalence**

Where studies have included males and females with conduct...
problems, the sex ratio is approximately 2.5 males for each female overall, with males further exceeding females in the frequency and severity of behaviors (Costello, Angold, Burns et al., 1996; Moffitt et al., 2001). In the light of the gender difference the question arises as to whether the sexes have different risk mechanisms. One study found that the individual and family factors associated with self-reported delinquency were the same for males and females, but were more common in males (Rowe, Vazsonyi, & Flannery, 1995).

This same conclusion was reached in a systematic analysis of a wide variety of risk factors comparing the males and females of the Dunedin longitudinal study (Moffitt et al., 2001). Reviews of twin studies have revealed no systematic differences between the sexes in the contributions of genetic and environmental factors (Rhee & Waldman, 2002). On balance, research suggests that the causes of conduct problems are the same for the sexes, but males have more conduct disorder because they experience more of its individual-level risk factors (e.g., hyperactivity, neurodevelopmental delays). However, recent years have seen increasing concern among clinicians about treating antisocial behavior among girls, and this is currently the topic of intense research (Pullatz & Bierman, 2004).

**Developmental Subtypes**

**Life-Course-Persistent Versus Adolescence-Limited**

There has been considerable attention paid to the distinction between aggressive and disruptive behaviors that are first seen in early childhood versus those that start in adolescence (Moffitt, 1993a; Patterson & Yoerger, 1993), and these two subtypes are encoded in the DSM-IV diagnostic system for CD. Early onset is a strong predictor of persistence through childhood, and early-onset delinquency is more likely to persist into adult life. Findings from the Dunedin longitudinal study following a 1972–73 birth cohort have shown that those with early onset differ from those with later onset in that they have lower IQ, more attentional and impulsivity problems, poorer scores on neuropsychological tests, greater peer difficulties and they are more likely to come from adverse family circumstances (Moffitt et al., 2001). Those with later onset, by contrast, are thought to become delinquent predominantly as a result of social influences such as association with other delinquent youths, or seeking social status through delinquent behaviors. Moffitt (1993a) termed the early-onset group “life-course-persistent” and the later-onset group “adolescence-limited,” thus linking developmental course to the differences in underlying deficits. The distinction between the two groups has been broadly supported in longitudinal studies of several cohorts from a dozen countries (Moffitt, 2006). Findings from the follow-up of the Dunedin cohort support relatively poorer adult outcomes for the early-onset group in domains of violence, mental health, substance abuse, work and family life (Moffitt, Caspi, Harrington et al., 2002). Follow-up to age 32 revealed that the early-onset life-course-persistent group had compromised physical health relative to other cohort men, as shown by increased injuries, primary care physician and hospital visits, and clinical tests of sexually transmitted infections, systemic inflammation, periodontal disease, decayed teeth and chronic bronchitis (Odgers et al., 2007a).

However, the “adolescence-limited” group was not without adult difficulties (Moffitt et al., 2002; Odgers et al., 2007a). As adults they still engaged in self-reported offending, and they also had problems with alcohol and drugs. The Cambridge Study in Delinquent Development, a longitudinal study of 411 London males from age 8 to 46 years, also found that those with antisocial behaviors starting in adolescence were likely to continue to commit undetected crimes in adult life, although their work performance and close relationships were not impaired (Nagin, Farrington, & Moffitt, 1995). Thus, the age-of-onset subtype distinction has strong predictive validity, but adolescent-onset antisocial behaviors may have more long-lasting consequences than previously supposed, and thus both childhood onset and adolescent onset conduct problems warrant clinical attention.

**Childhood-Limited Conduct Problems**

Robins (1966) first pointed out that half of children with conduct problems do not grow up to have antisocial personalities. Longitudinal studies aiming to document the continuity of antisocial behavior from childhood through adolescence to adulthood have repeatedly revealed the existence of an exceptional group of children who lack such continuity. These are often termed “childhood-limited” conduct problems (Moffitt, 2006). Some studies define this childhood-limited group broadly (as a large group of children having any elevated disruptive behavior), and these draw our attention to the ubiquity of temporary conduct problems in the healthy population of children, and show that so long as mild conduct problems do not persist they need not portend poor prognosis (Odgers, Milne, Caspi et al., 2007b; Tremblay, 2003). In contrast, other studies define this childhood-limited group more narrowly (as a small group of children exhibiting extreme, pervasive and persistent antisocial behavior problems only during childhood). These studies report that such childhood-limited antisocial boys develop into adult men who are depressed, anxious, socially isolated and have low-paid jobs (Farrington, Gallagher, Morley et al., 1988; Moffitt et al., 2002). Thus, boys whose conduct problems are severe and persistent enough to warrant a clinical diagnosis may not later develop antisocial personality, but they will suffer other forms of maladjustment as adults. Thus, all children with conduct disorders warrant clinical attention.

When a young child presents for assessment, the clinician’s task is to make a differential diagnosis between childhood-onset CD that will be only childhood-limited, versus childhood-onset CD that will in future have a life-course-persistent course and pathological prognosis. DSM-IV’s age-of-onset distinction cannot help with this task because all child patients, by definition, have childhood onset. Researchers have tried to distinguish life-course-persistent versus childhood-limited
CHAPTER 35

trajectory groups by using childhood risk factors, without much success (Moffitt, 2006). However, initial evidence indicates that comorbid attention deficit/hyperactivity disorder (ADHD), as well as family psychiatric history, characterize the persistent subtype but not the childhood-limited subtype. Alcohol problems in the child’s parents and grandparents seem particularly prognostic (Odgers et al., 2007b).

Associated Disorders and Conditions

Co-occurring Mental Disorders

Epidemiological studies concur that more than 90% of individuals having conduct or antisocial personality disorder also meet diagnostic criteria for other disorders (Moffitt et al., 2001; Robins & Regier, 1991), and conduct disorder has been shown to feature prominently in the developmental history of virtually every adult psychiatric disorder, including schizophrenia and eating disorders (Kim-Cohen et al., 2003). Particularly striking is the frequent overlap between antisocial behaviors and hyperactive-impulsive-inattentive behaviors in the young population (Waschbusch, 2002). A meta-analysis of associations among child psychiatric disorders estimated the odds ratio for ADHD in the presence of conduct disorder is 10.7 (7.7–14.8) (Angold, Costello, & Erkanli, 1999). Children who have both ODD/CD and ADHD have more varied and severe ODD/CD symptoms, greater levels of parental psychopathology, more conflictual interactions with parents, greater peer problems, school difficulties and psychosocial adversity, worse neuropsychological deficits and poorer prognosis into adulthood than those with either condition alone (Angold, Costello, & Erkanli, 1999; Lynam, 1996).

Twin studies suggest a common genetic component underlying ADHD and conduct disorder (Moffitt, 2005a). Lynam (1996) reviewed literature suggesting that children with the combination of conduct problems and hyperactivity-attentional difficulties are likely to be “fledgling psychopaths,” who warrant especial clinical attention and may be particularly difficult to treat.

Apart from ADHD, young people with conduct problems have also been shown to have other associated disorders at markedly elevated rates (Vermeiren, Jespers, & Moffitt, 2006). The disorders most consistently implicated are adolescent depression and substance abuse. In each case, comorbidity between conduct problems and the co-occurring disorder grows stronger with age, becoming more marked in adolescence. Diagnoses of learning disabilities and reading impairments are also highly prevalent among children with conduct problems (Carroll, Maughan, Goodman et al., 2005). When conduct disorder is diagnosed, any co-occurring behavioral or learning disorders should also be ascertained, as these may afford an opportunity for prevention.

Complicating Conditions

In addition to the aforementioned diagnosable disorders that often co-occur with conduct problems, certain conditions that are not diagnosable disorders also tend to complicate the clinical picture of children with conduct disorder. This section reviews four such conditions: psychopathy, autistic traits, victimization by others and violence between adolescent romantic partners.

Psychopathy

The characteristics of the psychopath include grandiosity, callousness, deceitfulness, shallow affect and lack of remorse (see chapter 51). These traits, as assessed by the Hare Psychopathy Checklist, have been shown to predict which individuals will engage in the most serious and violent crime careers, even among prison inmates (Hare, Hart, & Harpur, 1991). Can the “fledgling psychopath” be identified in childhood, as a high priority target for prevention? Contrasting approaches to this question have been taken. One approach has suggested that children showing hyperactivity/attentional problems and conduct problems are at risk for subsequent psychopathy (Lynam, 1996; Lynam & Gudonis, 2005). Another approach emphasizes callous unemotional traits such as lack of guilt, absence of empathy and shallow constricted emotions in children (Barry, Frick, DeShazo et al., 2000). A third approach proposes that psychopathy is associated with a failure to inhibit aggression in response to signs of distress in others, arising from a deficit in processing victims’ distress cues, and reduced ability to recognize fear and sadness (Blair, Mitchell, & Blair, 2005). A number of reliable instruments are now available for the clinical assessment and diagnosis of psychopathic traits in juvenile patients (Farrington, 2005). If childhood psychopathy proves a useful clinical concept, it will be crucial that this provides a more refined background to improved treatments, and not a means of writing off some children.

Autistic Traits

A very recent development connects conduct disorders with symptoms formerly thought to be key features of autism and limited to patients with autism (Gilmour, Hill, Place et al., 2004). Children with autism, children referred for clinical evaluation of conduct problems and children excluded from school for disruptive behaviors were compared, and all three groups were found to have similar high prevalences of pragmatic language skill deficits and social communication difficulties. Some of the difficulties measured might be secondary to externalizing disorder, such as disrupted social relationships with peers. However, other difficulties such as speech articulation and fluency deficits, misunderstanding of context cues, misuse of gesture and eye contact, and unusual rigid interests have not been previously identified as part of conduct disorder. The importance of this finding is as yet not established, but it may point to new modes of therapy for conduct problems.

Bullying

The past decade has witnessed growing concerns from parents and schools about young children involved in bullying at or after school (Spivak, 2003; Tolan, 2004). Surveys indicate that nearly half of children are involved in bullying at some
time in childhood, although chronic involvement as a victim is somewhat less common (Nansel, Craig, Overpeck et al., 2004). Bullying and cruelty toward other children are key symptoms for diagnosing conduct disorder. Risk factors for becoming a bully are thus the same as risk factors for conduct disorder in general (Olweus, 1993). Risk factors that invite victimization by a bully are somewhat different, including emotional problems, low self-regard and poor social skills, as well as physical characteristics such as obesity. Because such risk factors pre-exist involvement in bullying, researchers must control for them in order to determine whether involvement in bullying has any consequences. One longitudinal study was able to control for pre-existing risk factors at age 5 school entry. This study reported that children who were victims in the intervening 2 years before follow-up at age 7 developed more emotional problems, more disruptive behavior problems, fewer prosocial behaviors and were less happy at school (Arseneault, Walsh, Trzesniewski et al., 2006). Thus, being targeted by bullies appears to lead to wide-ranging maladjustment in children, and should be a clinical concern.

Crime Victimization
Whereas most attention is focused on the potential of youth with conduct problems to harm others, such youth are often victims of violence committed by other people in their communities. Much research has documented that adult psychiatric patients are frequent targets of violence. Although children and adolescents are less often studied as victims, conduct disorder and its co-occurring disorders also place young people in harm’s way (Smith & Ecol, 2007; Snyder & Sickmund, 2006). In the US national Addhealth cohort study, the advent of puberty brought increased victimization risk to adolescents (Haynie & Piquero, 2006). In another cohort study, young people who were regular alcohol and cannabis abusers were twice as likely than healthy young people to become the victim of threatened, attempted or completed physical and sexual assaults in their community, even after controlling for their own prior perpetration of antisocial behaviors (Silver, Arseneault, Langley et al., 2005). Clinicians and researchers should be alert to the potential that their patients will become crime victims, with ensuing symptoms of post-traumatic stress disorder (PTSD).

Adolescent Partner Violence
The terms “marital violence” and “domestic abuse” generate the impression that partner abuse takes place primarily among adults, but recent research exposes high rates of aggression in the romantic or sexual relationships of teenagers (Halpern, Oslak, Young et al., 2001). Indeed, the peak age for partner aggression is between ages 15 and 25, and early-onset participation in relationship aggression is ominous because it predicts continued high risk for more injurious violence in later adult relationships (Capaldi & Gorman-Smith, 2003). One of the strongest predictors that a teenager will become involved in partner aggression is his or her prior childhood history of conduct problems, suggesting that partner aggression is part of a pre-established long-standing tendency to use violence to solve interpersonal disagreements (Ehrensaft, Moffitt, & Caspi, 2004). Both boys and girls engage in aggression toward partners, but qualitative research with high-school pupils suggests the aggression has shared meaning for the sexes (Tolman, Spencer, Rosen-Renityso et al., 2003). Boys attributed their partner aggression to the need to appear sexually dominant to peers, aiming to establish their heterosexual credentials beyond doubt. Girls believed boys were sexual predators who exploit girls, but girls were willing to stay in an aggressive relationship rather than to be seen by peers to have no boyfriend. Thus, the almost compulsory pressure among adolescents to prove one can have and keep a heterosexual relationship seems an important context for relationship violence, which warrants attention from clinicians who see adolescents.

Etiology
Risk Factors
Risk factors for conduct problems have been extensively reviewed in many reference sources (Hawkins, Herrenkohl, Farrington et al., 1998; Hill, 2002; Hill & Maughan, 2001; Lahey, Moffitt, & Caspi, 2003; Rutter, Gillier, & Hagell, 1998). Here we briefly consider primary risk factors that are present in early childhood before the onset of conduct problems.

Individual Level Characteristics
Identified Genotypes
The search for specific genetic polymorphisms associated with conduct problems is a very new scientific initiative, and little has yet been accomplished. One genome-wide linkage study identified chromosomal regions that are good bets for harboring conduct problem-related polymorphisms, but the polymorphisms have not been specified and the regions have not been replicated (Stallings, Corley, Deneheley et al., 2005). The most-studied candidate gene in relation to conduct problems is the MAOA promoter polymorphism. The gene encodes the MAOA enzyme, which metabolizes neurotransmitters linked to aggressive behavior by previous research in mice, and among men in a Dutch family pedigree. Thus, MAOA was selected as the candidate gene to test a hypothesis that genetic vulnerability might moderate the effect of child maltreatment on later conduct problems in the cycle of violence (Caspi, McClay, Moffit et al., 2002).

Maltreatment history and genotype interacted to predict four different measures of antisocial outcome: diagnosed adolescent conduct disorder; a personality assessment of aggression; symptoms of adult antisocial personality disorder reported by informants who knew the study member well; and adult court conviction for violent crime. Replication of this study was of utmost importance because reports of associations between measured genes and disorders are notorious for their poor replication record. Positive and negative replication studies have appeared, and a meta-analysis of these studies showed the association between MAOA genotype and conduct
problems is modest but statistically significant (Kim-Cohen, Caspi, Taylor et al., 2006). Findings of specific genetic polymorphisms associated with antisocial behavior will probably not be applied for genetic diagnosis purposes, because of the inherent complexity of gene– behavior connections. Rather, gene– environment research will benefit efforts to understand how brain mechanisms connect external risk factors and genomic variation to the conduct disorders (Meyer-Lindenberg, Buckholz, Kolachana et al., 2006).

**Perinatal Complications**

Birth complications might be a contributory factor to neuropsychological deficits that are associated with conduct problems (Moffitt, 1993b). The evidence regarding this was mixed but recent reports from large-scale general population studies have found associations between life-course-persistent type conduct problems and perinatal complications, minor physical anomalies and low birth weight (Brennan, Grekin, & Mednick, 2003). Most studies support a biosocial model in which obstetric complications might confer vulnerability to other co-occurring risks such as hostile or inconsistent parenting (Arseneault, Tremblay, Boulerice et al., 2002; Kratzer & Hodgins, 1999; Raine, Brennan & Mednick, 1997; Tibbetts & Piquero, 1999). Studies have further indicated that smoking in pregnancy is a statistical risk predictor of offspring conduct problems (Brennan, Grekin, & Mednick, 2003), but a causal link between smoking and conduct problems has not been established (Fergusson, 1999).

**Temperament**

Individual differences in infancy that might contribute to subsequent risk of psychopathology were conceptualized by Thomas, Chess, and Birch (1968) in terms of temperament, which they viewed as inherited and not significantly influenced by experience. Several prospective studies have shown associations between temperament and conduct problems (Keenan & Shaw, 2003), and also predicted antisocial personality disorder and criminal offending into adulthood (Caspi, Moffitt, Newman et al., 1996). Temperament, as originally conceived, should be strongly heritable and experience-free. However, measures of temperament are only moderately heritable and a child’s engagement with the social world from birth means that temperament measures inevitably assess the outcome of social processes. It may be that the contributions of temperament will be seen most consistently in combination with environmental risk factors (Nigg, 2006).

**Neurotransmitters**

Neurotransmitters have been linked to antisocial behavior in adult samples, and in non-human animal models (Nelson, 2006). It would be a major advance if it were possible to link neurotransmitter levels and activity to conduct problems in children. However, in general, the findings with children have not been consistent (Hill, 2002). For example, in the Pittsburgh youth cohort, boys with long-standing conduct problems showed downward changes in urinary epinephrine level following a stressful challenge task, whereas prosocial boys showed upward epinephrine responses to the challenge (McBurnett, Raine, Stouthamer-Loeber et al., 2005). However, other studies have failed to find an association between conduct disorder and measures of norepinephrine in children (Hill, 2002). Some limited evidence supports the view that, as in adults, serotonin is linked with aggression in children, but findings for indices of serotonin function in children are also markedly inconsistent (Pine, Coplan, Wasserman et al., 1997). It should be borne in mind that neurotransmitters in the brain are only indirectly measured, most measures of neurotransmitter levels are crude indicators of activity and little is known about neurotransmitters in the juvenile brain.

**Verbal Deficits**

Children with conduct problems have been shown consistently to have increased rates of deficits in language-based verbal skills (Lynam & Henry, 2001; Nigg & Huang-Pollock, 2003). Conduct-disordered children, delinquent adolescents and adult antisocial individuals show poor performance on standardized tests of verbal ability, and in tests of IQ, poor verbal and performance scores. These associations hold after controlling for potential confounds such as race, socioeconomic status, academic attainment and test motivation (Lynam, Moffitt, & Stouthamer-Loeber, 1993). Longitudinal studies show that persistence in antisocial behavior over periods of years is predicted by low verbal IQ in childhood (Farrington & Hawkins, 1991; Lahey, Loeber, Hart et al., 1995; Lynam & Henry, 2001). Deficits in verbal capacities are found also with oppositional defiant disorder among preschool-aged clinic-referred boys (Speltz, McClellan, DeKlyen et al., 1999). Several possible ways in which poor verbal ability might influence behavior can be drawn from Luria’s theory of the role of verbal memory and verbal abstract reasoning in the development of self-control (Luria, 1961). The abilities to recall oral instructions and to use language to think through the consequences of actions contribute to the effective control of actions. Children who cannot reason or assert themselves verbally may attempt to gain control of social exchanges using aggression (Dodge, 1993). It is likely that there are also indirect effects in which low verbal IQ contributes to academic difficulties which in turn mean that the child’s experience of school becomes unrewarding, rather than a source of self-esteem and support.

**Executive Dysfunction**

Children and adolescents with conduct problems have been shown consistently to have poor tested executive functions (Ishikawa & Raine, 2003; Lynam & Henry, 2001; Moffitt, 1993b; Nigg & Huang-Pollock, 2003). Executive functions comprise those abilities implicated in successfully achieving goals through appropriate effective actions. Specific skills include learning and applying contingency rules, abstract reasoning, problem-solving, self-monitoring, sustained attention and concentration, relating previous actions to future goals and inhibiting inappropriate responses. These mental functions are largely, although not exclusively, associated with frontal
 lobes (Pennington & Ozonoff, 1996). Important data come from a Montreal cohort studied from the age of 6 years (Séguin, Boulerice, Harden et al., 1999). The study used executive function tests that have been shown to be associated with different anatomical structures in the brain, on the basis of lesion and functional imaging studies. Chronic aggression was associated with lower scores on tests tapping executive functions of the frontal brain region, and the findings held after controlling for general memory, IQ and ADHD. Although most studies of executive deficit involve adolescents, such deficits have also been linked with disruptive behaviors in very young preschool children (Hughes, Dunn, & White, 1998; Speltz, DeKlyen, Calderon et al., 1999).

**Autonomic Reactivity**

A low resting pulse rate or slow heart rate has been found consistently to be associated with antisocial behavior, and a meta-analysis of 40 studies suggested it is the best replicated biological correlate of antisocial behavior (Ortiz & Raine, 2004). For example, in the longitudinal Cambridge Study in Delinquent Development, slow heart rate was associated with convictions for violence after controlling for all other risk variables (Farrington, 1997). Other psychophysiological indicators of slow autonomic system reactivity have also been examined. For example, in a longitudinal study of Pittsburgh boys, those most antisocial and psychopathic were also slowest to show a skin-conductance response to aversive blasts of noise (Fung, Raine, Loeb et al., 2005). The explanation for the link between slow autonomic activity and antisocial behavior remains unclear.

**Information Processing and Social Cognition**

Dodge (1993) proposed the leading information-processing model for the genesis of aggressive behaviors within social interactions. The model hypothesizes that children who are prone to aggression focus on threatening aspects of others’ actions, interpret hostile intent in the neutral actions of others and are more likely to select and to favor aggressive solutions to social challenges. Several studies have demonstrated that aggressive children make such errors of social cognition. An extensive review of the many studies of social cognition among children with conduct problems has been presented elsewhere (Dodge, Coie, & Lynam, 2006). Dodge (1993) hypothesized that the tendencies to encode hostile aspects of situations and to attribute hostile intent to ambiguous social cues, and to access and favor aggressive responses to social challenges, are the result of repeated exposure to physical maltreatment. This prediction was tested prospectively (Dodge, Petit, Bates et al., 1995). Physical abuse documented in kindergarten was strongly associated with conduct problems in primary school; 28% of the abused group developed conduct problems compared to 6% of the non-abused. Encoding errors, hostile attributions and biases toward accessing and favoring aggressive responses were each associated with conduct problem outcome, and with having experienced physical abuse. Encoding errors and accessing aggressive responses mediated the link between physical abuse and conduct problems, but hostile attributions and positive evaluation of aggressive responses did not. This prospective study thus provided some support for the social cognition model.

**Risks Outside the Family**

**Risks in the Neighborhood**

It has long been assumed that bad neighborhoods have the effect of encouraging children to develop conduct problems. Parents strive to secure the best neighborhood and school for their child that they can afford. Although it is obvious that some local areas have higher crime rates than others, it has been difficult to document any direct link between neighborhood characteristics and child behavior, for a number of reasons. For example, neighborhood characteristics were conceptualized in overly simple structural demographic terms such as percentage of non-White residents or percentage of single-parent households. Moreover, research designs could not rule out the alternative possibility that families whose members are antisocial tend to selectively move into bad neighborhoods. A new generation of neighborhood research is addressing these challenges (Beyers, Bates, Petit et al., 2003; Caspi, Taylor, Moffitt et al., 2000; Sampson, Raudenbusch, & Earls, 1997). New research suggests that the neighborhood factors that are important go beyond structural demographic characteristics. Neighborhood-level social processes such as “collective efficacy” and “social control” do influence young children’s conduct problems, probably by supporting or failing to support parents in their efforts to rear children.

**Peer Influences**

Children with conduct problems have poorer peer relationships than non-disordered children in that they tend to associate with children with similar antisocial behaviors, they have discordant interactions with other children and experience rejection by non-deviant peers (Vitaro, Tremblay, & Bukowski, 2001). Three principal explanations have been tested, and evidence found for all three. Either children’s antisocial behaviors lead them to have peer problems, or deviant peer relationships lead to antisocial behaviors, or some common factor leads to both.

**Peer Rejection in Childhood**

Regarding the possibility that conduct problems lead to peer difficulties, there is ample evidence that children with established conduct problems are more likely to have more conflict with peers, and to be rejected by non-deviant peers (Coie, 2004). This peer rejection has been shown to contribute to declines in academic achievement and increases in aggression across the first year of primary schooling (Coie, 2004). One consequence of rejection by healthy peers is that from as young as 5 years aggressive-antisocial children are obliged to associate with other deviant children (Farver, 1996; Fergusson, Woodward, & Horwood, 1999).

**Peer Groups Promote Conduct Problems in Adolescence**

In the light of the limited evidence that peer difficulties prompt the onset of childhood conduct problems, and the rather more
CHAPTER 35

substantial evidence that children’s peer difficulties are a consequence of their conduct problems, is there any reason to think that peer processes influence the long-term course of conduct problems? Regarding the possibility that peers lead to conduct problems, this has been shown to come about in several ways. Youth who are aggressive are attracted to each other, and deviant youth reinforce each others’ antisocial behaviors and attitudes (Boivin & Vitaro, 1995). Evidence that peer influences do increase antisocial behaviors applies primarily to the adolescent developmental stage (Warr, 2002). Strong evidence comes from treatment experiments: in two controlled clinical trials, boys treated in groups did worse than untreated controls; treatment was followed by increased adolescent problem behaviors and poorer outcomes (Dishion, McCord, & Poulin, 1999). After group-level treatment brought the boys together they mutually reinforced each others’ antisocial activities, a finding that argues for individual treatment approaches. A natural experiment study tracked change in antisocial behavior among boys who joined a gang, to reveal that joining a gang increased each adolescent’s individual offending over his pre-gang baseline, whereas leaving the gang decreased each individual’s personal offending rate (Thornberry, Krohn, Lizotte et al., 1993). Overall, we must consider the dynamic and reciprocal manner in which children’s conduct problems influence who their friends are, and in which those friends later promote the young person’s conduct problems (Vitaro, Tremblay, & Bukowski, 2001).

Family Level Influences

Concentration of Crime in Families

Fewer than 10% of the families in any community account for more than 50% of that community’s criminal offenses (Farrington, Jolliffe, Loeber et al., 2001; Rowe & Farrington, 1997). This familial concentration of crime most certainly reflects the co-incidence of genetic and environmental risks, directing researchers who wish to understand the origins of conduct problems to look for interactions between both types of risk.

Familial Genetic Liability

There is now solid evidence from twin and adoption studies that conduct problems assessed both dimensionally and categorically are substantially heritable (Moffitt, 2005a; Rhee & Waldman, 2002). However, knowing that conduct problems are under some genetic influence is less useful clinically than knowing that this genetic influence appears to be reduced, or enhanced, depending on interaction with circumstances in the child’s environment.

Several genetically sensitive studies have allowed interactions between family genetic liability and rearing environment to be examined. Adoption studies have reported an interaction between antisocial behavior in the biological parent and adverse conditions in the adoptive home that predicted the adopted child’s antisocial outcome (Bohm, 1996; Cadoret, Yates, Troughton et al., 1995). The genetic risk was modified by the rearing environment. A twin study also yielded evidence that family genetic liability and environmental risks interact (Jaffee, Caspi, Moffit et al., 2005). In this study, the experience of maltreatment was associated with an increase of 24% in the probability of diagnosable conduct disorder among children at high genetic risk, but an increase of only 2% among children at low genetic risk. Thus, awareness of a familial liability toward psychopathology increases the urgency to intervene to improve a child’s social environment (Odgers et al., 2007b).

Family Poverty

There is an association between severe poverty and early childhood conduct problems (Farrington & Loeber, 1998). Early theories proposed direct effects of poverty related to strains arising from the gap between aspirations and realities, and from lacking opportunity to acquire social status and prestige. Subsequent research has indicated that the association between low income and childhood conduct problems is indirect, mediated via family processes such as marital discord and parenting deficits (Maughan, 2001).

As one example of this research, the Iowa longitudinal study of 378 rural families found that family economic stress was associated with adolescent conduct problems, but this was mediated via parental depression, marital conflict and parental hostility (Conger, Ge, Elder et al., 1994). Another study took advantage of a naturally occurring experiment (Costello, Compton, Keeler et al., 2003). Native American families in North Carolina, formerly living below the poverty line, benefitted from increased income from newly opened casinos. In many families, the children’s behavior problems decreased markedly as a result. However, the effect of increased income was mediated through better parent–child relationships. This mediation is not limited to poverty in recent times. Glueck’s study of delinquency from the historical period of economic depression also found that harsh discipline, low supervision and weak parent–child attachments accounted for the effects of poverty on children’s antisocial behaviors in the 1930s (Sampson & Laub, 1984).

Parent–Child Attachment

Parent–child relationships provide the setting for the development of later social functioning, and disruption of these attachment relationships (e.g., through institutional care) is associated with subsequent difficulties in relating (Robins, 1966; Rutter, Quinton, & Hill, 1990). Thus, conduct problems might be expected to arise from infant attachment difficulties. Indeed, attachment theory had its origins in Bowlby’s (1944) study of adolescent thieves.

However, the evidence is rather mixed (Vondra, Shaw, Swearingen et al., 2001). One study found an increased rate of each of the categories of insecure attachment (avoidant, ambivalent, controlling) in preschool boys referred with ODD (Speltz, DeKlyen, & Greenberg, 1999). However, in a follow-up of the clinic boys, attachment did not predict the severity of conduct problems. By contrast, another study found that ambivalent and controlling attachment predicted
disruptive behaviors after controlling for baseline differences (Moss, Smolla, Cyr et al., 2006). Early studies of low-risk samples, using the secure-insecure classification, failed to find robust associations with disruptive behavior problems, but subsequent studies of higher risk samples using the disorganized classification report that disorganized attachment can predict conduct problems (Van IJzendoorn, Schuengel, & Bakermans-Kranenburg, 1999). Disorganization is identified in Ainsworth’s Strange Situation Test if the child shows bizarre or contradictory behaviors with the caregiver when reunited after separation (Main & Solomon, 1986). However, low rates of infants with disorganized attachment in study samples mean that findings should be viewed with caution. Although it seems obvious that poor parent–child relations in general predict conduct problems, it has yet to be established whether attachment difficulties as measured by observational paradigms have an independent causal role in the development of behavior problems. Attachment classifications could be markers for other relevant family risks.

**Discipline and Parenting**

Patterns of parenting associated with conduct problems were delineated by Patterson (1982) in his seminal work *Coercive Family Process* and subsequent publications. In brief, parents of antisocial children were found to be more inconsistent in their use of rules; to issue more, and unclear, commands; to be more likely to respond to their children on the basis of mood rather than the characteristics of the child’s behavior; to be less likely to monitor their children’s whereabouts; and to be unresponsive to their children’s prosocial behavior. Patterson proposed a specific mechanism for the promotion of oppositional and aggressive behaviors in children. A parent responds to mild oppositional behavior by a child with a prohibition to which the child responds by escalating his or her behavior, and mutual escalation continues until the parent backs off, thus negatively reinforcing the child’s behavior. The parent’s inconsistent behavior increases the likelihood of the child showing further oppositional or aggressive behavior. In addition to specific tests of Patterson’s reinforcement model (Gardner, 1989; Snyder & Patterson, 1995) there is ample evidence that conduct problems are associated with hostile, critical, punitive and coercive parenting (Rutter, Giller, & Hagell, 1998).

In considering the role of coercive processes in the origins or maintenance of conduct problems, we need to consider possible alternative explanations: (i) that the associations reflect familial genetic liability toward children’s psychopathology and parents’ coercive discipline; (ii) that they represent effects of children’s behaviors on parents; and (iii) that coercive parenting may be a correlate of other features of the parent–child relationship or family functioning that influence child behaviors. There is considerable evidence that children’s difficult behaviors do evoke parental negativity. One experiment observed the interactions of normal and conduct disordered children when with their own parents, the parents of normal children and the parents of other conduct disordered children (Anderson, Lytton & Romney, 1986). Conduct disordered children elicited more negative reactions from all groups of parents than did non-conduct disordered children.

Adoption studies (Ge, Conger, Cadoret et al., 1996; O’Connor, Deater-Deckard, Fulker et al., 1998) have shown that adoptees at genetic risk of antisocial disorders are more likely than low-risk children to evoke negative parenting in the adoptive home. The role of the child in influencing parental monitoring has also received attention. Stattin and Kerr (2000) pointed out that studies of parental monitoring have generally assessed how much knowledge parents have of their children’s whereabouts, but not how parents acquired it. They showed, in a study of 14-year-olds, that the majority of this knowledge came from what the child chose to tell the parent, and conduct-problem adolescents told their parents less about what they were doing.

The fact that children’s behaviors can evoke negative parenting does not, however, mean that negative parenting has no impact on children’s behavior. One study reported that negative maternal control at age 4 was significantly associated with conduct problems at age 9, after controlling for children’s initial behavior problems at age 4 (Campbell, Pierce, Moore et al., 2006). Early studies of low-risk children exposed to an episode of maternal depression between ages 5 and 7 became even more aggressive by age 7 than children exposed to an episode of paternal depression showed that if E-Risk mothers experienced depression (Jaffee, Moffitt, Caspi et al., 2003). As expected, a prosocial father’s absence predicted more aggression by his children. But, in contrast, an antisocial father’s *presence* predicted more aggression by his children, and his harmful effect was exacerbated the more time each week he spent taking care of the children.

In another report, the E-Risk study evaluated the hypothesis that because depressed mothers provide inept parenting, maternal depression promotes children’s aggression (Kim-Cohen, Moffitt, Taylor et al., 2005). Children of depressed mothers often develop conduct problems, but it has not been clear that this correlation represents environmental transmission. Although the connection between mothers’ depression and children’s conduct problems decreased somewhat after stringent control for familial liability to psychopathology, it remained statistically significant. Further, depressed women might exaggerate their ratings of their children’s problem behaviors, but the pattern of findings remained the same when teachers rated the children’s behavior. A temporal analysis showed that if E-Risk mothers experienced depression only before their children’s birth, the children were not unusually aggressive. In contrast, only if mothers suffered depression while rearing their children the children likely to develop aggression. Finally, the possibility that the association was spurious because children’s aggression provoked their mothers’ depression was ruled out by documenting that children exposed to an episode of maternal depression between ages 5 and 7 became even more aggressive by age 7 than they had been at age 5. Taken together, these and other findings provide good evidence for the role of discipline in conduct problems (Moffitt, 2005b).
CHAPTER 35

Exposure to Adult Marital Conflict and Domestic Violence

It is likely that family processes other than parenting skills and quality of parent–child attachment relationships have a role. Many studies have shown that children exposed to domestic violence between adults are subsequently more likely to become aggressive themselves (Moffitt & Caspi, 1998). Davies and Cummings (1994) proposed that marital conflict influences children’s behavior because of its effect on their regulation of emotion. For example, a child may respond to frightening emotion arising from marital conflict by down-regulating his or her own emotion through denial of the situation. This in turn may lead to inaccurate appraisal of other social situations and ineffective problem-solving. Repeated exposure to family conflict is thought to lower children’s thresholds for psychological dysregulation, resulting in greater behavioral reactivity to stress (Cummings & Davies, 2002). Children’s aggression may also be increased by marital discord because children are likely to imitate aggressive behavior modeled by their parents (Bandura, 1977). Through parental aggression, children may learn that aggression is a normative part of family relationships, that it is an effective way of controlling others and that aggression is sanctioned, not punished (Osofsky, 1995).

Maltreatment

Physical punishment is widely used, and parents of children with conduct problems frequently resort to it out of desperation. However, links with conduct problems are not straightforward. One study found that physical punishment was clearly associated with behavior problems in White American children, but not in African-American children (Deater-Deckard, Dodge, Bates et al., 1996). Furthermore, the risk for conduct problems does not apply equally to all forms of physical punishment. The E-Risk longitudinal twin study was able to compare the effects of corporal punishment (smacking, spanking) versus injurious physical maltreatment using twin-specific reports of both experiences (Jaffee, Caspi, Moffitt et al., 2004). Results showed that children’s genetic endowment accounted for virtually all of the association between their corporal punishment and their conduct problems. This indicated a “child effect,” in which children’s bad conduct provokes their parents to use more corporal punishment, rather than the reverse. Findings about injurious physical maltreatment were the opposite. There was no child effect provoking maltreatment and, moreover, significant effects of maltreatment on child aggression remained after controlling for any genetic transmission of liability to aggression from antisocial parents.

Overall, associations between physical abuse and conduct problems are well established (Hill, 2002). In the Christchurch cohort, child sexual abuse predicted conduct problems, after controlling for other childhood adversities (Ferguson, Horwood, & Lynskey, 1996). In a large prospective study of court substantiated cases of abuse and neglect, 26% of abused and neglected adolescents were antisocial, contrasted with 17% in a well-matched comparison group, implying a modest but long-lasting effect of abuse and neglect (Widom, 1997). Investigating the relationship of child maltreatment to psychopathology is particularly difficult for ethical reasons. Little is known about the possible mechanisms linking maltreatment to conduct problems, although threats to security of attachment, difficulties in affect regulation, distortions of information processing and self-concept reviewed elsewhere in this chapter are likely to be relevant.

From Risk Predictor to Evidence for Causation

Associations have been documented between conduct problems and a wide range of risk factors. A variable is called a “risk factor” if it has a documented predictive relation with antisocial outcomes, whether or not the association is causal. The causal status of most of these risk factors is unknown; we know what statistically predicts conduct problem outcomes, but not how or why (Kraemer, 2003). Establishing a causal role for a risk factor is by no means straightforward, particularly as it is unethical to experimentally expose healthy children to risk factors to observe whether those factors can generate new conduct problems. There is no one solution to the problem, although the use of genetically sensitive designs and the study of within-individual change in natural experiments and treatment studies have considerable methodological advantages for suggesting causal influences on conduct problems (Moffitt, 2005b; Rutter, 2000; Rutter, Moffitt, & Caspi, 2006).

This chapter has emphasized risk factors that have research evidence to support a causal role in conduct problems. For example, above we have cited research that supports causation by depressed mothers’ poor discipline (Kim-Cohen, Arseneault, Caspi et al., 2005), child maltreatment (Dodge et al., 1995; Jaffee et al., 2004), family poverty (Costello et al., 2003), familial genetic liability (Moffitt, 2005a) and affiliating with delinquent peers (Dishion, McCord, & Poulin, 1999; Thornberry et al., 1993). These studies’ designs either took advantage of natural experiments or otherwise were able to rule out alternative explanations to causation (Moffitt, 2005b). Other risk factors described here have not been decisively tested for causation yet, but they do have evidence that they are robust predictors of conduct problems across many studies carried out in different contexts (e.g., perinatal complications, temperament, verbal and executive deficits, slow heart rate, social cognitions, exposure to parental conflict). Still other risk factors benefit from strong causal theory, warranting inclusion in this chapter, but the evidence base to show reliable association with conduct problems is not yet strong (e.g., attachment, neurotransmitters, MAOA genotype, pregnancy smoking, neighborhood context).

Contemporary Issues in Clinical Assessment and Diagnosis

How Young Can a Diagnosis of Conduct Disorder be Made?

One controversy about the diagnosis of conduct disorders is particularly current: How young can and should a child be
diagnosed? Evidence suggests that conduct problems emerge in preschoolers, that the youngest age of onset is associated with the poorest long-term prognosis and that long-established conduct problems are difficult to treat. This evidence base has resulted in calls for intervention at preschool ages to prevent conduct problems from becoming chronic. However, to intervene early in individual cases, valid methods must be available to diagnose conduct disorders in young children. Whether valid diagnoses of conduct disorders can, or should, be made in very young children has been a focus of controversy (Campbell, 2002; Keenan & Wakschlag, 2002). Some argue that disruptive behaviors in young children should not be pathologized, because aggressive, disruptive and defiant behaviors are thought to be common and developmentally normative in the preschool period, and most children will outgrow them. Others believe that children falsely identified as having conduct disorder will be stigmatized, and unnecessary referral for treatment will waste health care resources. Some argue that the predictive accuracy of conduct problems for prognosis improves only when children are older, and applying diagnostic criteria meant for older children may promote overdiagnosis.

One study tested the validity of the DSM-IV conduct disorder diagnosis for preschoolers, by applying it to screen a birth cohort of 2200 4- to 5-year-olds (Kim-Cohen et al., 2005). The diagnosis successfully identified the children in the cohort who most needed treatment: they were aggressive and antisocial, had co-occurring cognitive deficits and ADHD symptoms, came from adverse family backgrounds, and were likely to have experienced harsh parenting and physical maltreatment. Followed up 2 years later, at age 7, over half of the diagnosed children still met diagnostic criteria for conduct disorder, but even the apparently remitted children continued to evidence clinically significant behavioral and academic difficulties at school, suggesting preschool intervention with them would not have been wasted.

The study indicated that clinicians wishing to minimize false positives can adopt a conservative approach by requiring the more stringent number of criteria specified by DSM-IV for moderate conduct disorder (five symptoms) as opposed to mild conduct disorder (three symptoms). Even better, standardized interview, checklist, and observational methods and guidelines for diagnosing preschool children have been developed (Egger & Angold, 2006). Thus, when necessary to support intervention, the conduct disorder diagnosis can be made for a very young child, albeit with very careful attention to developmental considerations.

Resource Instruments and Multiple Informants to Enhance Diagnostic Validity

There are many different measurement instruments for assessing conduct problems for research and clinical practice; systematic evaluation of their strengths and weaknesses is beyond the scope of this chapter. Earlier we mentioned that juvenile antisocial behavior can be defined in terms of diagnostic categories or continuous distributions of symptom behaviors. Assessment tools reflect these two options. Structured interviews aim to operationalize the specific DSM and ICD criteria to achieve a categorical diagnosis (Costello et al., 1996; Goodman, Ford, Richards et al., 2000; Shaffer, Fisher, Lucas et al., 2000). Symptom checklists aim to broadly cover a variety of conduct and oppositional behavior problems, operating on the evidence-based principle that variety of antisocial behaviors is the best predictor of poor prognosis (Achenbach & Rescorla, 2000; Elander & Rutter, 1996; Goodman, 1997). Whatever instruments are applied, the field has reached consensus that information must be obtained from multiple informants, including if possible parents, teachers, police, clinicians and the child (Arseneault, Kim-Cohen, Taylor et al., 2005; Koot, Crijnen, & Ferdinand, 1999). Multiple informants are an essential part of assessment because no single reporter can have the opportunity to observe all manifestations of antisocial conduct and thus they provide complementary information. In addition, poor prognosis characterizes children who show conduct problems pervasively across multiple different settings such as home, school and neighborhood (Loeber, Green, Lahey et al., 1991).

Risk Assessment and Treatment Planning Approaches

A recent approach to diagnosis and assessment of children with conduct problems may prove especially useful for clinicians. In this approach, assessment is guided by a manual. Examples of such manuals are the SAVRY (Structured Assessment of Violence Risk in Youth; Borum, Bartel, & Forth, 2002), the EARL-20B (Early Assessment Risk List for Boys; Augimeri, Koegl, Webster et al., 2001) and the EARL-21G (Early Assessment Risk List for Girls; Levene, Augimeri, Pepler et al., 2001). These easy-to-use manuals are grounded in the scientific literature, providing operational definitions to assist clinicians in assessing risk factors that are the most valid predictors of a child’s poor antisocial prognosis. Scales are included for rating the severity of each risk factor, resulting in a risk profile that points to key intervention targets in a particular child’s life. Each child’s specific areas of strength are highlighted to exploit in treatment planning, as are specific factors known to predict engagement in treatment versus resistance to treatment. Risk and protective factors can then be linked to approaches for case management, tailored for each juvenile patient and their family members. Formal evaluation of these manual-guided assessments has not been reported, and their long-term predictive validity is unknown, but they are evidence-based and they have strong inherent appeal to many clinicians.

Interventions

The following sections cover treatment of children aged 2–12 years. (For prevention see chapter 61. For treatment of teenagers with conduct disorder, and of delinquents, including
CHAPTER 35

functional family therapy and multisystemic therapy, see chapter 68. For further reviews of treatments see Farmer, Compton, Burns et al., 2002; Bloomquist & Schnell, 2002.)

Principles of Intervention

Basing Treatment on the Assessment

The intervention needs to fit the particular needs of the child and family. Many risk factors have been delineated in this chapter, but usually not all occur in the same child. Intervention needs to be tailored according to the needs and strengths of the family revealed by the assessment, which should include all aspects of the child’s environment and functioning – the multiaxial framework of ICD-10 provides a helpful framework for doing this (World Health Organization, 1996).

Choosing Which Treatment Modality to Use

The behavior may predominantly occur in the home, at school, with peers, in the community, or it may be pervasive. If possible, interventions need to address each context specifically, rather than assuming that successful treatment in one area will generalize to another. Thus, improvements in the home arising from a successful parent training program will not necessarily lead to less antisocial behavior at school (Scott, 2002). Therefore, for cases with difficulties that are mainly at home, where the child is doing reasonably at school and has a friend or two, parent training would be the first line of treatment. If classroom behavior is a problem and a school visit shows that the teacher is not using effective methods, then advice to the teacher and other school staff can be very effective. Where there are pervasive problems including fights with peers, then individual work on anger management and social skills should be added; on its own, anger management is unlikely to be nearly as successful as when it is combined with other approaches. Medication is controversial and generally best avoided; possible indications are discussed below.

Developing Strengths

Identifying strengths of the young person and the family is crucial. This helps engagement, and increases the chances of effective treatment. Encouragement of abilities helps the child spend more time behaving constructively rather than destructively (e.g., more time spent playing football is less time spent hanging around the streets looking for trouble). Encouragement of prosocial activities (e.g., to complete a good drawing, or to play a musical instrument well) also increases achievements and self-esteem and hope for the future. Stattin and Magnusson (1995) found that for children with antisocial behavior living in high-risk areas (which the majority do), those with strengths or skills ended up with far lower rates of criminality than those without.

Engaging the Family

Any family coming to a mental health service is likely to have some fears about being judged as bad and possibly mad. Families of children with conduct problems are more likely to be disadvantaged and disorganized, to have had arguments with official agencies such as schools and welfare officers and to be suspicious of officialdom. Dropout rates in treatment for conduct problem families are high – often up to 60% (Kazdin, 1996a). Practical measures, such as assisting with transportation, providing child care and holding sessions in the evening or at other times to suit the family are all likely to facilitate retention. Forming a good alliance with the family is especially important, and Prinz and Miller (1994) showed that adding engagement strategies during the assessment such as showing parents that the therapist clearly understood their viewpoint led to increased attendance at treatment sessions. Once engaged, the quality of the therapist’s alliance with the family affects treatment success, accounting for 15% of the variance in outcome in the meta-analysis by Shirk and Carver (2003).

Treating Comorbid Conditions

Child antisocial behavior often affects others so strongly that comorbid conditions can easily be missed. Yet, in clinical referrals, comorbidity is the rule rather than the exception. Common accompaniments are depression and ADHD; a number will have PTSD (e.g., in the context of violence inflicted on them by a father, or witnessing beatings received by their mother from a partner). In recent years there has been increasing recognition of the overlap with autistic spectrum disorders (Gilmour et al., 2004), and that a minority will have psychopathic traits (see chapter 51). Each of these conditions requires appropriate management in its own right.

Promoting Social and Scholastic Learning

Treatment involves more than the reduction of antisocial behavior – for example, stopping tantrums and aggressive outbursts, while helpful, will not lead to good functioning if the child lacks the skills to make friends or to negotiate: positive behaviors need to be taught too. Specific learning disabilities such as reading retardation, which is particularly common in these children, need treatment, as do more general difficulties such as planning homework.

Making Use of Guidelines

The American Academy of Child and Adolescent Psychiatry (AACAP) has published sensible practice parameters for the assessment and treatment of conduct disorder (AACAP, 1997), and the UK National Institute for Health and Clinical Excellence (NICE, 2006) has published a “technology appraisal” of the clinical and cost effectiveness of parent-training programs. This sets out criteria for choosing parent-training programs, such as being backed by evidence from randomized controlled trials. NICE guidelines are strongly influential on service commissioners and should help improve practice considerably.

Treating the Child in their Natural Environment

Most of the interventions described below are intended for out-patient or community settings. Psychiatric hospitalization is very rarely necessary; there is no evidence that in-patient
admissions lead to gains that are maintained after the child is returned to their family. The objective of treatment is to enable the child to cope with the environment he or she lives in, and alter the environment where necessary. Where there is parenting breakdown or total inability to manage the child, then foster care may be necessary.

Family Interventions

Several studies have repeatedly found that family factors are strongly associated with antisocial behavior and, as reviewed above, these appear to have a causal role in many cases. Even where the antisocial behavior appears to have arisen “in a clear blue sky” without adverse family risk factors, living with a child with marked antisocial behavior can itself lead to coercive parenting styles, which in turn may exacerbate the problems (O’Connor et al., 1998). Therefore, improving family risk factors such as coercive parenting is likely to be beneficial, whether or not they were originally implicated as a cause. Family interventions can be divided into two main types, those derived from family systems theory, which tend to be more broadly based, and those derived from social learning theory, which tend to be more specifically focused on training parents to improve moment-to-moment interactions with their children.

Family Systemic Therapies

Typically, family systemic therapies involve all family members attending. Their goals differ according to the style and underlying theory of the particular variant of therapy. For example, structural family therapy as pioneered by leaders such as Minuchin (1974) would try to restore clear boundaries of authority of the parents over the child, because often antisocial children have become domineering in their own homes. Other forms of family therapy try to improve patterns of communication that have gone wrong, and “systemic” variants try to reveal and address relevant factors that impinge on the family system from both within and outside the family. There have been rather few good quality evaluations of family or systemic therapies for childhood antisocial behavior; for a fuller discussion see chapter 65. One exception is functional family therapy pioneered by Jim Alexander (Barton & Alexander, 1985), which is particularly focused on antisocial children and has several trials to support it (see chapter 68).

Parent Management Training

Parent management training programs are designed to improve parents’ behavior management skills and the quality of the parent–child relationship. Most target skills such as promoting play and developing a positive parent–child relationship, using praise and rewards to increase desirable social behavior, giving of clear directions and rules, using consistent and calm consequences for unwanted behavior, and reorganizing the child’s day to prevent problems. Parenting interventions may also address distal factors likely to inhibit change (e.g., parental drug or alcohol abuse, maternal depression and relational violence between parents). Treatment can be delivered in individual parent–child appointments, or in a parenting group. Individual approaches offer the advantages of in vivo observation of the parent–child dyad and therapist coaching and feedback regarding progress.

Examples of Good Practice

Helping the non-compliant child (McMahon & Forehand, 2003) and Parent Child Interaction Therapy (PCIT; Eyberg, 1988) are two examples of well-validated individual programs. Group treatment has been shown to be equally effective, and offers opportunities for parents to share their experience with others who are struggling with a disruptive child. Group treatments emphasize discussion among group leaders and parents, and may use videotaped vignettes of parent–child interactions that illustrate the “right” and “wrong” ways to handle situations. Two well-known group treatments are the Incredible Years Program (IY; Webster-Stratton, 1981) and the Positive Parenting Program (Triple P; Sanders & Markie-Dadds, 1996; Sanders, Markie-Dadds, & Turner, 2000).

Effectiveness

Behavioral parent training is the most extensively studied treatment for conduct problems, and there is considerable empirical support for its effectiveness (Weisz, Hawley, & Doss, 2004). Several of the programs are considered “well-established,” according to American Psychological Association criteria, with multiple randomized trials (e.g., Patterson, Chamberlain, & Reid, 1982; Webster-Stratton, Reid, & Hammond, 2001a) and replications by independent research groups (e.g., Scott, Spencer, Doolan et al., 2001). There have also been randomized trials showing the effectiveness of PCIT and Triple P (e.g., Bor, Sanders, & Markie-Dadds, 2002; Sanders, Markie-Dadds, Tully et al., 2000), and there is at least one independent replication of the PCIT model (Nixon, Sweeney, Erickson et al., 2003). Studies suggest that behavioral parent training leads to short-term reductions in antisocial behavior, with moderate to large effect sizes of $d = 0.5–0.8$. Follow-up studies suggest enduring effects at up to 6 years post-treatment (Hood & Eyberg, 2003; Reid, Webster-Stratton, & Hammond, 2003).

Recently, some programs have included an element training parents to read with their children in addition to behavior management, with the idea of targeting multiple risk factors for antisocial behavior. Although teaching parents to read with their children has not always proved successful, Scott, Sylva, Doolan et al. (in press) combined a 12-week behavior management program with a relatively intense, detailed reading program (10 2-hour sessions) for 5- and 6-year-olds. In a randomized controlled trial, this combination reduced the rate of ODD by half and increased reading age by 6 months; ADHD symptoms were also reduced. This kind of approach is promising because it is relatively inexpensive, using parents as the only vehicle for treatment, yet hits multiple risk factors for poor outcomes in antisocial behavior (parenting, ODD, ADHD symptoms, reading ability; for more details of parenting programs see chapter 64).
CHAPTER 35

Child Therapies
Cognitive-behavioral therapy (CBT) and social skills therapies can have several targets:

1. To reduce children’s aggressive behavior such as shouting, pushing and arguing.
2. To increase prosocial interactions such as entering a group, starting a conversation, participating in group activities, sharing, cooperating, asking questions politely, listening and negotiating.
3. To correct the cognitive deficiencies, distortions and inaccurate self-evaluation exhibited by many of these children.
4. To ameliorate emotional regulation and self-control problems so as to reduce emotional lability, impulsivity and explosiveness, enabling the child to be more reflective and able to consider how best to respond in provoking situations.

In practice, most programs cover all four target areas to a greater or lesser extent. While child CBT was originally mainly used with school-age children and older, more recently it has been successfully adapted for preschoolers. These interventions may be delivered in individual or group therapy formats. Although groups offer several advantages (e.g., opportunities to practice peer interactions), there is some research documenting iatrogenic effects (Dishion, McCord, & Poulin, 1999). This appears to be particularly problematic in larger groups and those with inadequate therapist supervision, where children may learn deviant behavior from their peers and encourage each other to act in antisocial ways. A lower patient : therapist ratio is therefore recommended for group work.

Examples of Good Practice
Two of the more popular treatment models for conduct disorder are Kazdin’s Problem Solving Skills Training with in vivo Practice (PSST-P; for a review see Kazdin, 1996b) and Lochman and Wells’ (1996) Coping Power Program. In PSST-P, which is used from the age of 7 upwards, the child receives individual training in interpersonal cognitive problem-solving techniques for 12–20 1-hour sessions. The focus is on identifying problem situations, learning a series of problem-solving steps and applying the steps first to hypothetical situations, then in role plays and finally in real-life situations. Therapeutic strategies include games, therapist modeling and role play with therapist feedback. A token system is used in session to reinforce children’s efforts to practice target skills. Parents are involved periodically for joint sessions, and may receive behavioral parent training as an adjunctive treatment. The Coping Power program is for children aged 8 years upwards, and is fairly lengthy, comprising 33 one-to-one and half-hour group sessions, with periodic (at least monthly) individual meetings. Training focuses on interpretation of social cues, generating prosocial solutions to problems and anger management with arousal reduction strategies. Treatment is delivered in groups of 5–7 children by a therapist and co-therapist. Sessions include imagined scenarios, therapist modeling, role plays with corrective feedback and assignments to practice outside of sessions. Parent and teacher training components have also been developed as adjunctive treatments.

Specifically targeting younger children with conduct problems aged 4–8, Webster-Stratton, Reid, and Hammond (2001b, 2004) have added a group child social skills training component to their IY program, called Dinosaur School. The program lasts for 20–22 2-hour sessions, during which parents usually attend a parallel parenting group. It covers interpersonal problem-solving for young children in a group format with about six children at a time. Sessions include discussion of hypothetical situations and possible solutions, therapist modeling of prosocial responses and practice role playing with therapist feedback. Videotaped vignettes are used to present situations for discussion. Puppets are used for interactive role plays, as well as child-friendly cue cards, coloring books and cartoons. The Dinosaur School program dovetails with other interventions in the IY program, including parent training and a curriculum to train teachers in classroom management skills.

Effectiveness
In two randomized controlled trials, Kazdin, Esveldt-Dawson, French et al. (1987) and Kazdin, Bass, Siegel et al. (1989) found that PSST results in significant decreases in deviant behavior and increases in prosocial behavior. Outcomes were superior to a client-centered relationship-based treatment and were maintained at 1-year follow-up. The addition of in vivo practice and a parent training component were both found to enhance outcomes. Evaluations of the Coping Power program demonstrate reductions in aggression and substance use, and improved social competence (e.g., Lochman & Wells, 2002). Treatment effects were maintained at 1-year follow-up, particularly for those who also received parent training components (Lochman & Wells, 2004). Now replications by independent research groups are needed. In studies by Webster-Stratton, Reid, & Hammond (2001b, 2004), Dinosaur School has been found to result in significant decreases in behavior problems and increased prosocial behavior; treatment gains appeared to be maintained after 1 year. These findings have been independently replicated (Hutchings, Lane, Owen et al., 2004).

The literature is generally not supportive of the effectiveness of individual psychodynamic psychotherapies, art and drama therapies in this population, especially when used as a sole treatment modality, although decisive studies are yet to be undertaken. One or two studies, although methodologically limited, suggest that an attachment-based approach (Moretti, Holland, & Peterson, 1994) or a classic exploratory approach (Fonagy & Target, 1993) might possibly be helpful, at least for a subset of antisocial children; again, properly conducted randomized controlled trials are needed.

Interventions in School
Interventions to Promote Positive Behavior
Typically, teachers are taught techniques that they can apply to all children in their class as well as to those exhibiting the most antisocial behavior. Successful approaches use proactive strategies and include a focus on positive behavior and group interventions, and combine effective instructional strategies with
effective behavioral management. Typically, they target four areas of functioning:
1. Promote positive behaviors such as compliance and following established classroom rules and procedures.
2. Prevent problem behaviors such as talking at inappropriate times and fighting.
3. Teach social and emotional skills such as conflict resolution and problem-solving.
4. Prevent the escalation of angry, acting out behavior.

A number of these targets can be met by training teachers in similar methods as parents, as described above. However, other techniques are classroom specific. For example, establishing and teaching rules and procedures involves setting rules such as “use a quiet voice,” “listen when others are speaking,” “keep your hands and feet to yourself” and “use respectful words.” Note that these rules are all expressed positively, describing what the child should do, rather than as prohibitions stating what they should not do. Streipling (1997) offers six “rules for making rules”:
1. Make few rules (3–6).
2. Negotiate them with the children.
3. State them behaviorally and positively.
4. Make a contract with the children to adhere to them.
5. Post them in the classroom.
6. Send a copy home to parents.

Crucial to all this is a systematic and consistent response to children following or not following the rules. Rewards can be social (teacher praise, peer recognition, notes home to parents), material (stickers, certificates, tokens to exchange for food, etc.), or privileges (e.g., extra breaktime, games, parties, computer time). Mild punishments include reprimands, response-costs procedures (losing privileges or points) and time out (being sent to the corner of the room or to another boring place).

Interventions to Promote Academic Engagement and Learning

These include self-management and self-reinforcement training programs, for example, to help children spend more time on task and to complete written work more quickly and accurately. An older review of 16 studies found moderate to large effects of such programs (Nelson, Smith, Young et al., 1991), and subsequent trials uphold this (e.g., Levendoski & Cartledge, 2000).

A number of programs build on the evidence that antisocial failing children often have parents who do not get involved in their academic schoolwork, and indeed may not value it highly. They do not read with their children, encourage homework or attend school meetings. Approaches include removing barriers to home-school cooperation through training parents to approach teachers positively (often their own memories of school and teachers will be negative and discouraging) and, equally, training teachers to be constructive in solving children’s difficulties and helping parents engage in academic activities with their children. Although there are good descriptions of programs (e.g., Christenson & Buerkle, 1999), to date rigorous evaluations are lacking. For more details of special education programs see chapter 74.

Medication

At present, there are no pharmacological interventions approved specifically for conduct disorder. Nonetheless, in the USA, medications are used relatively frequently and increasingly in this population (Steiner, Saxena, & Chang, 2003; Turgay, 2004). Primary care physicians are often placed in the position of managing such medications. Concerns have been raised because primary care clinicians often lack adequate training in developmental psychopathology, and adequate time for thorough assessment and monitoring (Vitiello, 2001). In the UK, medication would not generally be supported as good practice because, as discussed below, well-replicated trials of effectiveness are limited, particularly for children without ADHD.

The best-studied pharmacological interventions for youth with conduct problems are psychostimulants (methylphenidate and dexamfetamine), as used with children with comorbid ADHD and conduct disorder. In these circumstances, there is evidence that reduction in hyperactivity-impulsivity will also result in reduced conduct problems (Connor, Glatt, Lopez et al., 2002; Gerardin, Cohen, Mazet et al., 2002). There is insufficient reliable evidence to decide whether stimulants reduce aggression in the absence of ADHD; one study by Klein, Abikoff, Klass et al. (1997) found that improvements in conduct disorder symptoms were independent of ADHD symptom reduction, but this needs replication.

Other pharmacological approaches for antisocial behavior have tended to target reactive aggression and overarousal, primarily in highly aggressive and psychiatrically hospitalized youth. Medications used in these conditions include those purported to target affect dysregulation (e.g., buspirone, clonidine), mood stabilizers (e.g., lithium, carbamazepine). Whereas Campbell et al. found that lithium reduced aggression and hostility in psychiatrically hospitalized youth (Campbell, Adams, Small et al., 1995; Malone, Delaney, Ruebbert et al., 2000), others have failed to show effectiveness in out-patient samples (e.g., Klein, 1991) and in studies of shorter treatment intervals (i.e., 2 weeks or less; Rifkin, Karagi, Dicker et al., 1997). Carbamazepine failed to out-perform placebo in a double-blind placebo controlled study (Cueva, Overall, Small et al., 1996). In children with aggression and hyperactivity, Hazell and Stuart (2003) in a placebo controlled randomized trial of stimulants plus placebo versus stimulants plus clonidine found the latter was more effective. However, it should be noted that the use of polypharmacy treatment also carries the risk of increased side-effects (Impicciatore, Choonara, Clarkson et al., 2001).

In the last few years, the use of antipsychotics such as risperidone, clonidine and others in out-patient settings has been increasing. However, there is only modest evidence for their effectiveness in conduct disorder in normal IQ children without ADHD. The review by Pappadopoulos, Woolston, Chait et al. (2006) found that effect sizes were larger where ADHD
or intellectual disability were present. Findling, McNamara, Branicky et al. (2000), in a small \( n = 10 \) per group), double-blind placebo controlled study, found significant short-term reductions in aggression. The Risperidone Disruptive Behavior Study Group used a placebo controlled double-blind design to study the effects of risperidone in 110 children with sub-average IQ and conduct problems. Results suggested that risperidone leads to significant improvements in behavior versus placebo (Aman, De Smedt, Derivan et al., 2002; Snyder, Turgay, Aman et al., 2002), but it remains unclear whether the same findings would apply to normal IQ children. Even newer antipsychotics, while not especially sedating, have substantial side-effects (e.g., risperidone typically leads to considerable weight gain) and the prevalence of movement disorders in the long term is unknown. When might they be contemplated? Clinical experience suggests they can lead to dramatic reductions in aggression in some cases, especially where there is poor emotional regulation characterized by prolonged rages. Prescribing antipsychotics for relatively short periods (say, up to 4 months) in lower doses (say, no more than 1–1.5 mg/day risperidone) can help families cope; during this time it is crucial to introduce more effective psychological management.

**Conclusions and the Way Forward**

Conduct disorder is a common disorder among children, and intervention is essential because most children with conduct disorder show poor health and social outcomes for many years, ultimately accounting for a substantial proportion of the adult health burden. In coming years we expect to see new research into the following unanswered questions. First, given the plethora of statistical risk factors for conduct problems at the levels of individual, family and community, which among them are causal and which are the best candidates for intervention? Second, what factors can help clinicians predict long-term prognosis and select which youth with conduct problems most warrant scarce treatment resources? Third, given that preschool-onset conduct problems and psychopathic traits are good predictors of prognosis in research settings, how can these features be safely used in clinical settings without the iatrogenic effects of assigning derogatory labels to young children? Fourth, do girls with conduct problems need a different causal theory from boys, and perhaps different interventions? Fifth, what biomarkers are reliably associated with conduct problems, and do any of these suggest new treatment possibilities?

As our review of treatments demonstrated, psychological therapies are the mainstay of treatment for conduct problems. However, despite this strong evidence base, in both the USA and the UK only a minority of children receive any treatment, and even fewer receive empirically supported interventions. Further, the “effectiveness” of these interventions as practiced in community settings tends to lag behind documented “efficacy” in controlled trials (e.g., Curtis, Ronan, & Borduin, 2004). As can already be seen in recent efforts with many of the interventions described here, the next generation of evidence-based treatments for conduct problems will likely include much greater attention to dissemination, including strategies for ongoing training and supervision of practitioners to ensure treatment fidelity. The ultimate goal, of course, is to ensure that children with these disorders have access to high-quality empirically based care.

Substance Use and Substance Use Disorder

Andrew C. Heath, Michael T. Lynskey and Mary Waldron

Adolescent and pre-adolescent substance use and substance use disorder bring immediate risks of harm. The acute effects of intoxication can be devastating: alcohol-related motor vehicle accidents remain one of the leading causes of mortality among youth; sharing needles and related injecting paraphernalia has emerged as a leading vector for the transmission of blood borne viruses; and acute intoxication has also been associated with sexual risk taking, sexual victimization and unintentional injury (Hingson & Kenkel, 2004). In treatment samples, excessive alcohol use has been reported to be associated with neurocognitive deficits (Brown & Tappert, 2004) which, if confirmed to be a consequence of alcohol misuse rather than predisposing deficits, would raise the possibility of longer-term disadvantages as a consequence of misuse. Adverse health effects of smoking have been shown in adolescent smokers, including adverse effects on lung function (Gold, Wang, Wipij et al., 1996). Despite these risks, and despite the high rates of co-occurrence of substance use or substance use disorders with other childhood disorders seen in clinical practice (Abrantes, Strong, Ramsey et al., 2005; Wilens, Biederman, Abrantes et al., 1997), adolescent substance use has been relatively neglected in clinical practice and in research studies.

The societal costs of this neglect of adolescent substance use are high. The Global Burden of Disease project identified tobacco, alcohol and illicit drugs as, respectively the 2nd, 9th and 20th leading causes of mortality globally (Ezzati, Lopez, Rodgers et al., 2003). If current trends continue, tobacco smoking alone is projected to lead to 1 billion premature deaths globally during the 21st century (Mackey, Eriksen, & Shafey, 2006). Continued and heavy use of these substances has a spectrum of adverse outcomes including physical, social and legal consequences. While many of these conditions, and particularly those relating to physical ill health, develop only after chronic use spanning several decades, and are therefore rare in children and adolescents, an understanding of substance use and substance use problems during adolescence is critical to any approach aimed at lessening these consequences, as it is during childhood and adolescence that the use of these substances typically first occurs. Some studies suggest that, if substance use has not been initiated by age 21, it is unlikely to ever be initiated (Chen & Kandel, 1995). Further, age at initiation to substance use has consistently been shown to be associated with higher lifetime consumption, more risky patterns of use, and with the onset, duration and severity of dependence (see p. 570). While the interpretation of these associations remains controversial, it is clearly the case that early-onset use is a robust indicator of risk for future substance-related problems.

In this chapter we first outline research characterizing patterns of adolescent substance use, the assessment of substance use and substance use problems in adolescents, and diagnostic criteria for substance use disorders, including issues relating to the extent to which such criteria may be applicable to adolescents. We also examine outcomes associated with adolescent substance use. We next consider research findings on the etiology of substance use disorders, and their comorbidity with other disorders. Finally, we review treatment approaches and prevention strategies.

**Epidemiology**

Much of the literature on the prevalence of substance use in children and adolescents is hampered by methodological challenges including small and unrepresentative samples and varying definitions of substance involvement. We limit our consideration to a relatively small number of studies using large and representative samples that have examined prevalence of substance use. We attempt where possible to provide accurate estimates of the ages at which substance use has been assessed, because childhood and adolescence is a time of very rapid escalation in the prevalence of lifetime use and escalation in involvement and thus even relatively small age differences may be associated with quite large changes in the extent of substance use.

**Tobacco Use**

Tobacco, principally but not exclusively in the form of smoked cigarettes, is widely used among children and adolescents. Perhaps the most comprehensive information on patterns of licit and illicit drug use among children and adolescents comes from the USA Monitoring the Future project, which has conducted large surveys of the school-aged population at annual intervals since 1975 (Johnston, O’Malley, Bachman et al., 2006). The most recent data available from this study are for the year 2005, which indicate that about 50% of 12th grade
CHAPTER 36

students (ages 17–18) and 25.9% of 8th grade students (ages 13–14) have smoked cigarettes while 17.5% and 10.1%, respectively, have used smokeless tobacco products. Further, 13.7% of 12th graders and 4.1% of 8th graders reported smoking cigarettes daily during the 30 days preceding the survey while about 2.5% and 0.7% reported using smokeless tobacco products about once a day or more often.

While international comparisons show considerable variability in the prevalence of tobacco smoking and the use of smokeless tobacco products, the use of these products among youth is widespread. For example, the Global Youth Tobacco Survey, which surveyed 13- to 15-year-old school students from 131 countries, reported that rates of past 30-day tobacco use ranged from 11.4% to 22.2% of students (Warren, Jones, Eriksen et al., 2006).

Alcohol Consumption

In the 2005 Monitoring the Future study, by 12th grade, 75.1% of all students had used alcohol at least once and 37.5% reported having been drunk at least once, with corresponding percentages of 41% and 19.5% in 8th grade. By 12th grade, rates of lifetime alcohol use were approximately equal across genders (75.7% in males and 74.5% in females), although more males (60.5%) than females (54.4%) reported lifetime drunkenness. There was also evidence of a relatively small subgroup of students who were drinking heavily regularly: 18.1% of students in their final year at high school, and 18.1% of 8th graders, reported having five or more drinks in a row on at least two occasions in the preceding 2 weeks.

There is also information available on patterns of alcohol use internationally. Schmid, Ter Bogt, Godeau et al. (2003) reported on patterns of consumption among 15-year-olds in 22 countries: the prevalence of lifetime alcohol use across these countries ranged from 66% (in the USA and Norway) to 92.2% (in Greece and Denmark) among males and from 66% (in the USA) to 91% (in Denmark) among females. Among students who had drunk alcohol, the prevalence of ever having been drunk was 47–85% of males and 42–93% of females.

Illicit Drug Use

Prevalence estimates derived from the Monitoring the Future Survey lead to several important conclusions. First, at least some lifetime use of illicit drugs is widespread – 21.4% of 8th graders reported using illicit drugs on at least one occasion, and by the final year of high school in excess of 50% of school attendees report some illicit drug use. Second, cannabis is by far the most widely used illicit drug, with 44.8% of 12th graders and 16.5% of 8th graders reporting having used this drug. Relatively few individuals reporting lifetime use of illicit drugs have not used cannabis (22.9% of 8th graders and 11.1% of 12th graders who report any illicit drug use). The lifetime use of other illicit drugs is less prevalent but substantial minorities report some experience with amphetamines (13.1% of 12th graders, 7.4% of 8th graders), inhalants (11.4%, 17.1%, suggesting younger respondents are considering a wider range

of experiences as inhalant use, or older respondents are forgetting), sedatives (10.5%, no data for 8th graders), tranquilizers (9.9%, 4.1%), hallucinogens (8.8%, 3.8%), cocaine (8.0%, 3.7%), MDMA (ecstasy; 5.4%, 2.8%) and heroin (1.5%, 1.5%). In addition, there are marked gender differences with the prevalence of use of all drugs being higher among males than among females (e.g., 49.1% versus 40.2% for cannabis use among 12th graders). However, gender differences in the prevalence of illicit drug use appear to have declined in more recent years, with rates of use among females converging on rates among males, a trend that mirrors similar findings in the tobacco and alcohol literatures (Johnson & Gerstein, 1998).

Finally, rapid escalation in use occurs over the high school years: rates of ever use of cannabis rose from 16.5% among 8th graders to 44.8% among 12th graders.

While these estimates of the prevalence of illicit drug use may appear high, it is worth noting that, because of the sampling frame of this study (school attendees) it is likely, in fact, to underestimate the true prevalence of illicit drug use among youth. School surveys such as this exclude individuals who no longer attend school as well as those who, for whatever reason (e.g., habitual truancy), are unavailable on the day of testing, a group likely to have higher rates of illicit drug use (Johnston et al., 2006).

Finally, the figures cited above are for any lifetime use and it is also important to consider the frequency and progression of illicit drug use among youth. While the Monitoring the Future Survey does not provide good information on the frequency or extent of illicit drug use, it appears that the majority of those reporting any lifetime illicit drug use have used the drug on relatively few occasions. For example, while 44.8% of 12th grade high school students in the Monitoring the Future Survey reported lifetime cannabis use, 22.3% of these (10.0% of the entire sample) reported using cannabis on only one or two occasions in their life. Nonetheless, there is a smaller minority of youth who report relatively frequent illicit drug use: 4.9% of these students reported using cannabis on 10 or more occasions in the previous 30 days.

Substance Use Disorders

There is generally less information on the prevalence of substance use disorders (e.g., abuse, dependence as operationalized in DSM-IV [American Psychiatric Association, 2000]) in youth. This likely reflects a convergence of factors: potential difficulties in the application of standard abuse/dependence criteria to samples of youth (see p. 569); the need for exceptionally large and representative samples given the relatively low base rate of these disorders within the general population; and the fact that they are likely to be concentrated in subgroups of the population (e.g., homeless, those who have left school) who are difficult to capture using traditional survey methodologies. Although there have been a number of relatively large-scale epidemiological surveys of psychiatric disorders among children and adolescents, surprisingly few of these have yielded estimates of the prevalence of substance use.
disorders. Published studies have either not reported any information on the prevalence of substance abuse/dependence or have adopted the convention of combining all (typically non-tobacco) diagnoses to form a single category of substance use disorder. For example, in a representative sample of approximately 1000 New Zealand children studied at age 15 years, Fergusson, Horwood, and Lyskey (1993) reported that 7.7% of this sample met criteria for a substance use disorder, defined as nicotine dependence, or alcohol or other substance abuse or dependence. Such studies were reviewed by Costello, Egger, and Angold (2005), who reported that the median estimate from studies of substance use disorders was in the region of 5%, although there was wide variation among studies in these estimates.

An alternative strategy for estimating the prevalence of substance use disorders among youth is to consider reports of the age of onset of substance use disorders from large and representative samples of the general population. For example, in the NCS Replication survey of adults aged 18 years and older, Kessler, Berglund, Demler et al. (2005) reported, for 50% of all those meeting lifetime criteria for a substance use disorder (not including nicotine dependence), the onset of these disorders occurred before age 21 for alcohol abuse, before age 23 for alcohol dependence, before age 19 for drug abuse, before age 21 for drug dependence and before age 20 for any substance use disorder.

Implications for the Assessment of Adolescent Substance Use and Problems
Research suggests that face-to-face interview assessment leads to underreporting of substance use by adolescents. In the USA, the discrepancy between rates of self-reported substance use in early national household surveys of drug use that used traditional interview methods, and self-reports based on responses to questionnaires administered in schools, led to several changes in strategy: first to using a self-administered questionnaire, during an interview, to obtain drug use history information; and then to using a computer self-administered interview to obtain this same information (Gfroerer, Eyerman, & Chromy, 2006). Self-report data obtained by questionnaire (e.g., Rutgers Alcohol Problem Index: White & Labouvie, 1989; Drug Use Screening Inventory: Kirisci, Mezzich, & Tartar, 1995) or computer self-administered interview (Turner, Ku, Rogers et al., 1998), particularly where this can be supplemented by toxicology screens, are likely to become the norm for adolescent research assessment. We know of no research comparing the accuracy of information gathered by a standard clinician interview with supplementation by self-report checklist or computer-based assessment, but would anticipate that substantial underreporting at interview would also occur in this clinical context, suggesting that supplementation by checklist or computer-based assessment be used. Brief screens for use and problem use should be utilized across a spectrum of clinical settings as such use and/or problems are common – and elevated – in youth accessing treatment.

Diagnosis
At the time of writing, the development of the next generation of diagnostic criteria for drug use disorders by the American Psychiatric Association (DSM-V) remains a work in progress. However, while important innovations have been proposed (e.g., use of semicontinuous ratings for each dependence criterion, to permit a more nearly continuous assessment of level of problems), the need to preserve continuity of clinical and research practice, and lack of the necessary empirical base to support more radical change, are expected to limit changes from DSM-IV to DSM-V. The application of diagnostic criteria developed for drug use problems in adults to adolescents remains controversial, with many areas of difficulty (Crowley, 2006), but some of these difficulties highlight shortcomings in the existing diagnostic criteria. In discussions of the assessment and diagnosis of substance use problems in children and adolescents, four important shortcomings of existing evidence are faced. 1 The lack of large general population psychiatric surveys of children and adolescents of the magnitude (minimally, tens of thousands of participants) that is necessary to give confidence in attempts to use advanced statistical methods (e.g., Muthen, 2006) to refine diagnostic criteria for specific drug use disorders in general community samples. This has the implication that much of what we can guess about the applicability of diagnostic criteria sets to adolescent substance use disorders derives from retrospective recall of adults about their past history of drug use and problems. While such “back-testing” of diagnostic schema to determine their applicability to adolescents has been underutilized by researchers, the pitfalls associated with reliance on retrospective reports are considerable. 2 The lack of large-scale follow-up studies of clinically treated adolescents with drug use disorders with sample sizes of the magnitude (500–1000 or more participants) available for adults. This makes prospective validation of proposed diagnostic criteria sets, by comparing prediction of future course, treatment–response and other outcomes, a special challenge for pediatric substance use disorders. 3 The narrow focus of most contemporary research assessments of substance use disorders on existing (and in some cases earlier) diagnostic criteria sets, which leaves a weak evidence base for modifying existing criteria. 4 The predominant focus of much research on the nosology of substance use disorders on one drug, alcohol, because of its widespread use and the recognition by psychiatrists of the clinical significance of alcohol use disorders. Tobacco dependence, although widespread and associated with severe long-term physical health risks, is widely neglected in psychiatry. Cannabis use disorders, also increasingly prevalent, have likewise tended to be neglected, perhaps because viewed by many psychiatrists as benign.

The Dependence Syndrome
Current operationalizations of substance dependence, in both DSM-IV and ICD-10, derive ultimately from the formulation
of the “dependence syndrome” by Edwards (1986), developed initially with respect to alcohol dependence and then generalized to other drug classes, which represented an attempt to define a physiological syndrome of dependence. Primacy was given to:
1. The experiencing of repeated symptoms of withdrawal, with other defining symptoms being;
2. Relief or avoidance of withdrawal symptoms by further drug use;
3. Increased tolerance;
4. Subjective awareness of compulsion to use the drug, including loss of control;
5. Rapid reinstatement after abstinence;
6. Narrowing of the drug use repertoire; and
7. Salience of drug-seeking behavior.

Withdrawal, Withdrawal Relief; Tolerance
Both DSM-IV (American Psychiatric Association [APA], 2000) and ICD-10 (World Health Organization, 1996) specify withdrawal syndromes separately for each drug, but using the same criterion for each drug – namely, that the syndrome is due to the cessation or reduction in substance use that has been heavy or prolonged. In DSM-IV no cannabis withdrawal syndrome was recognized, but subsequent laboratory-based studies (Budney, Hughes, Moore et al., 2004), supported by psychometric data (Budney, 2006), make it likely that a cannabis withdrawal syndrome will be included in DSM-V, leaving hallucinogens as the main drug class with no known withdrawal syndrome. Tolerance is defined in DSM by a need for markedly increased amounts of a drug to achieve intoxication or a desired effect or (as may occur after a history of chronic heavy use) by a markedly diminished effect with continued use of the same amount (APA, 2000).

At least two schools of thought exist concerning the assessment of drug withdrawal, and of tolerance. One, in its most extreme form, emphasizes the severe and sometimes life-threatening withdrawal syndromes seen with very long-term opiate, alcohol or sedative dependence that may include grand mal convulsions and delirium tremens. Caetano and Babor (2006) emphasized the development of withdrawal after 25–30 years of heavy drinking, and contrasted this with the problems reported by young adults, arguing that the latter are not truly describing withdrawal symptoms. Likewise, it is possible to operationalize tolerance in such a way that it describes individuals with prolonged histories of excessive substance use (Caetano & Babor, 2006) whose acquired tolerance enables them to function at levels of consumption that would cause severe impairment in most of the population. From this perspective, the alcohol withdrawal syndrome will almost never be encountered in adolescents, and the tolerance reported by adolescents is the acquired behavioral tolerance (Vogel-Sprott, 1997) that comes from learning to adapt to intoxicating levels of alcohol or other drugs, rather than the chronic adaptations that occur after a prolonged history of substance use. However, a consequence of this approach is that the alcohol dependence syndrome as originally conceptualized (with withdrawal as a cardinal feature) becomes a severe but rare disorder, with the majority of individuals who experience problems with alcohol needing to be covered by a residual alcohol use disorder category, an unfortunate consequence given the desirability of providing clinical help before individuals reach the stage of such severe dependence. Alternatively, if a broader conceptualization of dependence is used, drug withdrawal and tolerance defined this stringently become essentially irrelevant to diagnosis, because most individuals reporting drug withdrawal or tolerance will also report many other less severe symptoms. While retention of stringent criteria for a severe withdrawal syndrome requiring careful medical management is clearly essential, this, together with stringently defined tolerance, will usually be irrelevant in pediatric practice.

The second school of thought considers withdrawal and tolerance as symptoms arising relatively early in the course of drug use, that may indeed impact the development of other symptoms of dependence. Tolerance may be defined more broadly, so that it is endorsed by many individuals with few or no other dependence symptoms (Muthen, 2006). For alcohol withdrawal, support for a broader operationalization (Muthen, 2006) derives primarily from research using structured diagnostic assessments with quite non-specific wordings to assess withdrawal, which may indeed be endorsed by youngsters who are confusing effects of alcohol intoxication with effects of alcohol withdrawal (Caetano & Babor, 2006). Other research studies that have used a more stringent operationalization of alcohol withdrawal find it to be a relatively severe symptom (e.g., Bucholz, Heath, Reich et al., 2006) that would be quite rare in adolescents.

We do not have good empirical data to support preference for either narrower or broader definitions, and need to be sensitive to the possibility that we are arbitrarily dichotomizing continuums of tolerance or withdrawal severity and thereby sacrificing diagnostic precision. Basic science studies have shown acute alcohol withdrawal effects after a single high dose (e.g., handling-induced seizures in mice; Metten et al., 1998) with evidence for genetic overlap of vulnerability to chronic versus acute withdrawal effects (Metten et al., 1998). It has been speculated that hangover in humans may represent such an acute alcohol withdrawal effect, and rates of reported hangover are certainly elevated in those at high risk of alcohol dependence by virtue of a positive family history of alcoholism (Fiascki, Sher, Slutske et al., 2005). Such acute withdrawal effects may be not uncommon in adolescent heavy drinkers, because many have a typical pattern of intermittent heavy consumption; they simply have not been usually assessed, because not a part of the DSM-IV criteria, and their prognostic significance is therefore unknown.

Consideration of tobacco dependence suggests that tolerance and withdrawal can be important in adolescence. Koob (2006) cited evidence that “measures of brain reward function during acute abstinence from all major drugs with dependence potential have revealed increases in brain reward thresholds as measured by brain stimulation reward,” suggesting that withdrawal symptoms involving dysphoria may be a common feature, across drug classes, of drug withdrawal. Nicotine
withdrawal symptoms, which in DSM-IV predominantly involve affective symptoms, are reported by adolescents relatively early in their smoking careers, as well as by adults (Prokhovov, Hudmon, de Moor et al., 2001), and it is plausible that this pattern for affective symptoms of withdrawal will be confirmed across drug classes. In contrast with alcohol, nicotine is not a drug used for intoxication (hence the more severe operationalizations of tolerance are irrelevant for this drug), and most smokers would not describe their smoking in terms of achieving a “desired effect” (Hughes, 2006). Nicotine in doses smoked by some heavy smoking adolescents (e.g., 20 cigarettes per day; Hurt, Croghan, Beede et al., 2000), however, would be extremely toxic in someone with no prior smoking history: by this example, tolerance is clearly acquired by many adolescent smokers.

In the absence of careful laboratory-based studies of adolescent withdrawal, and of real-time field assessments of adolescent withdrawal and tolerance (such as are now possible using palm-pilot based ecological momentary assessment techniques), the present state of the science must be to assess both broadly and stringently and determine whether either or both measures have predictive value for adolescent substance use disorders.

Compulsive Use – Loss of Control; Difficulty Quitting/Cutting Down
The notion of “loss of control,” as experienced by an individual with alcohol problems who, across repeated drinking sessions, intends to limit his or her drinking but drinks to intoxication, has little relevance to tobacco dependence, where the smoker typically maintains a very stable pattern of smoking from day to day. If defined broadly (the language of DSM-IV includes “often taken in larger amounts... than intended,” relaxing the requirement for intoxication), it does not discriminate very well in heavy-drinking cohorts (Bucholz et al., 1996). Loss of control is more likely to be experienced by a smoker as difficulty quitting, despite a persistent desire to quit. Concern has been expressed about whether adolescents understand questions about such experiences in the same way as adults, and thus may overreport dependence symptoms because of difficulty distinguishing symptoms from the normal fluctuations of adolescence (Prokhovov, Hudmon, Cinciripini et al., 2005). It may also be the case that an adolescent who has progressed from occasional experimentation to more regular use of a drug is actually a better informant about the experience of compulsion to use than, say, an adult chronic heavy smoker who has adapted to drug use over a period of many years. DSM-IV defines as a separate dependence symptom (also considered an indicator of compulsive use) spending a great deal of time obtaining, using or recovering from the effects of the substance, which applies in quite different ways to illicit drug use (seeking out drugs from a dealer), drinking (recovering from effects of hangover) and also is made to apply to smoking (by giving chain-smoking as an example of spending a great deal of time using), but the connection with compulsive use appears far more remote in these cases.

Continued Use Despite Negative Consequences
Hasin, Hatzenbuehler, Keyes et al. (2006) correctly drew attention to the rather idiosyncratic ways in which continued use despite substance-related problems is handled in current diagnostic criteria. In DSM-IV, continued use despite knowledge that this is causing physical or emotional problems is considered a symptom of dependence. Giving up important social, occupational or recreational activities because of substance use is considered a separate symptom of dependence. Both are inferred to be manifestations of loss of control, although the evidence to support the implicit assertion that it is the compulsion to use that leads ultimately to the pattern of continued use despite negative consequences is not supplied.

In contrast, continued use despite interference with major role responsibilities (e.g., schooling, parenting, work); continued use despite social problems (e.g., disruption of relationships) or legal problems; or continued use in situations that are physically hazardous (e.g., drunk driving), are considered manifestations of “abuse,” a residual category whose survival or demise in DSM-V remains controversial (Schuckit & Saunders, 2006). DSM-IV uses the phrase “recurrent” to describe these latter problems (although continued use is clearly implied). It is precisely the latter types of problem that adolescents are more likely to encounter through substance use. Continued use despite being aware of other negative consequences that do not involve immediate physical hazard (e.g., heavy drinking leading to inappropriate sexual behavior by an adolescent) is discounted. Continued smoking that is increasing an individual’s long-term risk of cancer is also discounted. The adolescent who is continuing to use at medically unsafe levels, or the adolescent who is experiencing distress because their substance use is leading to inappropriate sexual behavior or sexual risk-taking, may be experiencing symptoms of comparable importance to the older adult who is already experiencing physical problems associated with their substance use, but these problems are classified quite differently.

Clinically Significant Distress/Impairment
DSM-IV includes a requirement, for a diagnosis of substance abuse or dependence, that there be evidence of clinically significant distress or impairment, thereby excluding all those cases whose significance lies purely in the realm of physical medicine (e.g., alcohol-related liver damage; smoking-related health risks), or where individuals’ behavior puts themselves or others in danger (e.g., recurrent driving under the influence) without personal remorse or impairment in daily life. Reliance on subjective evaluations of distress or impairment may be particularly problematic for adolescents whose social milieu discourages recognition of impairment. The wisdom of such exclusions must be questioned.

Reconceptualizing Adolescent Substance Use Disorder
There remains debate about how well criteria for substance use disorders developed for adults apply to adolescents, and whether indeed separate criteria should be developed for
CHAPTER 36

adolescents or young adults (Crowley, 2006; Martin, Chung, Kirisci et al., 2006). We argue that consideration of: (i) heaviness of use (indexed by tolerance); (ii) loss of control (including difficulty quitting); (iii) continued use despite awareness of negative consequences of use; and in some cases, (iv) problems associated with cessation of use (withdrawal) will identify significant numbers of adolescents experiencing substance-related problems; and that the same profile of problems occurring in a 17-year-old and a 47-year-old would not be an indicator that the 47-year-old does not have problems.

There is accumulating evidence in support of a “dimensional” conceptualization of alcohol dependence symptoms (which have been more extensively studied than is the case for other substance use disorders), with individuals with more severe problems more likely to endorse particular symptoms, individuals with less severe problems less likely to endorse the same symptoms, but with no unique symptom profiles identifying particular subclasses of dependent patients (e.g., Bucholz et al., 1996). Under these conditions, defining diagnostic criteria that correctly classify severely affected chronic substance dependent individuals is easy; the real challenge is posed by ensuring that individuals with milder problems are correctly classified, a group in which an increased proportion of adolescents will be represented. From this perspective, difficulties identified in the application of diagnostic criteria to adolescents are highlighting broader limitations of these criteria.

Risks Associated With Early Use

A consistent – albeit controversial – finding is that age of initiation to substance use is strongly associated with later risks of problems. For example, using data from a diagnostic interview survey of a representative sample of US adults (the NESARC study), Hingson, Heeren, and Winter (2006) reported that age of onset of alcohol use was inversely related not only to lifetime risks of alcohol dependence, but also to the severity and duration of dependence. Specifically, individuals who commenced drinking before age 14, compared to those who commenced after age 21, were more likely to meet the criteria for alcohol dependence in the 10 years immediately following drinking initiation, in the 12 months prior to the interview and ever in their lifetimes. They were also more likely to experience multiple distinct episodes of alcohol dependence. Comparisons restricted to those experiencing lifetime alcohol dependence indicated that early-onset alcohol dependence was also associated with higher rates of long duration episodes and with meeting six or more dependence criteria.

Hingson, Heeren, Zakocs et al. (2003) reported a 3.5-fold increased risk of being involved in an alcohol-related accident among individuals who began drinking at age 14 relative to those who started drinking after age 21. Importantly, these associations persisted after control for a range of covariates including alcohol dependence and length of drinking career, and when consideration was limited to alcohol-related accidents in the 12 months prior to the interview. These results parallel findings from other studies that an earlier age of alcohol initiation is associated with heavy and more prolonged drinking (Fergusson, Horwood, & Lynskey, 1995; Pitkanen, Lyrra, & Pulkkinen, 2005), alcohol dependence (Hingson, Heeren, & Winter, 2006) and unsafe sexual practices (Hingson et al., 2003). Analogous, although less striking, results have also been reported for tobacco use, with early-onset tobacco use being associated with heightened risks for the development of nicotine dependence (Hu, Davies, & Kandel, 2006) and also for illicit drug use (Lynskey, Heath, Bucholz et al., 2003).

Some commentators have implied that these associations are causal and therefore advocated delaying the onset of alcohol use as a potential means of reducing longer-term exposure to alcohol-related harm (Pitkanen, Lyrra, & Pulkkinen, 2005). Alternatively, it has been argued that these associations are likely to be non-causal and arise from the effects of social, family and related (including genetic) factors preceding the onset of alcohol consumption that increase risks both of early initiation of alcohol use and of subsequent alcohol-related harm, for which there may have been inadequate statistical control (Prescott & Kendler, 1999). Prescott and Kendler (1999), using a genetically informative research design, reported that apparent associations between age of onset of alcohol consumption and lifetime alcohol dependence could largely be attributed to shared genetic vulnerabilities. An alternative possibility, not excluded by those analyses, is that genetic differences in dependence risk and early-onset alcohol use are combining interactively (a genotype × early-onset use interaction effect) to determine dependence risk, so the controversy remains unresolved.

The Gateway Hypothesis

A highly controversial theory concerns whether early-onset cannabis use may act as a risk factor that increases risks for the initiation and escalation in use of other drugs such as heroin and cocaine. This theory, sometimes referred to as the stage or gateway theory, is largely based on findings that, among those reporting the use of drugs such as heroin or cocaine, nearly all people report having also used cannabis and also, among these individuals, use of cannabis is almost always initiated before the use of these other drugs. These findings, and the interpretation placed on them, have been described as one of the most influential research findings in drug policy and have been used as a major rationale for sustaining legal prohibitions against cannabis in the USA and other countries where cannabis use and possession remain illegal. However, temporal sequence alone does not imply causality and it is equally possible that the observed patterns of association between cannabis use and other drug use could be explained by a model assuming no causal associations between cannabis use and subsequent use of illicit drugs (Morrall, McCaffrey, & Paddock, 2002).

Nonetheless, a number of studies that have attempted to control for observed covariates have reported that, even after such control, significant associations remain between early-onset cannabis use and subsequent illicit drug use (Fergusson,
Boden, & Horwood, 2006). Using a cotwin methodology to control for both genetic and shared environmental risk factors that may be associated both with early-onset cannabis use and with subsequent use of other illicit drugs, Lynskey et al. (2003) reported that early-onset cannabis users had odds of sedative, hallucinogen, cocaine/other stimulants and opioid use that were 2.6–5.2 times higher than those of their non-early using cotwin. Subsequent studies using a variety of genetically informative research strategies have also failed to discount the possibility that the use of cannabis may influence subsequent risks for the development of illicit drug use (Agrawal, Neale, Prescott et al., 2004; Lynskey, Vink, & Boomsma, 2006).

There are a number of different possible explanations for the mechanisms underlying the observed associations. First, it remains possible that the associations are wholly non-causal and arise both from the joint influence of shared risk factors (including genetic and shared environmental risk factors that were controlled for in the genetically informed research studies mentioned above), and from non-shared risk factors – such as peer affiliations – that were not controlled. While popular interpretations of the “gateway” properties of cannabis imply pharmacological effects of adolescent exposure to cannabis, such mechanisms seem unlikely; the levels of exposure typically employed in animal models are often many times higher than is typical in early-onset cannabis users. An alternative explanation of the observed associations is that they arise because use of and access to cannabis increase exposure and opportunity to use other drugs (Wagner & Anthony, 2002).

**Psychosocial and Genetic Risk Factors**

In evaluating pertinent literature on the etiology of substance use disorders, ideally one would wish to know about at least four dimensions of risk:

1. Predictors of early onset, because early initiation of substance use will itself predict increased risk of later problems (see p. 570);
2. Predictors of heaviness of use (or other aspects of substance use patterning that may be associated with increased risks of problems);
3. Predictors of dependence vulnerability, conditional upon duration and heaviness of use; and
4. Predictors of desistance (i.e., protective factors that may facilitate quitting or overcoming substance use-related problems). It is rare to find that these different dimensions of risk have been considered in a single study.

**Genetic Research**

We know relatively little about the genetics of adolescent substance use and substance use disorder, with the limited information deriving from a small number of studies (McGue, Iacono, Legrand et al., 2001; Rose, Dick, Viken et al., 2004; Slutsker, Cronk, Sher et al., 2002a) that are mostly ongoing at the time of writing but should eventually provide important information about how genetic influences on adolescent substance use and substance use disorder overlap with genetic influences on adult substance use disorder. For the time being, what we may anticipate in adolescents is largely guided by information about genetic contributions to risk of adult substance dependence, which derives from multiple sources.

**Family, Including Prospective High-Risk Studies**

From the 1950s onwards, a growing literature acknowledged the strong familiarity of alcoholism, with some families having large numbers of alcohol-dependent cases. In the recent multisite US COGA study, rates of alcohol dependence in the relatives of an index case ascertained through treatment sources were increased three- to eight-fold, varying by gender (Reich, Edenberg, Goate et al., 1998). This work has been extended to examine outcomes associated with index case illicit drug dependence (Merikangas, Stolar, Stevens et al., 1998; Rounsaville, Kosten, Weissman et al., 1991), with research finding support for at least partial drug specificity of familial risks. Intergenerational transmission of smoking has been surprisingly weak in many studies (Avenevoli & Merikangas, 2003), although this may in part reflect generational change in the determinants of smoking associated with pronounced secular changes in rates of smoking and recognition of the health hazards of smoking: sibling and twin correlations typically have been much higher (Avenevoli & Merikangas, 2003; Heath & Madden, 1995).

Increasingly, family studies have been implemented for the purposes of discovering genetic linkage (i.e., co-segregation of a genetic marker and a “trait” locus that influences risk of a disorder) in order to identify individual genes that contribute to risk, with some positive findings reported initially for alcohol dependence (Prescott, Sullivan, Kuo et al., 2006; Reich et al., 1998) and more recently for other substance use disorders including cocaine dependence (Gelernter, Panhuysen, Weiss et al., 2005), opiate dependence (Gelernter, Panhuysen, Wilcox et al., 2006) and tobacco dependence (Li, Payne, Ma et al., 2006). Specific features of the design of a study (e.g., an emphasis on ascertainment of large extended pedigrees; Reich et al., 1998) may also define the types of genes that are more or less likely to be discovered in that study (in this case, making it less likely that genetic risk factors associated with antisocial alcoholism will be discovered, because of the decreased likelihood of large full sibships in the case of an antisocial personality disordered father).

The evidence for significant parent–offspring and sibling correlations from family studies establishes the importance of familial factors, but of course does not exclude non-genetic causes for family resemblance. Family studies also provide evidence for significant spousal concordance for substance use and substance use disorder which, at least some studies suggest (Agrawal, Heath, Grant et al., 2006) may be explained by assortative mating, the tendency for like to marry like, and which may vary over time. Any increased tendency for an alcoholic to marry another alcoholic (or, more broadly, substance abusing) partner will increase genetic risk to the offspring.
CHAPTER 36

generation, compared to random mating. Thus, while the genes that are segregating in a population will not change over time, and thus cannot account for secular changes in rates of disorder, changes in the intensity of assortative mating (e.g., in periods of disruption such as war) do have the potential to impact on the distribution of risk in the next generation.

Recognition of the strong familiality of alcoholism has in turn produced a large literature of high-risk research studies contrasting outcomes in offspring of alcohol-dependent parents (typically fathers) and controls (Sher, Walitzer, Wood et al., 1991), with some important prospective studies beginning either in early childhood (Zucker, Wong, Puntler et al., 2003) or in adolescence (Chassin, Rogosch, & Barrera, 1991). Such studies can provide important information about early precursors of substance use disorders, but at the cost of lengthy delays before early outcomes can be conclusively linked to adolescent or adult substance use. Because of the extensive psychiatric comorbidity of substance use with other psychiatric disorders, and the extensive environmental risk-exposures of offspring of a parent with a substance use disorder history (which typically will be associated with risks that are not specific to offspring substance use disorder), it is only by the time that offspring are mostly through their period of risk for substance use disorder onset that the connection of early behaviors with later substance use disorder can be confirmed. The sampling strategy used to ascertain high-risk families incurs important limitations to the generalizability of findings from a particular study: for example, the work of Chassin (Chassin, Rogosch, & Barrera, 1991) is unusual in requiring that a custodial parent be alcoholic at the time a family was entered into the study but, in the general population, a relatively high proportion of families with parental alcoholism will have experienced parental divorce by the time the offspring reach early adolescence (see p. 575).

Of particular note have been the prospective high-risk studies of Schuckit (e.g., Schuckit, Smith, Pierson et al., 2006), using an alcohol challenge paradigm, with administration of a standardized dose of alcohol under the controlled conditions of the research laboratory, to compare level of response to alcohol in young adult offspring from high-risk with control families. While the precise interpretation of Schuckit’s findings remains controversial, because the adult offspring that he was testing were not alcohol-naïve, it is clear that level of response to alcohol, indexed by such measures as self-reported intoxication, differentiates high-risk from control offspring, and is prospectively predictive of alcohol dependence risk, with low level of response associated with familial alcoholism history and independently predictive of increased risk of dependence, findings that emphasize that individual differences in drug response may themselves be important (and heritable; Heath, Madden, Dinwiddie et al., 1999) determinants of risk. A similar association is also seen in a (non-genetic) prospective study of marijuana reactions and subsequent dependence risk (Fergusson, Horwood, Lynskey et al., 2003).

The high-risk paradigm has been relatively fruitful in alcohol research, but underutilized for illicit drug dependence (but see e.g., Tarter, Kirisci, Mezzich et al., 2003). A new generation of studies is emerging as the children and adolescent offspring of adult linkage samples are followed prospectively, which should allow prospective characterization of the behavioral effects of genes identified as associated with alcohol dependence risk in the parental generation.

Adoption, Twin and Children-of-Twins Studies

Detailed reviews of individual studies are available elsewhere for alcoholism (Heath, Slutske, & Madden, 1997), smoking (Heath & Madden, 1995) and marijuana dependence (Agrawal & Lynskey, 2006). Here we emphasize overall findings and conceptual issues concerning the interpretation of research from these studies, noting that most have been based on adult samples from older twin cohorts (typically born in the 1970s or earlier), but that a new generation of prospective studies including studies of international adoptees (McGue, Sharma, & Benson, 1996) and of open adoptions (where the biological mother remains in contact with the adoptive family), and prospective twin studies (cited earlier), as well as the emerging children-of-twins studies (Jacob, Waterman, Heath et al., 2003) are characterizing adolescent substance use and its adult outcomes.

From the adoption study literature, there is very consistent evidence that alcoholism or more broadly defined substance dependence (which will be chiefly alcohol or marijuana dependence) in adoptees is significantly correlated with alcoholism or antisociality in biological fathers, and uncorrelated, or only weakly correlated, with alcoholism in adoptive parents. A similar pattern is seen for antisocial traits (Langbehn, Cadoret, Yates et al., 1998). This consistency of evidence is seen despite considerable variability in how biological parent alcoholism was assessed: by direct interview in the original Danish adoption study (Goodwin, Schulsinger, Hermansen et al., 1973); by a record review that would have classified positive individuals with a single drunk-driving conviction (i.e., defining a relatively mild, high-prevalence phenotype) in the case of the Scandinavian adoption studies (Cloninger, Bohman, & Sigvardsson, 1981); and by a record review that disproportionately identified alcoholic fathers through the prison and hospital systems, defining a low-prevalence severe antisocial alcoholic/substance abusing paternal phenotype, in the case of the Iowa adoption studies (Cadoret, Troughton, & Woodworth, 1994). However, the adoption study literature is less consistent with the hypothesis that the comorbidity of depression and alcoholism is largely determined by genetic factors (Cadoret, Winokur, Langbehn et al., 1996).

The adoption study literature must be interpreted with recognition of certain important limitations. Because of the much higher prevalence of alcoholism in males than females, particularly for the older birth cohorts from which the older adoption studies were based, the studies have mainly been informative about outcomes associated with paternal alcoholism, although the Swedish studies do provide some data about associations with maternal alcoholism. Selective placement (i.e., the possibility that individuals from high-risk genetic
backgrounds will be more likely to be placed with high-risk adoptive parents) is probably an overstated problem, given the typically quite limited sophistication, from a psychiatric perspective, of the evaluations conducted in the adoption process, and random placement a closer approximation to reality. On the other hand, it is clear that by selecting children given up for adoption, there is overrepresentation of biological parent antisociality, and, conversely, adoptive home environments may not represent the full range of environmental adversity encountered in non-adoptive families (because adoptive parents will include fewer young parents with active substance use disorder at the time of their parenting). (However, rates of prenatal substance exposure may be more elevated in adoptees, given higher rates of maternal antisociality, and mothers who were not planning to keep their offspring: certainly prenatal effects appear more pronounced than would be anticipated for general population samples; Yates, Cadoret, Troughton et al., 1998.) Thus, the early adoption studies are most likely to be informative about genetic influences on alcoholism occurring in the context of a history of antisocial traits, and while the adoption study design may provide useful insights into pertinent environmental risk mechanisms, it is information that cannot easily be generalized, in terms of magnitude of effects or their importance relative to other environmental risk mechanisms, to non-adoptive families. A new generation of studies is emerging that takes advantage of international adoptions (McGue, Sharma, & Benson, 1996) and open adoptions (where adoptive and biological parents remain in contact with one another) in the USA that may overcome some of the limitations of the earlier studies.

**Twin Studies**

A series of diagnostic interview and record-linkage twin studies provide additional support for the importance of genetic factors in the familial transmission of alcohol dependence risk (Heath, Slutske, & Madden, 1997; Knopik, Heath, Madden et al., 2004). A smaller number of diagnostic interview studies have provided evidence for genetic influences on nicotine dependence (Lessov, Martin, Statham et al., 2004) and illicit drug dependence (Agrawal, Lynskey, Bucholz et al., 2007; Kendler, Jacobson, Prescott et al., 2003), although many questionnaire studies have documented genetic effects on various non-diagnostic aspects of smoking behavior including heaviness of smoking and persistence versus successful desistance (Heath & Madden, 1995). As far as concerns alcoholism, studies have ranged from analyses of medical record or hospital discharge data in the Swedish and US World War II twin panels – which will have defined a relatively severe alcoholism phenotype – to diagnostic interview surveys which typically will have defined a much broader phenotype.

In general, these studies have confirmed the inference of important genetic effects on substance use disorder inferred from adoption studies, and provided evidence for important genetic influences in women (where assessed) as well as men, and for severe phenotypes as well as milder phenotypes. If one twin has a history of substance use disorder, it is much more likely that the cotwin will also have a history if the cotwin is monozygotic (genetically identical) than if the cotwin is dizygotic (an ordinary full sibling). Quantity of alcohol consumed also appears to be influenced by genetic factors (Heath & Martin, 1994), emphasizing that genetic effects on dependence risk may be at least partially, or substantially, mediated through effects on consumption patterns (Whitfield, Zhu, Madden et al., 2004). Multivariate genetic analyses have also documented high genetic correlation between substance use disorder (principally alcohol dependence) and traits that might be broadly characterized as indicators of behavioral disinhibition (Iacono, Malone, & McGue, 2003; Slutske, Heath, Madden et al., 2002b), but also moderately strong genetic correlation between history of major depression and alcohol dependence risk (Kendler, Heath, Neale et al., 1993).

As with adoption studies, limitations of the traditional twin study design must be considered carefully. Foremost is the question of whether the assumption of equally correlated environmental exposures in monozygotic compared to dizygotic pairs is justified for drug use. While investigations of this question for a broad range of behavioral and psychiatric phenotypes have generally found support for this assumption (Hettema, Neale, & Kendler, 1995; Kendler, Neale, Kessler et al., 1994), the very low proportion of monozygotic pairs who are discordant for use of some drug classes (e.g., tobacco) must make us suspect that frequently once one twin uses, he or she initiates his or her cotwin. Where investigated, it has not been found that this biases inferences about the later outcomes of substance use: for example, conditioning upon whether or not a twin pair start smoking at the same time still leads to consistent estimates for the importance of genetic effects on later smoking outcomes (Pergadia, Heath, Agrawal et al., 2006).

Additional limitations to consider in the interpretation of twin data are: (i) the confounding of shared environmental and non-additive genetic effects, which can lead to the underestimation of the importance of shared environmental influences on risk; and (ii) the confounding of genetic and genotype × shared environment interaction effects, which leads to reported genetic variances or heritabilities (or, in the multivariate case, genetic correlations) combining both the main effects of genes on risk, and the effects of genotype × shared environment interaction (Heath, Todorov, Nelson et al., 2002). It is possible to model explicitly the interaction of latent genotype with a measured environmental modifier, however, power to detect such interaction effects will be low, particularly if a low-prevalence binary environmental modifier is used for analysis, and published reports have not always excluded the full range of alternative explanations before claiming such interaction effects (e.g., variance differences between exposure conditions can lead to erroneous inference of G × E effects, unless appropriately modeled). Thus, while convincing demonstration of the importance of G × E interaction effects in the substance use disorder literature have been relatively few, we shall see in our review of environmental risks (see p. 574) that it is probably quite unsafe to assume the absence of such effects.
CHAPTER 36

An informative extension of the classic twin design examines outcomes of children of twins who are concordant or discordant for history of substance use disorder (Jacob et al., 2003). Assuming adequate statistical control for psychopathology in the coparent (Jacob et al., 2003), the children-of-twins design allows contrasts of outcomes in children at high genetic and high environmental risk (twin parent has a history of substance use disorder); high genetic but reduced environmental risk (twin parent is unaffected but parent’s monzygotic [MZ] cotwin has a history of substance use disorder); intermediate genetic but reduced environmental risk (twin parent is unaffected but parent’s dizygotic [DZ] cotwin has a history of substance use disorder); and low genetic and low environmental risk (twin parent, and parent’s cotwin, both have no history of substance use disorder).

Unexpectedly, the one study for which results have been published to date found increased offspring risk of alcohol use disorder only in the presence of both genetic risk (parent or MZ cotwin alcohol dependent) and environmental exposure (the parent, if not alcohol dependent, had a history of alcohol abuse; Jacob et al., 2003). However, these are results for a single study, whose offspring were relatively early in their period of risk for the onset of alcohol use disorder, so it remains to be determined whether this pattern (for which one interpretation is important genotype × shared environment interaction effects) is confirmed.

Genetic Association Studies: Effects of Metabolism

Genes

We shall not attempt to review the early case–control literature on genetic association studies of substance use disorders: by contemporary standards, most early research was severely underpowered, lacked correction for multiple testing of the very many plausible candidate genes that can be identified for substance use disorders, and thus had high probability of generating false positive findings. More systematic approaches guided by linkage findings are now beginning to identify and replicate genetic associations (Edenberg & Faroud, 2006), and the new era of Genome-Wide Association Studies and high-throughput candidate gene studies (Bierut, Madden, Breslau et al., 2007; Saccone, Hinrichs, Saccone et al., 2007), provided studies are adequately powered, is likely to lead to rapid advances in this literature. Some of the same studies that have been used to identify genetic linkage have also been obtaining prospective data from the pre-adolescent and adolescent offspring in their families, so findings of more direct relevance to adolescent substance use disorder are to be anticipated.

We use a concrete example to illustrate some of the issues raised, for clinical practice as well as research, by the identification of a gene with (in this example) important effects on risk. Arguably the best example of how a polymorphism at a single genetic locus may affect a major psychiatric phenotype is provided by the example of alcoholism, and its associations with ALDH2 (aldehyde dehydrogenase) genotype in individuals of Asian ancestry. Ethanol is converted by the enzyme alcohol dehydrogenase to the toxic metabolite acetaldehyde, which in turn is converted by the enzyme acetaldehyde dehydrogenase to acetic acid. A single point mutation in the gene for ALDH2 leads to an inactive enzyme, so that those who are heterozygotes (ALDH2*1/*2) have substantially elevated blood acetaldehyde concentrations after ingestion of alcohol and experience a characteristic flushing response (Wall, Peterson, Peterson et al., 1997). Individuals who are homozygous for the null allele but develop alcohol problems are extraordinarily rare, reflecting their typically very low consumption of alcohol (a 10-fold difference in average consumption in males between the normal and null homozygotes in one community sample; Higuchi, Matsushita, Muramatsu et al., 1996).

In the Japanese context where much of this research was conducted, pronounced genotype × gender effects are also seen, with women with the high-risk genotype drinking at the same level as men with the lowest risk genotype (Higuchi et al., 1996). Heterozygotes are also rarer in alcoholic patient series than in control series, although at least among Japanese this difference appears to be declining over time (Higuchi, Matsushita, Imazeki et al., 1994), a trend that the authors attributed to increased social pressures on Japanese males to drink after work. At the same time, those heterozygotes who progress to heavier drinking appear to be at increased risk of adverse medical consequences, including increased frequency of alcohol-related cancers (e.g., Hori, Kawano, Endo et al., 1997), presumably because of impaired metabolism of alcohol. Among Asian American youth, however, genotype effects on consumption levels have not been found (Hendershot, MacPherson, Myers et al., 2005). Thus, in considering this single example we find evidence for: (i) an important single gene effect on alcohol dependence risk, which may at least in part be mediated through heaviness of consumption; (ii) important modifiers of this effect, including gender, age-cohort and/or society, and secular change in drinking practices; and (iii) evidence for increased vulnerability (to adverse medical outcomes) in the heterozygote group that were at low risk of becoming heavy drinkers. This example also raises the interesting issue of whether genetic information should be used in counseling adolescents (or adults) about their substance use. In this case, a subset of youth, of Asian ancestry, are at substantially increased risk of adverse medical consequences from alcohol misuse, but they and their families may be unaware of this (particularly in the case of international adoptions by European ancestry parents).

Environmental Risks

The existing research literature has identified a range of environmental risk factors that are associated with increased rates of adolescent substance use and substance use problems. These risk factors are not specific to substance use problems, being also associated with increased risk of conduct disorder (see chapter 35) and in many cases other disorders (e.g., major depression and attention deficit/hyperactivity disorder [ADHD]; see chapters 37 and 34), but their associations with substance use are not, in general, limited to those with co-
occurrence of these other disorders. A brief summary of key domains of putative risk is provided below, with comment on methodological considerations pertinent to each domain. We conclude with a discussion of significant clustering observed among environmental risks and between environmental risks and parental substance use disorder history.

Prenatal Alcohol and Other Drug Exposure
Maternal heavy alcohol use during pregnancy is now rare in most contemporary western cultures. Its association with fetal alcohol syndrome is well documented and characterized in clinical follow-up studies, with an extensive supporting basic science literature (see chapter 30). Broader literatures have also developed examining possible consequences of milder levels of prenatal alcohol exposure (fetal alcohol effects) as well as effects of other prenatal drug exposures, and in particular tobacco and cocaine.

Parental history of substance use disorder is associated with increased risk of offspring prenatal alcohol and other substance exposure (Yates et al., 1998), which in turn predicts cognitive and behavioral self-regulation difficulties (Knopik, Sparrow, Madden et al., 2005; Weissman, Warner, Wickramaratne et al., 1999), which also increase risk of adolescent substance abuse and abuse (Biederman, Monuteaux, Mick et al., 2006). However, it is by no means clear that these associations are causal. Higher rates of substance use disorders and antisocial traits in both the pregnant woman who smokes or uses other drugs during pregnancy, and her partner (Knopik et al., 2005), will predict increased risk of externalizing problems for her offspring, quite apart from any prenatal exposure effect. In the Iowa adoption study (Yates et al., 1998), maternal alcohol use during pregnancy, as abstracted from adoption records (and therefore most probably limited to cases of heavy alcohol use) was predictive of increased risk of offspring drug involvement. However, because biological mothers’ psychopathology could be inferred only indirectly from records, it is quite possible that reported maternal alcohol use during pregnancy is functioning merely as an index of greater maternal antisociality, so the possibility of genetic confounding cannot be excluded. This possibility will become clearer with a new generation of studies taking advantage of open adoptions, where the biological mothers can be directly evaluated.

While basic science literatures have developed that indicate that deficits associated with prenatal exposure might be anticipated (for reviews see Ernst, Moolchan, & Robinson, 2001; Slawecki, Thomas, Riley et al., 2004), imperfect control for parental and situational risk factors is likely to make identification of such effects in clinical research challenging. More convincing characterization of such prenatal exposure effects will arise only when systematic within-mother between-pregnancy comparisons are made of full sibling offspring born to mothers who used during one pregnancy but not during a second pregnancy, so that heritable traits in the biological parents can be controlled for. Even these comparisons will have important limitations, because the most severely dependent mothers are the least likely to have refrained from substance use during at least one pregnancy.

Child Maltreatment and Abuse
Childhood neglect, physical abuse (PA), sexual abuse (CSA) and other forms of childhood maltreatment are predictive of early onset tobacco, alcohol, marijuana and other illicit drug use (Anda, Croft, Felitti et al., 1999; Dube, Felitti, Dong et al., 2003; Dube, Miller, Brown et al., 2006), and alcohol or other drug problems during adolescence (Fergusson, Horwood, & Lynskey, 1996) and into adulthood (Molnar, Buka, & Kessler, 2001; Nelson, Heath, Lynskey et al., 2006), especially among women (Widom, Ireland, & Glynn, 1995). Whereas the association between childhood trauma (CSA, in particular) and early and escalating substance involvement observed during adolescence is well documented, debate continues regarding the magnitude of reported effects, and importantly, the causal role of maltreatment in the development of problem substance use. Methodological differences, such as use of retrospective versus prospective assessments and recruitment of study participants from individuals in treatment for substance use disorder or other psychiatric disorders versus large-scale community or population-based sampling, contribute to continued debate. In addition, abuse during childhood is variously defined in terms of age of onset and severity, with some researchers limiting analysis to abuse occurring during younger childhood years (e.g., before age 12 or 16) or to more severe forms of abuse, such as CSA involving penetration or intercourse, or court documented cases of abuse.

Researchers also differ in whether or not, and to what extent, potential third variable confounds are controlled. Rates of maltreatment are higher for children raised in families characterized by a host of other risks, including parental substance use disorder, which might directly impact on vulnerability to early and problem substance use during adolescence. Thus, parental substance use disorder and correlating risks that pre-date both maltreatment and substance initiation may account for at least some of the reported effects. Many recent studies of childhood maltreatment and later outcome include statistical controls for a variety of potentially confounding risk factors; however, few include prospective assessment of offspring outcomes and/or confounded risks. Work by Fergusson, Horwood, and Lynskey (1996) on CSA is an exception, and one of few population-based longitudinal studies in which adolescent substance use disorder is examined.

With growing interest in identifying causal mechanisms underlying the association between childhood maltreatment and early and problem substance involvement, genetically informed methodologies have been increasingly employed to rule out heritable third variables that might independently contribute to substance use disorder risk in adolescence and adulthood. To date, genetically informed research is limited to the examination of substance use disorder in adults. In several studies employing a discordant twin design, higher rates of substance use and substance use disorder among individuals reporting CSA have been observed (Kendler, Bulik, Silberg et al., 2000;
CHAPTER 36

Nelson et al., 2006). However, even in discordant twin comparisons it is not clear to what extent substance use outcomes are secondary to other deficits and early disadvantages that are not shared by members of the twin pair.

Marital Conflict, Parental Divorce and Repartnering

Parental divorce, subsequent repartnering and marital conflict often preceding separation, are associated with increased rates of offspring alcohol, tobacco, marijuana and other illicit drug use initiation (Hoffman & Johnson, 1998), heavier use of these substances (Doherty & Needle, 1991; Hoffman, 1995; Needle, Su, & Doherty, 1990) and greater risk of problem use (Fergusson, Horwood, & Lynskey, 1994; Hoffman & Johnson, 1998; Needle, Su, & Doherty, 1990). However, interpretation of these associations is complicated by confounded risks associated with family disruption that might independently contribute to offspring substance involvement, including parental substance use disorder. Results from a handful of studies that assess prospectively offspring outcomes and/or confounded risks that pre-date family disruption suggest small but significant effects of family disruption on adolescent substance use and substance use problems (Fergusson, Horwood, & Lynskey, 1994; Doherty & Needle, 1991).

In addition, behavioral genetic studies have noted genetic effects on the risk of divorce (McGue & Lykken, 1992), a not unexpected finding given the importance of genetic effects on parental characteristics such as substance use disorder history that are associated with increased divorce risk. Thus, it may be questioned to what extent risks associated with parental divorce are mediated environmentally, rather than by genetic transmission.

This issue has been the focus of a number of recent genetically informed studies of substance use disorder in adults. For example, Kendler, Neale, Prescott et al. (1996) examined environmental mediation of parental loss effects on risk for alcoholism in a large sample of adult female twins. Kendler reported parental loss through separation (but not death) had both causal and non-causal effects. Specifically, associations between alcoholism risk and parental separation were mediated by environmental factors specific to parental separation as well as genetic factors associated with susceptibility to alcoholism. In a recent study of adolescent and young adult offspring of Australian twins discordant for divorce, D’Onofrio, Turkheimer, Emery et al. (2005) report divorce-specific environmental mediation of associations between parental divorce prior to age 16 and marijuana use. However, mediation by environmental factors specific to divorce either before or after age 16 was not observed for ever use of alcohol or cigarettes, age at first use of alcohol, cigarettes or marijuana, having experienced alcohol intoxication, or age at first alcohol intoxication. In both studies, inferences about environmental mediation are model-dependent, so that unmeasured genetic confounders in the parental generation would potentially lead to false positive (or false negative) inference. Additional, more robust support for environmental mediation of divorce effects (and parental psychopathology) on offspring substance involvement is provided by Cadoret, Troughton, O’Gorman et al. (1986), who in an early report on a cohort of Iowa adoptees found an increased risk for drug abuse among adoptees whose adoptive parents divorced or had a history of psychiatric difficulties compared to adoptees whose adoptive parents remained together and had no history of psychiatric difficulties. Similar results were reported in a separate study of male adoptees (Cadoret, Yates, Troughton et al., 1995), with marital and psychiatric problems in adoptive parents contributing to adoptee risk of drug abuse independently of genetic influences.

Overall, it is clear that children in disrupted families show increased risk of early substance involvement and abuse and/or dependence, but the underlying mechanisms remain uncertain. It remains unclear whether, and certainly cannot be assumed that, removal of a parent with a history of substance use disorder from the home produces better outcomes for offspring: indeed, one study using a children-of-twins design failed to find any significant effect of duration of paternal presence in the home as a moderator of paternal alcoholism effects (Duncan, Scherrer, Fu et al., 2006).

Parenting Influences

Results from cross-sectional and an increasing number of prospective longitudinal studies of adolescent substance involvement support the importance of a range of parenting influences. Inconsistent, ineffective discipline and poor supervision and monitoring (Chilcoat & Anthony, 1996), parent–child conflict (Brook, Brook, Gordon et al., 1990; Sokol-Katz, Dunham, & Zimmerman, 1997), low levels of parent support and parent–child attachment (Allen, Hauser, & Borman-Spurrell, 1996) and permissive or tolerant attitudes about substance use (Ary, Tildesley, Hops et al., 1993; Brook, Whiteman, Gordon et al., 1986) are among parenting behaviors predictive of both early and problem alcohol, tobacco, marijuana and other illicit drug use during adolescence.

Identification of mediating and moderating effects of parenting on adolescent substance involvement is the focus of much recent research on parenting influences. In addition to parsing direct from indirect effects of parental substance use disorder (Urberg, Goldstein, & Toro, 2005), this work has documented significant moderation by parenting of associations between parental substance use disorder and adolescent substance use and misuse (Doherty & Allen, 1994). Consistent with results from cross-sectional studies (Brook et al., 1990; Kung & Farrell, 2000), there is now longitudinal evidence that some parenting behaviors, particularly monitoring, work to moderate peer influences on adolescent substance use and substance use problems (Ary, Duncan, Duncan et al., 1999; Barnes, Hoffman, Welte et al., 2006; Marshal & Chassin, 2000).

Peer Influences

Whereas deviant peer affiliation continues to be one of the best predictors of early and problem substance use during the
adolescent years (Fergusson, Swain-Campbell, & Horwood, 2002), mechanisms underlying this association remain largely unknown. Among competing explanations is the possibility that deviant peers have a direct influence through peer pressure and socialization, both modeling and providing reinforcement of alcohol and other drug use. However, selective processes are also likely; for example, parental substance use disorder increases risk for both substance involvement and affiliation with deviant peers, and might thereby account for their association. In addition, substance-using adolescents may seek out peers who also use substances, a form of social homophily (Bauman & Ennett, 1994).

To disentangle direct and indirect effects of deviant peer affiliation on early and problem use of alcohol and other substances, an increasing number of researchers are capitalizing on the strengths of prospective longitudinal designs in attempts to rule out third variable confounds. Results from this work largely support both socialization and selection explanations, together suggesting parental substance use disorder, along with impairments in parenting, increase the likelihood of affiliating with substance-using peers (Fergusson & Horwood, 1999; Larzelere & Patterson, 1990) which, in turn, has direct effects on adolescent substance involvement.

**Conclusions: Clustering of Risks**

In interpreting the literature on putative risk factors, it is important to note the high degree of overlap or clustering of these risk factors, and their associations with conduct disorder and other disorders. For example, prenatal drug exposure is more common among children of parents with substance use disorder. These offspring are also at heightened risks for experiencing family disruption, childhood abuse, neglect and otherwise compromised parenting that together increase the likelihood of affiliations with delinquent or substance-using peers. Despite the high degree of overlap and clustering of risk factors, most of the accumulated literature on potential risk factors in fact derives from research that has considered relatively few risk factors, ignoring others, and that may have imperfect or no characterization of parental psychopathology. However, these challenges do not reduce the importance of considering the total effects, both direct and through correlated environmental risks, in so far as they help identify particular groups of individuals (e.g., children of divorced parents; children with a history of abuse) at increased risk of early substance involvement and problems.

A further issue concerns the interplay between genetic and environmental risks. Despite the extensive evidence for genetic effects on risks of substance use disorders, it must be remembered that most of this evidence derives from non-adopted families, so that genetic effects are occurring in these same contexts of environmental risks such as prenatal substance exposures, early trauma and parental conflict and separation/divorce. While there has been only limited characterization of gene-environment interaction effects at the time of writing, the likely importance of such effects should not be ignored.

**Behavioral and Pharmacotherapies**

The efficacy of pharmacotherapies for adolescent drug use disorders has not been established, although some promising pharmacotherapies are emerging for use with adults. Clinical trials with adolescents have been few in number and underpowered. Whereas some studies using complex combination cognitive-behavioral interventions have been able to demonstrate improved adolescent desistance rates, there is at this time limited understanding of the mechanisms by which adolescent desistance or reduction in use is achieved, and of the risk or protective factors that influence these outcomes, whether in or out of the context of treatment. Thus, while appealing treatment programs have been developed for therapy with adolescent substance abusers (MacPherson, Frissell, Brown et al., 2006), the evidentiary base for identifying particular components of therapy as critical for successful outcome, or particularly efficacious with particular adolescents, does not yet exist. This is further complicated by substantial comorbidity between substance use disorders and the range of psychiatric disorders, particularly disruptive behavior disorders, and mood disorders. Despite high rates of comorbidity, there is relatively little research evidence addressing the extent to which specific treatment approaches may be best suited for specific patterns of co-occurring substance use and psychiatric disorders.

In summary, randomized clinical trials focused on adolescent substance abusers have been rare and typically single-site (therefore of uncertain generalizability to patient populations across diverse clinical settings), underpowered and with little attention to the potential influence of comorbid conditions on clinical outcomes.

Some insights can be obtained from randomized clinical trials with adult patient populations; however, such trials have the advantage of adult participants who have usually volunteered to participate precisely because they are at a point in their life where they are motivated to change their pattern of drug use; the challenge with adolescents, who commonly are referred to treatment through parental, school or legal influences, is much greater. Furthermore, the specific ethical challenges of clinical research with minors (requirement to obtain parental consent for participation; potential for confidentiality breach in obtaining parental consent) raise additional (but not insurmountable) difficulties.

**Tobacco**

It is common in psychiatric practice for smoking and tobacco dependence to be ignored, a peculiar oversight given that smoking accounts for a substantial proportion of early deaths in most western societies. This relative neglect of tobacco use has been no less the case for children and adolescents. While nicotine replacement therapy (NRT) has been used successfully for adult smoking cessation, an early open-label trial using nicotine patch with adolescent smokers desiring to quit reported no benefit (5% abstinence rate at 6 months; Hurt, Croghan, Beede et al., 2000), and a single underpowered clinical trial
failed to find a significant improvement in abstinence rates at 6 months using the nicotine patch (Grimshaw & Stanton, 2006; Moolchan, Robinson, Ernst et al., 2005). Use of amfetabutone, in combination with NRT patch, for adolescent smoking cessation has also not been found to be useful (Grimshaw & Stanton, 2006).

In adults, there is a substantial clinical trial literature documenting improved smoking cessation rates with NRT (1.5- to two-fold, across a range of different modalities for nicotine administration, compared with placebo or other control group; Silagy, Lancaster, Stead et al., 2006), and some antidepressants (amfetabutone, nortriptyline; a doubling of the odds of cessation) but not selective serotonin reuptake inhibitors (Hughes, Stead, & Lancaster, 2004). There have also been promising developments using a selective α4β2-nicotinic receptor partial agonist, with a phase II trial reporting, at the 1 mg twice daily dose, increased long-term success rates compared to sustained-release amfetabutone and to placebo, with 48% reporting 4 or more weeks without smoking during the 6-week treatment phase (versus 33%, 17%) and continuous quit rates at 12-month follow-up also higher (approximately a three-fold increase: 14.4% versus 6.3%, 4.9%); Nides, Oncken, Gonzales et al., 2006). A phase III trial with a 12-week treatment phase has confirmed increased rates of continuous abstinence, compared with both placebo and amfetabutone, during the final month of treatment, and at follow-up at up to 52 weeks (Jorenby, Hays, Rigotti et al., 2006).

Given the weak evidentiary basis for assessing pharmacotherapy effects for adolescent smokers, and the fact that NRT products in many countries are available over-the-counter, it seems premature to conclude that pharmacotherapies for smoking cessation by adolescents will not be successful. Despite shorter smoking histories, a significant number of adolescents are smoking at levels similar to those of adults being entered into clinical trials (e.g., 20 cigarettes per day, scores on the Fagerstrom Test of Nicotine Dependence of 5 or more; Hurt, Croghan, Beede et al., 2000). However, the case for efficacy for pharmacological treatment of adolescent smokers remains to be established.

Some evidence from controlled trials for efficacy of behavioral interventions for smoking cessation in adolescents has been obtained (Grimshaw & Stanton, 2006). Some of this has been generated within the theoretical framework of the Transtheoretical Model (TTM; DiClemente, Prochaska, Fairhurst et al., 1991) and, despite the considerable limitations of the TTM framework (Sutton, 2001), these studies have achieved reasonable increases in rates of adolescent smoking cessation (pooled odds ratio of 1.70 at 12 months), a testament to the loose coupling between theoretical perspective and behavioral intervention results. Cognitive–behavioral therapy (CBT) interventions (pooled odds ratio 1.87) and interventions including a motivational interviewing component (pooled odds ratio 2.05) have also shown some success. These effect sizes are generally consistent with those obtained using non-pharmacological individual or group-based treatments in adult smoking cessation (Lancaster & Stead, 2005; Stead & Lancaster, 2005).

### Alcoholism and Illicit Drug Use Disorders

The treatment of adult alcoholism has shifted from in-patient to out-patient-based treatments. While this change occurred largely because of economic factors, it appears that the effectiveness of out-patient-based treatment is comparable to in-patient treatment, except in cases of serious comorbid medical or psychiatric conditions (Finney, Hahn, & Moos, 1996). Large-scale multisite randomized clinical trials of alcoholism have been limited to samples of adults. In the 1990s, the US Project MATCH (Project MATCH Research Group, 1997a,b) investigated matching client characteristics to treatments, but found approximate comparability of outcomes with the three contrasted approaches: motivational enhancement therapy (MET), which uses structured feedback to motivate the client to utilize his or her resources to change behavior; 12-step facilitation, an approach popular in the USA which makes use of the 12-step framework developed by Alcoholics Anonymous (AA) and makes attendance at and participation in AA meetings an important component of recovery; and a CBT-based approach. There is only limited evidence for the value of patient–treatment matching.

There have been no multisite randomized clinical trials of pharmacotherapies for alcoholism in adolescents, and in the absence of such data, the most recent findings from large US multisite trials with adults suggest that behavioral interventions should remain the treatment of choice for adolescents with alcohol problems. In a multisite trial involving almost exclusively males, with chronic severe alcohol dependence (n = 627, median age approximately 50), supplementation of 12-step facilitation counseling with short-term (3 month) or long-term (12 month) administration of naltrexone (50 mg/day), an opioid receptor antagonist, compared with placebo, produced no differences in time to relapse at 13 weeks, nor in percentage drinking days or drinks per drinking day, at 12-month follow-up. Substantial decreases in percent days abstinent were achieved across all conditions (from approximately 35% at baseline to 82% at 12-month follow-up), with more modest reductions in number of drinks per drinking day (from 13–14 at baseline to 9–10 at 12-month follow-up; Krystal, Cramer, Krol et al., 2001). Other studies using naltrexone have reported modest short-term and medium-term improvements in time to first drink and diminished craving, compared with placebo, with some evidence for improved outcome when combined with an intensive psychosocial treatment (Srisurapanont & Jarusuraisin, 2005).

More recently, Project COMBINE (Anton, O’Malley, Ciraulo et al., 2006), using a 16-week treatment period (n = 1383, two-thirds male, median age 44), found no improvements in outcome associated with use of acamprosate (a medication that had been reported to be efficacious in some European trials; 3 g/day), either alone or in combination with naltrexone or a combined behavioral intervention (CBI); a modest increase in abstinence days (versus 25% at baseline) compared with placebo plus medical monitoring (75%) under conditions of naltrexone administration (100 mg/day) plus medical monitoring (81%), or the combined behavioral intervention plus
medical monitoring (79%), but not both (77%), these differences being rather modest and no longer significant (but with trends in the same direction) at 12 months. While Project COMBINE was in very many respects a model for its quality control procedures, one unfortunate aspect of its design complicates interpretation of findings: a CBI-only group was included that showed worse outcomes (67% days abstinent) compared to the CBI plus placebo plus medical monitoring group. However, medical management involved an initial baseline 45-minute session with 20-minute follow-ups at 1, 2, 4, 6, 8, 10, 12 and 16 weeks, conducted by a nurse, physician, pharmacist or physician assistant, and included a focus on the alcohol dependence diagnosis and negative consequences of drinking, and the importance of medications compliance, at baseline, with review of medication compliance, adverse effects, and drinking and overall functioning, at subsequent follow-ups. The medical practitioner contact under the CBI-only condition was more limited, leaving open the possibility that it was the intermittent nurse/physician contact, combined with CBI, rather than taking of pills, that explained the improved success under the CBI plus placebo condition.

From these studies of older adults one may conclude that in adults wishing to overcome problems with alcohol, substantial harm reduction may be achieved through behavioral interventions in terms of reduction in drinking days, even without the use of pharmacotherapy, as other have noted (Miller, Walters, & Bennett, 2001). Given the absence of adolescent pharmacotherapy trial data, reliance on behavioral interventions seems the preferred strategy at this time. Unfortunately, rigorous clinical trial data on the components of behavioral interventions that are effective with adolescents, and the mechanisms by which changes in drinking are achieved, are lacking: thus, the clinician is left to select from a menu of strategies that have been found to give improved outcome (e.g., motivational enhancement; cognitive–behavioral skills training), sometimes packaged as an esthetically pleasing package (MacPherson et al., 2006) but nonetheless having relatively weak empirical support to justify the necessity of individual components of the package.

Although there is now considerable evidence that methadone maintenance – and other opioid agonist maintenance agents such as buprenorphine – are effective at reducing illicit opioid use (Ward, Hall, & Mattick, 1999), relatively little research has been conducted on the effectiveness of these treatments in children and adolescents. This may be a reflection of a number of factors including the lower rate of heroin dependence (relative to tobacco or alcohol) in the general population, the later mean age of onset of this disorder and a widespread belief among clinicians that maintenance therapies are better suited to older individuals with a long-term history of chronic heavy opioid use. Nonetheless, findings from the limited adolescent-focused research converge on those from larger, more carefully controlled studies with adult samples to suggest that methadone (and, by extension, other maintenance therapies) is likely to be effective in reducing long-term use of heroin and other illicit opioids in those adolescents who have developed severe dependence (Kellogg, Melia, Khuri et al., 2006).

There is considerably less research on pharmacotherapies for cannabis or other illicit drugs, although there are a number of possible therapies being considered for use. These include the use of antidepressant medication, particularly among those with comorbid substance use disorders and major depressive disorder (Cornelius, Clark, Bukstein et al., 2005), the use of CBI agonists specifically for tobacco dependence (Cohen, Kodas, & Griebel, 2005), and maintenance stimulant prescription for treatment of cocaine and other illicit stimulant dependence (Grabowski, Shearer, Merrill et al., 2004). There is little research evaluating these treatments empirically, what literature is available is based almost entirely on adult, rather than adolescent samples and evaluations of the efficacy of these alternative pharmacotherapies have produced, at best, equivocal results regarding their efficacy (DeLima, Soares, Reisser et al., 2002).

Coerced Treatment

Largely in the area of illicit drug use and related problems, there has been ongoing interest in the extent to which mandated or coerced treatment, either as an adjunct to, or in replacement of, criminal justice interventions (e.g., imprisonment), may be efficacious in reducing the use of illicit drugs and related problems (Harrison & Scarpitti, 2002). While such interventions, including so-called drug courts, have been most popular in the USA (Turner, Longshore, Wenzel et al., 2002), there is increasing interest in implementing them in other countries (Bean, 2002). Evaluations of such programs have generally shown them to be both effective and cost effective (relative to alternatives), suggesting that, provided the myriad ethical issues involved in such mandated treatment (Caplan, 2006) can be addressed, they may have a role in the treatment of drug use problems, particularly among those more severely afflicted.

Similarly, diversion from the criminal justice system for more minor drug offences (principally possession of small amounts of cannabis) may be an effective strategy to continue discouraging illicit drugs while avoiding imposing the potentially heavy individual consequences of a drug conviction for what may be relatively minor drug use (Barratt, Chanteloup, Lenton et al., 2005). As with many issues surrounding the legal status of illicit drugs and legal approaches to limiting the use of licit drugs (e.g., taxation, licensing hours), consideration of such interventions raises a number of social, political and ethical issues, the resolution of which may be only slightly influenced by empirical evidence of effectiveness.

Brief Interventions

Spanning the intersection of treatment and public health interventions, there has also been considerable interest in the extent to which brief interventions, targeted at individuals who may be using substances heavily but who are not seeking treatment
 CHAPTER 36

nor necessarily meet criteria for a substance use disorder, may reduce substance use and/or prevent escalation to heavier, problematic or dependent use. Evaluations of such interventions have been conducted in a number of settings including general medical practices, hospital emergency departments and other health care providers and have generally been positive. For example, in a sample of 152 13- to 17-years-olds presenting at an emergency department after an alcohol-related event, Spirito, Monti, Barnett et al. (2004) reported that a brief intervention involving motivational interviewing reduced the average number of drinking days per month and frequency of heavy drinking at 12-month follow-up, relative to those receiving standard care. Similarly, Colby, Monti, O’Leary Teyyaw et al. (2005) reported 6-month follow-up in a group of 85 14- to 19-year-olds randomized to receive a brief intervention or no intervention for tobacco use, delivered in medical settings (hospital outpatient or emergency departments). Results indicated some reductions in smoking among those treated, but overall reductions were small. Whereas the bulk of brief interventions with adolescents have been targeted at either tobacco or alcohol use, there is emerging evidence of their feasibility for use with cannabis use (Martin, Copeland, & Swift, 2005) and across multiple substances, including illicit drugs (McCambridge & Strang, 2004).

Prevention

Legislative Approaches Aimed at Limiting Availability of and Access to Substances Among Youth

These include policies regulating the sale and availability of alcohol (Chikritzhs & Stockwell, 2006; Stockwell & Grunewald, 2004), restrictions on the sale of alcohol and tobacco to youth (Ahmad & Billimek, 2007; Wagenaar & Toomey, 2002), as well as legal prohibitions against the supply and possession of cannabis and other illicit drugs (MacCoun & Reuter, 2001). In terms of the licit drugs – tobacco and alcohol – there seems to be considerable evidence supporting the efficacy of legal and policy approaches limiting access to these substances among youth.

Research indicates that raising the minimum legal age for purchasing alcohol results not only in a reduction in use, but also a reduction in alcohol-related harm among youth (Wagenaar & Toomey, 2002), while demonstrated price elasticity of cigarettes indicates that raising prices through the imposition of taxation is likely to decrease both the prevalence of cigarettes and the frequency of smoking among youthful smokers (Hopkins, Briss, Ricard et al., 2001; Zhang, Cohen, Ferrence et al., 2006). Evidence in favor of legal sanctions for reducing illicit drug – and especially cannabis – use appears more mixed (MacCoun & Reuter, 2001) with cross-national comparisons indicating that lifetime prevalence of cannabis use is lower in some countries that have relatively liberal legal approaches (e.g., the Netherlands) compared to countries with more restrictive legal approaches (e.g., the USA; Vega, Aguilar-Gaxiola, Andrade et al., 2002) highlighting that differences in legal approach alone cannot explain the often quite large differences between countries in rates of substance use and substance use disorders.

Community and Mass Media Campaigns

There have also been a variety of media campaigns or interventions including both laws to limit or eliminate tobacco or alcohol advertising and mass media campaigns designed to limit or reduce licit and illicit drug use. Within the tobacco field there is evidence that such campaigns can be successful (Farrelly, Niederdeppe, & Yarzebski, 2003), although it is uncertain what specific components of these campaigns are likely to be most effective. Similarly, some alcohol-related campaigns, focused primarily on reducing alcohol-related harm rather than alcohol use per se, have been shown to be effective in reducing such behaviors (Elder, Shults, Sleet et al., 2004), although, to the extent that these have often been implemented in the context of a comprehensive array of interventions, it is often difficult to isolate the impact of a specific intervention. Within the illicit drug field, it has also been recently suggested that there may be a synergistic effect between media and school-based interventions aimed at reducing the uptake of illicit drugs. Thus, the greatest benefit of these programs may be in helping to provide a milieu that is supportive of and conducive to other more intensive interventions by helping to create a social milieu that is generally supportive of drug abstinence.

School and Educational Interventions

A variety of school-based interventions – including both knowledge-based educational programs and others focused more broadly on social skills, assertiveness and related training – have been widely adopted. Nonetheless, the enthusiasm with which such programs are adopted appears to be unmatched by empirical evidence of efficacy or effectiveness. Indeed, there is controversy surrounding the extent to which some such interventions – and particularly those focused on imparting knowledge about drugs – may actually increase experimentation and use of these substances. Nonetheless, there is some evidence that well-conducted interventions not focusing on drug knowledge but instead focusing on social skills training may lead to consistent, yet modest, reductions in drug use uptake (Faggiano, Vigna-Taglianti, Versino et al., 2005). Increasingly in the USA there has been interest in implementing drug-testing procedures whereby students are tested on a regular basis. Comprehensive assessments of the efficacy of such programs appear lacking and, whereas a study indicated that rates of self-reported drug use did not differ between schools with drug testing programs and those without (Yamaguchi, Johnston, & O’Malley, 2003), problems with the interpretation of such findings (in particular, the fact that there are likely to be pre-existing differences in rates of drug use between schools that adopt such measures and those that do not), mean that it is difficult to draw any firm conclusions regarding the utility of such programs.
Parenting Programs
Interventions aimed at parents include broad community-based interventions, such as media campaigns discussed above, more family focused interventions aimed at delaying or preventing substance use in adolescents (Gerrard, Gibbons, Brody et al., 2006; Komro, Perry, Veblen-Mortenson et al., 2006) and highly intensive interventions, typically targeted at families identified as “high risk” (Fergusson, Grant, Horwood and highly intensive interventions, typically targeted at families identified as “high risk” (Fergusson, Grant, Horwood et al., 2003; Olds, Robinson, Pettitt et al., 2004). Such interventions often address a range of risk factors and, while not targeted specifically at substance use, likely have the advantage of limiting risk across a range of adverse outcomes including substance use, delinquency and psychiatric disorder.

Harm Reduction Initiatives
Whereas a major focus of many prevention efforts involves the delay or avoidance of substance use onset and/or cessation of use (particularly for tobacco and the illicit drugs), there are also a number of interventions aimed at limiting or reducing the harm caused by substance use, even if substance use itself continues. These include campaigns that aim to reduce alcohol-related harm not necessarily by reducing alcohol consumption but by reducing driving under the influence (Elder, Shults, Sleet et al., 2004). Similarly, needle and syringe exchange programs have been successful in reducing transmission of blood-borne viruses without reducing drug use per se (Lurie & Drucker, 1997; Wodak & Cooney, 2006), although it is also important to note that, despite claims by critics of these programs, there is no evidence indicating that such programs increase either the prevalence of drug use or the frequency of drug use among users (Fisher, Fenaughty, Cagle et al., 2003).

Conclusions
Throughout this chapter we have emphasized the need for greater attention to be paid to adolescent substance use and dependence, both in clinical practice and in research. We have tried to draw attention to areas of uncertainty in the literature on adolescent substance use disorders, including uncertainty concerning classification and diagnosis, etiology, consequences of adolescent substance use and substance use disorder, and treatment, prevention and intervention strategies. We have also attempted to encourage critical awareness of the limitations of many existing research strategies. We have done so because we see this area of research as being extraordinarily rich in opportunities for rapid research advances, but currently underserved by the research community. Given the long-term economic costs of substance use disorders in most western societies and their origins in adolescence, and the immediate personal, family and societal costs of adolescent substance use disorder, the relative neglect of this area of research cannot be justified. The problem of adolescent substance use and substance use disorders, more than most areas of child and adolescent psychiatry, also has a strong societal component. As the substantial reductions in rates of smoking that were achieved in California illustrate (Fichtenberg & Glantz, 2000), much can be achieved through local and national policies to reduce rates of adolescent (and adult) substance use. We differ from some (Merikangas & Risch, 2003), however, in believing that whereas social change can reduce rates of substance use and substance use disorder, there will always remain a core group of individuals requiring clinical assistance, who merit our best research efforts at understanding the causes and consequences of adolescent substance use disorder.

CHAPTER 36

In this chapter we describe the clinical picture of unipolar depressive disorders, diagnostic subcategories, differential diagnosis and common comorbidities. The descriptive epidemiology, onset, course, sequelae and predictors are discussed. Evidence-based psychopharmacological and psychosocial acute and continuation treatments of depression are presented, along with current controversies. More general issues of clinical management such as determination of intensity of care and the role of hospitalization are also reviewed.

Clinical Picture

Clinical Presentation and Classification
Depressive disorders in childhood and adolescence are characterized by persistent and pervasive sadness, anhedonia, boredom or irritability that is functionally impairing, and relatively unresponsive to pleasurable activities, interactions and attention from other people. In one of the first studies of the clinical picture of depression in preschoolers, anhedonia was found to be characteristic of depression in these children (Luby, Heffelfinger, Mrakotsky, et al., 2003). Functional impairment is most salient in distinguishing depression from the “normal ups and downs” of childhood and adolescence.

Depressive disorders exist on a continuum, and are classified on the basis of severity, pervasiveness and presence or absence of mania. At the mildest end of the spectrum are adjustment disorders with depressed mood, which are mild, self-limited and occur in response to a clear stressor. Depression not otherwise specified (NOS), also referred to as “minor” or subsyndromal depression, is diagnosed in the presence of depressed mood, anhedonia or irritability, and up to three symptoms of major depression. This term “minor” depression is misleading in so far as depression NOS is associated with functional impairment and increased risk of major depression (Fergusson, Horwood, Ridder et al., 2005). Dysthymic disorder also has fewer symptoms than major depression, but its most notable characteristic is its chronicity, lasting a minimum of a year. In explaining this condition to parents and children, it may be helpful to describe major depression as a “cloudy sky,” and dysthymia as “partly cloudy” (Birmaher, Ryan, Williamson et al., 1996b). The co-occurrence of dysthymic disorder and major depression, termed “double depression,” is associated with a chronic course. Major depression is the “full-blown” condition, with either sad or irritable mood, or anhedonia, along with at least five other symptoms, such as social withdrawal, worthlessness, guilt, suicidal thoughts or behavior, increased or decreased sleep, decreased motivation and/or concentration, and increased or decreased appetite (American Psychiatric Association, 2000). Rarely, depressed patients also have psychotic symptoms such as auditory hallucinations or delusions, usually with some self-derogatory, paranoid or depressive content.

Differential Diagnosis

The most important differential diagnosis is between unipolar and bipolar depression (see chapter 38), the latter being characterized by past or current mania or hypomania (e.g., expansive mood, hypersexuality, grandiosity, decreased need for sleep). Often, young bipolar patients present with either rapid cycling or a mixed state (an admixture of depressive and manic symptoms), so that detection of bipolarity requires care, persistence and longitudinal follow-up (Birmaher, Axelson, Strober et al., 2006).

Anxiety disorders are often associated with significant dysphoria that is relieved if the anxiogenic situation, such as that of separation or social situations, is eliminated. The social withdrawal of depression should be differentiated from the avoidance of social situations because of anxiety.

Altered concentration is not only a symptom of depression, but is also a key feature of attention deficit/hyperactivity disorder (ADHD; see chapter 34). Concentration difficulties in ADHD are not associated with changes in mood-related symptoms. Moreover, ADHD usually has a much earlier onset. Children with ADHD often become demoralized because of peer rejection and difficulties at school. This demoralization can be ascribed to ADHD in absence of other depressive symptoms.

Irritability is a prominent symptom of conduct and oppositional disorders (see chapter 35), and, in the absence of other mood symptoms, this symptom is more likely to be caused by the behavioral disorder than depression. Substance abuse (see chapter 36) can mimic mood disorder by disrupting sleep, concentration, motivation and appetite; moreover, these conditions frequently co-occur with mood disorders in clinical practice. A careful history and, when warranted, a drug toxicology screen
is often the only way to detect this important and serious condition. Patients with eating disorders (see chapter 41) often show lassitude and dysphoria, which can in part be attributed to poor nutritional status. A diagnosis of current depression in an eating disordered patient should not be made until adequate nutritional status has been restored.

**Comorbidity**

Differential diagnosis notwithstanding, comorbidity is the rule rather than the exception in depressed children and adolescents, especially in clinical samples (Angold, Costello, & Erkanli, 1999; see also chapter 2). Comorbidity may result from shared etiology, or as a cause or consequence of depression. Comorbid conditions affect both the course and outcome of depression. Anxiety is frequently a precursor of mood disorder. Anxiety and depression may be comorbid because of a shared genetic diathesis (Middeldorp, Cath, van Dyck et al., 2005). ADHD and depression are also often comorbid. Comorbidity between depression and behavioral disorders and substance abuse may be attributable to shared family risk factors, such as abuse, exposure to family violence and discord, and parental substance abuse (Fergusson & Woodward, 2002). Alcohol, drug and tobacco abuse are associated with depression, and longitudinal studies suggest a bidirectional causality, with substance abuse both leading to, and occurring as a consequence of depression. Depression increases the likelihood of initiation and development of substance abuse problems, but substance abuse problems lead to life events that increase the likelihood of depression (Kuo, Gardner, Kendler et al., 2006; Libby, Orton, Stover et al., 2005). Conduct disorder is frequently comorbid with depression, particularly in prepubertal samples (Harrington, 2000).

**Assessment**

The psychiatric interview is the “gold standard” for assessment of depressive diagnoses (Myers & Winters, 2002). The main advantages of psychiatric interview over self- or parent-report are that interviews can determine the temporal sequence, course and functional significance of different symptoms, determine to what extent these symptoms should be attributed to a depressive disorder or to another condition, and facilitate the integration and resolve discrepancies between parent and child sources of information. The main disadvantages of direct interviews are cost and time, and for semistructured interviews a high level of training and ongoing quality monitoring. Interviews are conducted with both the parent and the child. Parents are usually better informants about past history treatment and symptoms that are tied to external behavior, such as social withdrawal, decline in school performance and agitation. Children are better reporters about internal experiences and thoughts, such as suicidal ideation, anhedonia, guilt, psychosis and lack of motivation. Epidemiological studies have found fairly consistent results using both fully structured (Diagnostic Interview Schedule for Children [DISC] and Composite International Diagnostic Interview [CIDI], the latter just in adolescents; Shaffer, Fisher, & Lucas, 2004) and semi-structured interviews (Schedule for Affective Disorders and Schizophrenia–Epidemiological version [K-SADS-E], Schedule for Affective Disorders and Schizophrenia for School-Age Children–Present and Lifetime version [K-SADS-PL], Child and Adolescent Psychiatric Assessment [CAPA]; Angold, Prendergast, Cox et al., 1995; Kaufman, Birmaher, Brent et al., 1997a). The Preschool Age Psychiatric Assessment (PAPA), a downward extension of the CAPA, shows good reliability and internal consistency with regard to assessment of preschool psychopathology, including depression (Egger, Erkanli, Keeler et al., 2006). The advantages, disadvantages and psychometric properties of each of these instruments are reviewed in more detail in chapter 19.

The most commonly used continuous interview-based measure of depressive symptomatology is the Children’s Depression Rating Scale–Revised (CDRS-R), a 17-item assessment that is analogous to the Hamilton Depression Rating Scale (Poznanski, Freeman, & Mokros, 1985). The measure ranges from 17 to 113, with 40 or above associated with clinically significant depression, and less than 29 with symptomatic remission. Discriminant and convergent validity, as well as sensitivity to treatment effects, have been demonstrated (Emslie, Rush, Weinberg et al., 1997). Among its limitations are that the CDRS-R emphasizes neurovegetative rather than cognitive symptoms and has less than straightforward anchor points for the suicide ideation item.

The Mood and Feelings Questionnaire (MFQ) is the only self-report scale validated for both children and adolescents and comes in a 37-item and 13-item form; the latter is useful for screening for depressive disorders (Thapar & McGuffin, 1998). This measure also has a parent report version. Internal consistency, convergent and discriminant validity have been reported, with the ability to discriminate depression from anxiety and from conduct disorder.

The Children’s Depression Inventory (CDI) was developed as a downward extension of the Beck Depression Inventory (BDI), and has a self, parent and teacher report form, although usually the former is used in the literature (Kovacs, 1985). The CDI is highly correlated with other measures of depression, but does not discriminate well from anxiety disorders and so is better used as a measure of emotional disturbance rather than depression per se.

The Center for Epidemiological Studies–Depression Scale (CES-D) has been used in several epidemiological and treatment studies of adolescents of diverse ethnic origin, works well as a screen for depression, has good discriminant validity and is sensitive to treatment effects (Dierker, Alban, Clarke et al., 2003; Lewinsohn, Rohde, & Seeley, 1998). One weakness is that it does not have a suicide ideation item. The Beck Depression Inventory (BDI) is very widely used in studies of adolescents, is a good screen for depressive disorders, is sensitive to treatment effects and may be a more effective screen for major depression than the CES-D (Dierker, Alban, Clarke et al., 2001; Roberts, Lewinsohn, & Seeley, 1991). It has strong psychometric properties of the adolescent instruments but emphasizes the cognitive component of depressive disorders.
The Reynolds Adolescent Depression Scale (RADS) is another scale with very good psychometric properties that is sensitive to treatment effects (March, Silva, Petrycki et al., 2004; Reynolds & Mazza, 1998). The Preschool Feelings Checklist is a 16-item parent report measure that, in a preliminary report, appears to have high sensitivity and specificity for preschool depressive disorders (Luby, Heffelfinger, Koenig-McNaught et al., 2004). Studies of adults in primary care have shown that a two-item screen (about low mood and anhedonia) is as efficient as longer self-report inventories, but no studies in children or adolescents have yet been published (Whooley, Avins, Miranda et al., 1997).

**Descriptive Epidemiology**

The point prevalence of depressive disorders is 1–2% in prepubertal children and 3–8% in adolescents, with a lifetime prevalence by the end of adolescence of around 20% (Costello, Mustillo, Erkanli et al., 2003; Fergusson, Horwood, Ridder et al., 2005; Lewinsohn, Rohde, & Seeley, 1998). The point prevalence of clinically significant depressive symptomatology in multinational studies is even higher (10–13% in boys and 12–18% for girls; Ruchkin, Sukhodolsky, Vermeiren et al., 2006). The prevalence of depression in preschoolers is unknown. The rate of depressive disorders may be increasing from the 1950s to the early 1990s (Costello, Erkanli, & Worthman, 1998), perhaps mediated by increases in estradiol and testosterone. The higher female than male rate of depression may also be a result of higher rates of anxiety disorder in females, greater tendency to engage in ruminative thinking, greater total cortisol excretion after the corticotropin-releasing hormone challenge and increased interpersonal sensitivity, all of which may increase vulnerability for depression (Breslau, Schultz, & Peterson, 1995; Nolen-Hoeksema, Larson, & Grayson, 1999; Stroud, Papandonatos, Williamson et al., 2004).

Prepubertal depression appears to be of two types. The first, more common presentation of pre-pubertal depression is with comorbid behavioral problems, parental criminality, parental substance abuse and family discord. The course of these children resembles those with conduct disorder much more than those with mood disorders, without an increased risk for recurrence of depression into adult life (Harrington, Rutter, Weissman et al., 1997; Weissman, Wolk, Wickramaratne et al., 1999a). The second, less common, form is highly familial, with multigenerational loading for depression, with high rates of anxiety and bipolar disorder, and recurrences of depression in adolescence and adulthood. Adolescent onset depressive disorder has a high risk of recurrent mood disorder into adulthood (Harrington, 2000; Harrington, Rutter, Weissman et al., 1997; Weissman, Wolk, Goldstein et al., 1999b). Twin studies suggest a greater genetic component in adolescent versus pre-pubertal onset depression, supportive of the view that child and adolescent onset depression may differ in etiology (Scourfield, Rice, Thapar et al., 2003). In clinical samples, depressed adolescents, compared to depressed children, showed more hopelessness, decreased energy, and fatigue, hypersomnia, suicidality and substance abuse, whereas depressed children showed more comorbid separation anxiety and ADHD (Yorbik, Birmaher, Axelson et al., 2004).

**Age and Gender**

There is an upsurge in the rate of depression that accompanies the onset of puberty, at which point the dramatic female predominance in mood disorders first emerges (Angold, Costello, & Worthman, 1998), perhaps mediated by increases in estradiol and testosterone. The higher female than male rate of depression may also be a result of higher rates of anxiety disorder in females, greater tendency to engage in ruminative thinking, greater total cortisol excretion after the corticotropin-releasing hormone challenge and increased interpersonal sensitivity, all of which may increase vulnerability for depression (Breslau, Schultz, & Peterson, 1995; Nolen-Hoeksema, Larson, & Grayson, 1999; Stroud, Papandonatos, Williamson et al., 2004).

Prepubertal depression appears to be of two types. The first, more common presentation of pre-pubertal depression is with comorbid behavioral problems, parental criminality, parental substance abuse and family discord. The course of these children resembles those with conduct disorder much more than those with mood disorders, without an increased risk for recurrence of depression into adult life (Harrington, Rutter, Weissman et al., 1997; Weissman, Wolk, Wickramaratne et al., 1999a). The second, less common, form is highly familial, with multigenerational loading for depression, with high rates of anxiety and bipolar disorder, and recurrences of depression in adolescence and adulthood. Adolescent onset depressive disorder has a high risk of recurrent mood disorder into adulthood (Harrington, 2000; Harrington, Rutter, Weissman et al., 1997; Weissman, Wolk, Goldstein et al., 1999b). Twin studies suggest a greater genetic component in adolescent versus pre-pubertal onset depression, supportive of the view that child and adolescent onset depression may differ in etiology (Scourfield, Rice, Thapar et al., 2003). In clinical samples, depressed adolescents, compared to depressed children, showed more hopelessness, decreased energy, and fatigue, hypersomnia, suicidality and substance abuse, whereas depressed children showed more comorbid separation anxiety and ADHD (Yorbik, Birmaher, Axelson et al., 2004).

**Developmental Factors**

Girls with earlier onset of puberty may be at increased risk for depression and other disorders (Graber, Seeley, Brooks-Gunn et al., 2004). The relationship between early onset of puberty and depressive symptoms is complex, because early onset of puberty is related to factors that are also related to risk for depression onset, including maternal depression, mother–child discord and child–step-parent discord (Ellis & Garber, 2000). As girls undergo the transition to adolescence, there is also an increase in child-generated parent–child and peer–peer interpersonal conflict, which may increase the likelihood of depressive disorder (Rudolph & Hammern, 1999). A greater physiological need for sleep, along with a tendency to actually obtain less sleep may also increase vulnerability to depression (Dahl, 2004).

**Course and Outcome**

**Episode Length and Recovery**

Depression is a chronic and recurrent condition. The duration for depressive episodes is 3–6 months for community samples and 5–8 months for referred samples (Birmaher, Arbelaez, & Brent, 2002). Greater episode length is associated with comorbid dysthymic disorder, comorbidity with anxiety disorder or substance abuse, greater initial severity of the depressive condition, current or past suicidal ideation or behavior, chronicity and number of episodes of parental depression and other disorders and family discord (Birmaher, Brent, Kolko et al., 2000a; Kovacs, Feinberg, Crouse-Novak et al., 1984a; Warner, Weissman, Hendrich et al., 1992). In both clinical and community samples, around 20% of adolescents with a lifetime history of depression have a persistent depression of 2 years or greater (Birmaher, Arbelaez, & Brent, 2002; Lewinsohn, Rohde, & Seeley, 1998).

**Risk for Recurrence**

In one meticulously conducted study that examined the course of depressive disorder in 8- to 13-year-olds, the risk
of recurrence was 40% in 2 years, and 72% in 5 years (Kovacs, 1996; Kovacs, Feinberg, Crouse-Novak et al., 1984b). Other longitudinal studies have shown that the risk for recurrent depression in adolescent depression followed forward is extremely high, with the rate of relapse or recurrence ranging 30–70% in 1–2 years of follow-up in clinical samples, and 16–33% in 2–4 year follow-up in community samples (Birmaher, Arbelaez, & Brent, 2002; Lewinsohn, Rohde, & Seeley, 1998). Prepubertal depressed children with a family history of depression have a similar risk of recurrence (Birmaher, Williamson, Dahl et al., 2004; Harrington, Rutter, Weissman et al., 1997). Risk factors for recurrence include early onset of mood disorder in a parent, lack of complete recovery (defined as either subsyndromal depression or return to a dysthymic baseline), pre-existing social dysfunction, history of sexual abuse and family discord (Birmaher, Arbelaez, & Brent, 2002; Lewinsohn, Rohde, & Seeley, 1998).

Other Sequelae
Both depressed children and adolescents are at increased risk for conduct disorder, personality disorders, alcohol, tobacco and drug abuse, and suicidal behavior (Fergusson & Woodward, 2002; Lewinsohn, Rohde, Seeley et al., 2003). They also are at increased risk for obesity, risky sexual behavior, unfulfilling and problematic social relationships, and educational and occupational underachievement (Fergusson & Woodward, 2002; Pine, Goldstein, Wolk et al., 2001). Whereas some studies conclude that most negative sequelae are the residue of incomplete depressive symptom resolution (Lewinsohn, Rohde, Seeley et al., 2003), others find that these “sequelae” may result from common factors that contribute to risk for depression, and for other problems, namely, parental criminality, parental substance abuse, physical or sexual abuse and family discord (Fergusson & Woodward, 2002).

Alcohol and Substance Abuse
Whereas alcohol and substance abuse are more likely to occur in depressed adolescents, many predictors of alcohol and substance abuse are also risk factors for depression, including comorbid behavior disorder, neuroticism, parental history of substance abuse, parental criminality, history of sexual abuse, low parental education, family discord and association with a deviant peer group (Fergusson & Woodward, 2002; Rao, Ryan, Dahl et al., 1999). Alcohol and substance abuse appears to be a consequence of depression, but can also lead to negative life events that precipitate depression (Libby, Orton, Stover et al., 2003; Kuo, Gardner, Kendler et al., 2006).

Suicidal Behavior
Depression is a strong predictor of suicide attempts and completion (Brent, Baugher, Bridge, et al., 1999; Gould, King, Greenwald, et al., 1998; Shaffer, Gould, Fisher, et al., 1996). Among depressed children and adolescents, greater severity and chronicity of depression, current ideation with a plan or a history of a suicide attempt, comorbid conduct disorder, substance abuse, or impulsive-aggressive personality traits, greater hopelessness, a family history of suicidal behavior, a history of abuse, family conflict and lack of support, distinguish depressed suicide attempters and non-attempters both cross-sectionally and prospectively (Bridge, Goldstein, & Brent, 2006; and see chapter 40).

Risk for Bipolar Disorder
The risk of bipolar disorder in early onset depression is estimated to be around 10–20% (Geller, Zimerman, Williams et al., 2001), with elevated risk in patients who present with hypomania in response to treatment, psychotic features, hypersomnia (in some studies) and a family history of bipolar disorder (Geller, Zimerman, Williams et al., 2001; Strober & Carlson, 1982). Children and younger adolescents exposed to antidepressants, according to one pharmaco-epidemiological study, are at particularly high risk for manic switch (Martin, Young, Leckman et al., 2004).

Risk Factors
Genetic
Twin studies demonstrate that depressive symptoms have a greater concordance among monozygotic than among dizygotic twins, with a heritability of around 40% (Glowinski, Madden, Bucholz et al., 2003; Todd & Botteron, 2002). If cases are defined by longitudinal, rather than just cross-sectional data, the heritability of depression is higher, around 65% (O’Connor, Neiderhiser, Reiss et al., 1998; Todd & Botteron, 2002). Thus, 35–60% of variance is explained by non-genetic factors, such as family adversity and protective factors described below. Adolescent onset depression symptomatology has a greater heritable component than does child onset depressive symptomatology (Scourfield, Rice, Thapar et al., 2003). However, this finding of developmentally mediated differential heritability of depression may be because of the relatively low number of younger children in these twin samples, or due to an increase in the number of behavior-dependent life events that emerge in adolescence (Rice, Harold, & Thapar, 2003; Todd & Botteron, 2002). There is evidence that liability to depression is co-transmitted along with anxiety symptoms, with heritability of co-transmission estimated to be 61–65% (Hudziak, Rudiger, Neale et al., 2000; Thapar & McGuffin, 1997). The genetic relationship between anxiety and depression, according to one series of twin studies, is as follows:

1. Genes that affect liability to anxiety also lead to an increased sensitivity to life events; and
2. Genes that increase risk for anxiety also increase the likelihood of exposure to depressogenic life events (Eaves, Silberg, & Erkanli, 2003).

This formulation is consistent with several longitudinal studies that show an association between child characteristics, child-generated life events and eventual depression (Daley, Hammen, Davila et al., 1998).

The first-degree relatives of depressed children or adolescents have a two- to four-fold increased risk of depression (Kovacs et al., 1997). Risk factors for bipolar disorder include early onset of depression, low parental education, family discord (Fergusson & Woodward, 2002).
& Devlin, 1998). Family studies of prepubertal depressives find increased parental rates of criminality, abuse, antisocial disorder and mania (Harrington, Rutter, Weissman et al., 1997; Wickramaratne, Warner, & Weissman, 2000b). In contrast, family studies of adolescent depression have more consistently found an increased rate of mood disorders in first-degree relatives (Harrington, Rutter, Weissman et al., 1997; Wickramaratne, Warner & Weissman, 2000).

“Top-down” studies have also shown an increased risk of depressive disorder in the offspring of depressed parents (Klein, Lewinsohn, Rohde et al., 2005). Greater family loading, such as depression in two generations and increased rates of parental anxiety disorders, was associated with an increased risk and earlier onset of depression, and an increased rate of anxiety disorders, further supporting the view that the liability to depression and that to anxiety are co-transmitted (Weissman, Pilowsky, Wickramaratne et al., 2006; Williamson, Birmaher, Axelson et al., 2004).

There are ongoing genetic studies of recurrent depression that suggest linkage, but none has focused particularly on childhood and adolescent depression (McGuffin, Knight, Breen et al., 2005). The risk of depression, in the presence of stressful life events, is higher in those who had a shorter allele variant of the serotonin transporter (SLC6A4), which results in less vigorous transcription of this gene (Caspi, Sugden, Moffitt et al., 2003). A polymorphism of the gene encoding brain-derived neurotrophic factor (BDNF) has been reported to be associated with early-onset depression, both alone and in interaction with early childhood adversity (Kaufman, Yang, Douglas-Palumberi et al., 2006; Strauss et al., 2005).

**Cognitive Bias and Emotional Regulation**

Depressed individuals have been shown to have a cognitive bias towards a negative view of self, future and the world. Prospective studies have found that in non-depressed individuals, especially those at risk for depression, these biases predispose to depressive symptomatology when confronted with stressful life events (Garber, Keiley, & Martin, 2002; Hammen, 1988; Lewinsohn, Joiner, & Rohde, 2001). Moreover, the relationship between negative mood and self-critical cognitions appears to be bidirectional (Kelvin, Goodyer, Teasdale et al., 1999; Park, Goodyer, & Teasdale, 2003; Rudolph, Hammen, & Burge, 1997; Stewart, Kennard, Lee et al., 2004). Depressive symptoms are correlated positively with experimental increases in rumination and negatively with distraction (Lyubomirsky, Caldwell, & Nolen-Hoeksema, 1998).

Neurocognitive studies of depressed adolescents and youth at risk for depression are consistent with the cognitive theory of depression. Both currently and previously depressed youth show greater attention to negative affect, sad words and other negative emotional distractors, whereas youth at low risk for depression show greater attention to positive distractors (Kyte, Goodyer, & Sahakian, 2006; Ladouceur, Dahl, Williamson et al., 2005). Other probes of emotional regulation in children and adolescents at risk for depression, compared to those at low risk, show greater difficulty in inhibition of negative affect, less use of active distraction and less ability to generate positive affect in the face of distraction (Forbes, Fox, Cohn et al., 2006a; Goodyer, 2002; Silk, Shaw, Skuban et al., 2006). It is unclear if these deficits in inhibition are affectively specific, or reflect more global executive function difficulties, consistent with deficits in categorical autobiographic memory and poorer decision-making on gambling tasks associated with adolescent depression (Kyte, Goodyer, & Sahakian, 2006; Park, Goodyer, & Teasdale, 2002). For example, children with a past depression showed deficits in memory for fearful faces (Pine, 2004).

**Comorbid Diagnoses**

The trait of fearfulness, as well as anxiety disorder per se, and especially social phobia, are associated with increased risk of depression (Goodwin, Fergusson, & Horwood, 2004b; Pine, Cohen, & Brook, 2001; Pine, Cohen, Gurley et al., 1998). The rates of depression are increased both in patients with ADHD and their parents (Faraone & Biederman, 1997). Early symptoms of impulsivity and hyperactivity have been reported as precursors of depression (Jaffee, Moffitt, Caspi et al., 2002). The rates of depression are elevated in children with conduct disorder, perhaps because of shared risk factors (Fergusson & Woodward, 2002). Furthermore, conduct-disordered individuals tend to associate with like-minded peers, which leads to further conduct difficulties, resultant stressful life events (e.g., getting arrested) and more depressive episodes (Fergusson, Wanner, Vitaro et al., 2003).

**Family Environmental Factors**

Twin studies show a greater role for shared environment in explaining concordance of depressive symptoms in prepubertal children by comparison with adolescents, for whom non-shared environment has a much larger role than shared environment (Scourfield, Rice, Thapar et al., 2003). Family discord and expressed emotion directed towards the child predicted onset or recurrence in at-risk subjects (Asarnow, Goldstein, Tompson et al., 1993; Frye & Garber, 2005). Greater chronicity and severity of maternal depression have been related to greater liability for parent-child conflict, and for cognitive distortions, both of which increase liability for and persistence of child depressive symptoms (Garber & Flynn, 2001). Longitudinal studies show reciprocal interrelationships between maternal and child interpersonal and emotional difficulties, child cognitive distortions and child depressive outcome (Frye & Garber, 2005; Garber & Robinson, 1997; Garber, Keiley, & Martin, 2002; Hammen, Burge, & Stansbury, 1990).

Physical and sexual abuse are among the most potent family-environmental risk factors for the onset and recurrence of depression, and also increase risk for comorbid post-traumatic stress disorder, substance abuse, conduct disorder and suicidal behavior (Barbe, Bridge, Birmaher et al., 2004; Fergusson, Horwood, & Lynskey, 1996; and see chapters 28 and 29). These effects are strongest for more severe and chronic abuse, such as sexual abuse resulting in intercourse (Fergusson, Horwood, & Lynskey, 1996). However, it is difficult to
CHAPTER 37

isolate the effects of abuse from the other adverse aspects of parental functioning and home environment that are associated with it: parental mood disorder, substance abuse, criminality, lower parental education and income, and marital discord. The relationship between depression and abuse is much stronger in the presence of other family–genetic risk factors such as a family history of depression and a specific genotype of an SLC6A4 polymorphism (Casp, Sugden, Moffitt et al., 2003; Kaufman, Birmaher, Brent et al., 1998a).

Bullying and Same Sex Attraction

Both bullies and the bullied have higher rates of depression than controls (Ivarsson, Broberg, Arvidsson et al., 2005; Kaltiala-Heino, Rimpela, Rantanen et al., 2000). Same sex attraction, activity, and bisexual or homosexual identification have been related to increased rates of depression, as well as substance abuse and suicidal behavior (Fergusson, Horwood, & Beautrais, 1999). The relationship between sexual attraction/activity/orientation and depression may be mediated by gender atypical behavior, peer rejection, bullying and parental rejection (D’Augelli, Grossman, Salter et al., 2005).

Bereavement and Other Stressful Life Events

Most generally, there is a relationship between stressful life events and depressive disorder in children and adolescents, observed both prospectively and concurrently (Brent, Perper, Moritz et al., 1993; Lewinsohn, Rohde, & Seeley, 1998; Williamson, Birmaher, Ryan et al., 2003), and experience of stress is more likely to result in depression in those with a diathesis as determined by family history or presence of certain genotypes (Brent, Perper, Moritz et al., 1993; Caspi, Sugden, Moffitt et al., 2003; Kaufman, Birmaher, Brent et al., 1998a, 2006). Studies of bereaved children and adolescents find rates of diagnosable depression around 30% within a year of the death, but these occur almost exclusively among those who are at risk because of other factors such as a previous personal or family history of depression (Brent, Perper, Moritz et al., 1993). The impact of parent loss may be mediated by a cascade of other factors, such as a drop in living standard, geographic dislocation and mental health of the surviving parent (Tremblay & Israel, 1998).

Protective Factors

A positive connection to parents and to school may protect against depression and associated health risk behaviors such as suicidal behavior, substance use, binge eating and binge drinking, tobacco use and lack of exercise (Resnick, Bearman, Blum et al., 1997). More specifically, these protective factors include a positive connection between parent and child, active parental supervision and clear behavioral and academic expectations on the part of the parent for the child, parents and children spending leisure and meal time together, academic success, a positive connection between child and school, and a pro-social peer group (Conrad & Hammen, 1993; Fergusson & Lynskey, 1996; King, Schwab-Stone, Flisher et al., 2001). Surprisingly few of these findings have found their way into the intervention literature, with some notable exceptions (Thompson, Eggert, Randell et al., 2001).

Comorbid Medical Illness

A relationship between less than ideal physical health and depression has been reported in community studies of adolescents (Lewinsohn, Rohde, & Seeley, 1998). Lewinsohn, Rohde, & Seeley (1998) posit that illness interferes with activities that are likely to be enjoyable or enhance a sense of mastery, which in turn predisposes to depression. There may also be systemic effects of some chronic illnesses or their treatments in diseases such as epilepsy (Jones, Hermann, Barry et al., 2003; Pliophy, 2003), juvenile onset diabetes (Kovacs, Goldston, Obrosky et al., 1997), inflammatory bowel disease (Addolorato, Capristo, Stefanini et al., 1997) and asthma (Goodwin, Fergusson, & Horwood, 2004a). Twin studies suggest co-transmission of liability to eczema and mood disorder (Wamboldt, Hewitt, Schmitz et al., 2000). There is also an increased risk of medical problems in depressed offspring of depressed parents, suggesting that factors associated with risk for depression may also increase risk for ill health, an observation also made in a genetic linkage study of early-onset recurrent depression (Kramer, Warner, Olfson et al., 1998; Zubenko, Zubenko, Spiker et al., 2001).

Neuroendocrine

Direct measures of cortisol secretion have not distinguished between early-onset depressives and controls (Feder, Coplan, Goetz et al., 2004; Puig-Antich, Dahl, Ryan et al., 1989). There were no differences between depressed children and controls with regard to adrenocorticotropic hormone (ACTH) release, after stimulation with corticotropic releasing hormone (CRH), although a small subgroup of melancholic children showed a blunted response (Birmaher, Dahl, Perel et al., 1996a), and ACTH release was increased in depressed children who had a history of abuse (Birmaher, Birmaher, Perel et al., 1997b). Increased cortisol secretion around sleep onset is associated with adolescent depression and predicts depressive recurrence and substance abuse in young adults who were studied during adolescence (Dahl, Ryan, Puig-Antich et al., 1991; Rao, Ryan, Dahl et al., 1999). Goodyer et al. found that in adolescents at high risk for depression, increased morning dehydroepiandrosterone (DHEA) was associated with onset of depression, and high morning cortisol:DHEA ratio at intake was related to persistence of depressive symptoms (Goodyer, Herbert, & Tamplin, 2003; Goodyer, Herbert, Tamplin et al., 2000). A decrease in growth hormone (GH) release in response to a provocative challenge of growth hormone releasing hormone (GHRH), which may be related to central norepinephrine neurotransmission, has been reported in depressed children versus controls during both episode and recovery, and in never-depressed children of depressed parents (Birmaher, Dahl, Williamson et al., 2000b; Dahl, Birmaher, Williamson et al., 2000). In a longitudinal study of depressed children grown up, increased amount of GH release in the first 4 hours of sleep was related to recurrence of
depression and suicide attempt (Pine, Coplan, Wasserman et al., 1997).

A blunted cortisol and exaggerated prolactin response (the latter in girls only) to L-5 hydroxytryptophan (L-5HT) has been found in both depressed children and never-depressed children at risk for depression due to parental depression, compared to controls (Birmaher, Kaufman, Brent et al., 1997; Ryan, Birmaher, Perel et al., 1992a), consistent with central dysregulation of serotonin neurotransmission. Increased gastrointestinal distress in response to this challenge predicted an increased risk of anxiety or depression over time (Campos, Dahl, Williamson et al., 2003). However, similar neuroendocrine responses to provocative challenge may be found in those with adverse home environments, and with high levels of aggression (Kaufman, Birmaher, Perel et al., 1998b; Pine, Coplan, Wasserman et al., 1997).

Sleep
Subjective sleep complaints are a very prominent component of early-onset depression, although subjective complaints and objective observations of sleep in a sleep laboratory are not closely correlated (Bertocci, Dahl, Williamson et al., 2005). Decreased rapid eye movement (REM) latency and increased latency of sleep-onset are not frequently observed in prepubertal depression, although the presence of these markers was associated with greater depressive severity (Dahl, Ryan, Puig-Antich et al., 1991). Decreased REM latency and increased latency of sleep-onset is observed in depressed adolescents, but only after a strict sleep–wake schedule was imposed. Decreased REM latency, increased REM density and decreased sleep efficiency have been reported to be associated with depressive onset, recurrence and persistence more consistently in older adolescents (Dahl & Lewin, 2002).

Studies of Hemispheric Lateralization
Studies of infants and children at high risk for depression have found evidence of decreased left hemisphere electroencephalogram (EEG) activity (Dawson, Frey, Panagiotides et al., 1997; Tomarken, Dichter, Garber et al., 2004). Low left frontal EEG activity was also related to greater negative affect and less positive affiliative behavior in babies of depressed mothers (Bruder, Tenke, Warner et al., 2005; Forbes, Shaw, Fox et al., 2006b). In adolescent and adult offspring of depressed and non-depressed parents, those at risk for depression had less activity over right central and parietal regions, whereas those offspring with a history of depression had less left frontal activity (Bruder, Tenke, Warner et al., 2005; Kentgen, Tenke, Pine et al., 2000; Shankman, Tenke, Bruder et al., 2005).

Neuroimaging Studies
Structural imaging studies of adult subjects with early-onset familial depression as well as in adolescents with depression have found reduced volume of the left subgenual prefrontal cortex, with others finding more global differences between familial and non-familial pediatric depression (Bohmer, Raichle, Drevets et al., 2002; Drevets, Price, Simpson et al., 1997; Lyoo, Kyu Lee, Hyun Jung et al., 2002; Nolan, Moore, Madden et al., 2002). Preliminary studies of female adolescent depressed twins suggest that this structural difference is genetically transmitted and may mediate the heritability of depression (Todd & Botteron, 2002). Decreased amygdala size has been reported in depressed children and adolescents (Rosso, Cintron, Steingard et al., 2005). Steingard, Renshaw, Hennen et al. (2002) reported decreased prefrontal cortex and increased third and fourth ventricular volume in depressed adolescents, although these findings have now been reported in a variety of neuropsychiatric disorders and may be a marker for the effects of chronicity. Other findings, such as altered hippocampal size, may be attributable to early trauma (Kaufman & Charney, 2001; Vythilingam, Heim, Newport et al., 2002).

In studies using magnetic resonance imaging (MRI) spectroscopy, lower glutamate concentrations have been reported in the anterior cingulate cortex in depressed children and adolescents versus non-depressed controls (Mirza, Tang, Russell et al., 2004). The degree of functional impairment was inversely correlated with glutamate concentration. However, this finding is not specific to major depression, as lower anterior cingulate glutamate is also found in children with obsessive-compulsive disorder (Rosenberg, Mirza, Russell et al., 2004). Increased choline concentrations in the left dorso-lateral and in orbitofrontal prefrontal cortex of depressed children and adolescents have also been reported (Farchione, Moore, & Rosenberg, 2002; Steingard, Yurgelun-Todd, Hennen et al., 2000).

Thomas, Drevets, Dahl et al. (2001) evaluated responses of depressed and anxious children and control children to fearful faces, and found increased amygdala activation in anxious children and decreased amygdala activation in depressed children. In contrast, increased amygdala activation has been found in depressed adolescents during recall of fearful faces. Increased amygdala activation was also found in depressed adolescents, relative to controls, during participation in reward-related decision-making and response to outcome (Forbes, May, Siegle et al., 2006c; Roberson-Nay, McClure, Monk et al., 2006).

Clinical Management
Risk Assessment and Treatment Planning
The first determination in the assessment of a depressed child or adolescent is whether the child can safely be treated as an out-patient. A patient with suicide ideation with a plan and intent, or who has made a recent suicide attempt with continued intent, should initially be hospitalized or treated in a more acute setting than out-patient unless the patient, clinician and family can develop a safety plan for coping with future suicidal urges upon which all can mutually agree (Birmaher & Brent, 2007; National Institute for Health and Clinical Excellence [NICE], 2005; Shaffer & Pfeffer, 2001; see also chapter 40). In addition, patients who are acutely psychotic, in a bipolar mixed state or are substance dependent may not be able to be treated as out-patients. Patients who are being abused at home should be removed from the home.
temporarily, although not necessarily to hospital. Whereas most US standards of care recommend psychiatric hospitalization for greater acuity and safety concerns, there has been almost no empirical assessment of the value of psychiatric hospitalization versus other types of treatment. Therefore, if a patient and family refuse hospital admission, unless there appears to be an obvious clinical counterindication (e.g., patient psychotic and refusing to eat), it may be preferable to preserve an alliance with the patient and family and schedule out-patient visits several times per week in the initial stabilization phase. As a general framework, clinicians need to consider the following hierarchy of priorities:
1. Life-threatening issues (e.g., suicidality, homicidality, exposure to domestic violence, intravenous drug use);
2. Therapy-threatening issues (hopelessness about treatment, chronically depressed parent who is unable to bring the child for treatment); and

Patient and Family Education
Because depression is often a chronic and recurrent illness, it is vital to establish a long-term partnership with the patient and family with regard to its management. This can be achieved by providing the patient and family with all the requisite information about depression and its treatment, and then making treatment decisions collaboratively (Brent, Poling, McKain et al., 1993). As described in Table 37.1, education focuses on depression as an illness, recognition and monitoring of depressive symptomatology, knowing risks and benefits of different treatments, and, if symptom relief is achieved, development of a plan to prevent relapse and recurrence.

Family, Social and Individual Context
The treatment plan for depressed children and adolescents should consider four levels of contextual factors: parents, peers, school and individual. Depressed children and adolescents who are clinically referred often have parents who have active psychiatric difficulties, most commonly depression, anxiety and substance abuse (Hammen, Rudolph, Weisz et al., 1999). These difficulties may make it very difficult for the family to comply with treatment recommendations, and may also create stressors that make it less likely for the patient to respond to treatment. For example, three different research groups have reported that current parental depressive symptoms make it less likely that a child will respond to cognitive–behavioral therapy (CBT) for depression or anxiety (Brent, Kolko, Birmaher et al., 1998; Lewinsohn, Rohde, & Seeley, 1998; Southam-Gerow, Kendall, & Weersing, 2001). Treatment of maternal depression is associated with amelioration of child symptomatology (Weissman, Pilowsky, Wickramaratne et al., 2006). Therefore, facilitation of a treatment referral for the depressed parent should be part of the child’s treatment plan. Abuse, exposure to family violence or high levels of criticism or discord must be addressed because of safety issues for the child as well as the negative impact of these factors on duration and recurrence of depressive episodes. When parents are unable to provide the necessary support for treatment, they sometimes are willing to allow involvement of adult surrogates, such as older siblings, other relatives or close friends who may temporarily step in and help with transportation and even monitoring of treatment response.

Depressed adolescents, particularly those with comorbid behavioral traits and substance use, often are involved in friendships with similarly depressed, substance abusing and disaffected youth, which tend to reinforce depressive attitudes and also encourage antisocial acts that in turn lead to depressogenic life events (Fergusson, Wanner, Vitaro et al., 2003). Therefore, the possibility of developing more prosocial relationships should be on the treatment agenda.

As a result of decreased energy and concentration and motivational difficulties, depressed children and adolescents often fall behind in school, which in turn leads to a sense of failure, increased anxiety and a tendency to give up and disconnect from school. There also may be specific school-related stressors that contribute to depressive symptomatology, such as being the target of bullying, or teasing by students or teachers. Conversely, cross-sectional data and one intervention study suggest that a positive connection between school and student, as well as high parental academic expectations appropriate to the child, are protective against depression (Resnick, Bearman, Blum et al., 1997; Thompson, Eggert, Randell et al., 2001). Therefore, the clinician should assess the depressed child’s current school function, identify any school-related stressors, and, if the patient has fallen behind academically, develop a plan, in conjunction with the school, for a reduced workload and a plan for catching up that is mutually acceptable to school, family and student.

With regard to individual context, it is important to identify comorbid risk behaviors or psychiatric disorders that are likely to be life-threatening or disruptive to therapy, in which case, they should be attended to first. Life-threatening behavior, like intravenous drug use, aggressive criminal behavior or non-compliance with a serious chronic illness, should be addressed prior to treatment of depression, even recognizing that depression may be contributing to this problem. Higher priority to targeting comorbid conditions should be given if these symptoms are causing the greatest functional impairment and if the treatment of depression is likely not to

Table 37.1 Psychoeducation: key elements for parents and patients.

be successful unless the other condition is addressed first. For example, the treatment of a patient with both depression and ADHD whose main difficulties are decrease in motivation, suicidal ideation and hopelessness should probably initially focus on the depression, whereas a patient with similar comorbidity whose depression emerges secondary to school and peer failure due to impulsivity and inattention should probably have the ADHD addressed first.

Treatment
There are currently three treatments for adolescent depression with some empirical support: antidepressant treatment, CBT and interpersonal therapy. Meta-analyses show support for the efficacy of fluoxetine in prepubertal depression but, because of small numbers and a smaller effect size, not for other agents (Bridge, Iyengar, salary et al., 2007). There has been considerably less research on treatment of prepubertal children with depression, although there is some support for the efficacy of antidepressants. Each of these three approaches will be discussed, followed by a recommendation for “best practice” which is based on both empirical support and expert consensus (Brent, 2004; Brent & Birmaher, 2002; Birmaher & Brent, 2007; NICE, 2005). Because of the controversies surrounding the efficacy of antidepressants and of psychotherapy for pediatric depression, we provide a synopsis of the effect sizes of the extant clinical trials in Tables 37.2–37.4.

### Antidepressant Medication

#### Evidence of Efficacy

Both the single largest placebo-controlled comparison study of tricyclic antidepressants (TCAs) and placebo, and a subsequent meta-analysis showed no difference between drug and placebo (Hazell, O’Connell, Heathcote et al., 1995; Keller, Ryan, Strober et al., 2001), whereas several studies have demonstrated efficacy with selective serotonin reuptake inhibitor (SSRI) antidepressants, especially using fluoxetine (Bridge, Iyengar, Salary et al., 2007). This may be reflective of an overall developmental difference in so far as adolescents and younger adults may respond better to serotonergic agents, whereas older adults respond equally as well to serotonergic and to noradrenergic agents (Mulder, Watkins, Joyce et al., 2003).

Fluoxetine is the best-studied antidepressant with the strongest efficacy data, and consequently is the only antidepressant to receive US Food and Drug Administration (FDA) and Medicine and Healthcare Products Regulatory Agency (MHRA) approval for the treatment of depression in children and adolescents (Emslie, Rush, Weinberg et al., 1997, 2002; March, Silva, Petrycki et al., 2004). In the three published studies of fluoxetine, a higher proportion of those treated with fluoxetine were “much or very much improved” compared to those treated with placebo (52–61% versus 33–37%), with a number needed to treat (NNT) = 5. In the Treatment of

CI, confidence interval; NNH, number needed to treat to harm; NNT, number needed to treat to benefit.

* Clinical Global Impression-Improvement Score (CGI-I) <2.
Adolescent Depression Study (TADS), fluoxetine was more efficacious than both cognitive–behavior therapy and placebo (proportion “significantly improved,” 61% versus 43% versus 35%; March et al., 2004). However, combined treatment (fluoxetine plus CBT) resulted with the highest rate of symptomatic remission (37% versus 20% on fluoxetine alone; Kennard, Silva, Vitiello et al., 2006).

A meta-analysis of all available clinical trials, both published and unpublished, shows that SSRIs are superior to placebo, with the average response rate for drug versus placebo for antidepressants 60% versus 49%, with NNT = 9, with a comparable effect size on scalar measures (Hedges’s G = 0.23; Bridge, Iyengar, Salary et al., 2007; see Table 37.2). The relatively low effect size in SSRIs versus placebo in child and adolescent depression is caused in part by the high placebo response rate. The drug–placebo difference was inversely proportional to the number of study sites involved in the trial, suggesting that some studies with large numbers of sites may have been less selective in recruitment (Bridge, Iyengar, Salary et al., 2007). Duration was also inversely proportional to response. Other explanations for the relative modest effects of antidepressants include use of inadequate dosage, duration of treatment too short to achieve the full effect, and aggregation of results of children and adolescents when, in some studies, there were significant effects for adolescents but not for children.

Besides fluoxetine, other drugs with published efficacy data include citalopram, paroxetine and sertraline (Keller, Ryan, Strober et al., 2001; Wagner, Ambrosini, Rynn et al., 2003, 2004), although the effect sizes were relatively small and there are other negative studies for these agents (Emslie, Kratochvil, Vitiello et al., 2006; von Knorring, Olsson, Thomsen et al., 2006). A review of the published and unpublished studies indicates that, for paroxetine and for venlafaxine, the response to medication was superior to placebo for adolescents, but not for children (Emslie, Yeung, Kunz et al., 2007). In some studies, such as those for venlafaxine, the doses appeared to be substantially below those recommended for clinical practice (Emslie, Kratochvil, Vitiello et al., 2006).

Amfebutamone, a monocyclic aminoketone that inhibits the reuptake of dopamine and norepinephrine, has been found in open trials to improve depressive symptoms and ADHD symptoms in patients comorbid for both conditions (Daviss, Bentivoglio, Racusin et al., 2001), but this agent has not been studied in randomized trials in depressed children or adolescents. Antidepressant efficacy is correlated with concentration of amfebutamone and metabolites, most significantly, hydroxyamfebutamone (Daviss, Perel, Brent et al., 2006).

**Adverse Events in Antidepressant Treatment**

The US FDA conducted a meta-analysis that found a higher rate of spontaneously reported suicide-related adverse events on drug than on placebo (4% versus 2%; Hammad, Laughren, & Racoosin, 2006). There were relatively few suicide attempts, no completions and most suicidal events occurred early in treatment. The increased risk for suicidality was found in subjects treated for depression, obsessive compulsive disorder (OCD) and anxiety. Another meta-analysis that included additional studies not reported on in the FDA meta-analysis and using random rather than fixed effects models reported rates of suicidal adverse events for drug and placebo of 2.5% versus 1.7%, respectively, for a risk difference of 0.8%, and a number needed to harm (NNH) of 125. Thus, the number of those who benefit from SSRIs (NNT = 10) compared to those who become suicidal (NNH = 125) is around 14 : 1. (Bridge, Iyengar, Salary et al., 2007).

Baseline predictors of spontaneously reported events in all pooled studies using paroxetine identified suicidal ideation at intake, agitation at baseline and female gender as risk factors (Apter, Lipschitz, Fong et al., 2006). No mechanism has been established that explains the relationship between SSRI use and suicidality, although some speculate that it could be a result of rapid metabolism, non-compliance and/or withdrawal symptoms, induction of a mixed state (combination of manic and depressed symptoms), akathisia or SSRI-induced disinhibition (Brent, 2004).

The clinical significance of these spontaneously reported suicide-related adverse events is unclear. Almost all are increased suicidal ideation or suicidal threats, with very few attempts and no completions in over 4300 subjects (Hammad, Laughren, & Racoosin, 2006). Moreover, no difference between drug and placebo has been detected in the subset of studies that also assessed for suicidality using standard measures, although there was an effect of medication on suicidality on the Suicide Ideation Questionnaire in the TADS study (Emslie, Kratochvil, Vitiello et al., 2006). If SSRIs significantly increased suicidal risk, one would expect to see a recent increase in the rate of adolescent suicide, given the dramatic increase in the use of SSRIs in adolescents. However, the adolescent suicide rate has declined over the past decade, and some pharmaco-epidemiological studies find a relationship between increased prescription and sales of SSRIs and a decline in completed suicide, which is particularly notable among the young (Brent, 2004; Gibbons, Hur, Bhaumik et al., 2006; Olfson, Shaffer, Marcus et al., 2003). In one record linkage study, the rate of attempted suicide in both adults and adolescents started on SSRIs was highest in the month before initiation of medication (Simon, Savarino, Uperskalski et al., 2006). Nonetheless, caution and close monitoring for increased suicidality are warranted in mood-disordered patients treated with SSRIs.

In addition to the concern over suicide and self-injurious behavior, antidepressants are associated with increased incidence of sleep disruption, vivid dreams, nausea and gastrointestinal distress, increase in agitation, akathisia, anxiety, headache, serotonin syndrome (particularly in combination with other serotonergic agents) and bruising (caused by a prolongation of clotting time; Goldstein & Goodnick, 1998). The last side-effect is usually not clinically significant, but can become so in patients with intrinsic coagulation disorders or who are undergoing surgery. One pharmaco-epidemiological study found that the risk of SSRI-treatment-associated mania
was greatest in patients under the age of 14 (Martin, Young, Leckman et al., 2004).

Predictors of Antidepressant Response
One naturalistic study found that comorbid attentional problems predicted poorer response to an SSRI in depressed adolescents (Hamilton & Bridge, 1999). A naturalistic follow-up after a clinical trial found that poorer outcome was predicted by family discord, comorbidity and greater severity at intake (Emslie, Rush, Weinberg et al., 1998). In the TADS study, predictors of poor outcome, regardless of treatment assignment, were severity (depressive symptoms and functional impairment), complexity (comorbidity) and chronicity (Curry, Rohde, & Simons et al., 2006).

A higher dose may lead to better outcome in those patients who fail to respond to a lower dose of SSRI (Heiligenstein, Hoog, Wagner et al., 2006). There is evidence that adolescents metabolize sertraline, citalopram and paroxetine (but not fluvoxamine) faster than do adults, so that higher doses than typically recommended for adults may be needed (Axelson, Perel, Birmaher et al., 2002; Findling, McNamara, Stansbrey et al., 2006; Labellarte et al., 2004).

Biological Predictors of Response
Two small studies found a correlation between percent re-uptake of serotonin in platelet receptors and clinical response (Axelson et al., 2005; Sallee, Hilal, Dougherty et al., 1998). One study found an association between up-regulation of glucocorticoid type II receptors and response to sertraline (Sallee, Nesbitt, Dougherty et al., 1995). Several studies found that the short allelic variant of the serotonin transporter gene (SLC6A4) is associated with a poorer response to SSRIs in adults (Lerer & Macciardi, 2002), and preliminary data in depressed children and adolescents are consistent with these findings. Depressed adults who responded to CBT showed high amygdala and low subgenual cingulate cortex response to sustained emotional processing. Depressed adults who responded to fluoxetine showed greater left versus right hemisphere activation to dichotic listening, whereas the reverse predicted poor outcome (Bruder, Stewart, Tenke et al., 2001; Siegle, Carter, & Thase, 2006).

Role in Continuation
In patients who have been successfully treated with fluoxetine for the acute phase, a 32-week double-blind comparison of continuation treatment with fluoxetine versus placebo showed a relapse rate of 30% on continuation versus 60% on placebo, with a median time to relapse of 6 versus 2.3 months (Emslie, Heiligenstein, Hoog et al., 2004).

Cognitive–Behavior Therapy
Theory and Techniques
CBT is based on the theory of depression that holds that depressed individuals show “distortions” in their thinking and information processing, tending to emphasize the negative aspects of a situation and to underemphasize the positive, as has been demonstrated in self-report and neurocognitive evaluations (see p. 604; Beck, Rush, Shaw et al., 1979). This tendency to focus differentially on the negative appears to have a role in the genesis and maintenance of depressive episodes and negative mood states during times of stress (Garber & Robinson, 1997; Garber, Keiley, & Martin, 2002; Lewinsohn, Joiner, & Rohde, 2001).

CBT treatments for depression focus on interrupting this cycle of negative thinking, depressed mood and maladaptive behavior, through a variety of cognitive techniques and behavioral skill-building exercises. Central to CBT is cognitive restructuring, that is, making the patient aware of negative “distortions” and teaching the individual how to counteract them, with subsequent relief of depression. Another key component of CBT is behavioral activation; for example, encouraging patients to normalize their routine and engage in rewarding activities, even if they do not feel like it at the time. This component of CBT is derived from the observation that depressed mood has been shown to fluctuate proportionally to the degree of involvement in potentially reinforcing activities (Lewinsohn, Rohde, & Seeley, 1998).

However, the content of CBT treatment manuals, tested in clinical trials, varies greatly in the emphasis on each of these techniques (behavior activation, cognitive restructuring) and the inclusion of other adjunctive skill-building elements (e.g., problem-solving, emotion regulation, relaxation, social skills training). In addition, CBT approaches vary with regard to the length, structure and emphasis format (e.g., group or individual), which makes differences in outcome across studies difficult to interpret.

Efficacy of CBT
Many pioneering studies of CBT for child depression involved symptomatic volunteers (Weisz, McCarty, & Valeri, 2006). However, in order to allow comparability to the above-noted medication trials, we focus our review on studies enrolling samples that meet formal diagnostic criteria for a depressive disorder (Table 37.3). All of these investigations are in depressed adolescents; as yet there are no published CBT efficacy trials in diagnosed samples composed primarily of prepubertal youth, although an open trial of a psychosocial treatment with a focus on emotional regulation with some cognitive elements, described below, has been reported (Kovacs, Sherrill, George et al., 2006). A comprehensive meta-analysis of child psychotherapy studies found an overall effect size for CBT treatment of depression of 0.34, although in the absence of the large, and essentially negative contrast between CBT and placebo in the TADS study, the overall effect size was 0.48 (Weisz, McCarty, & Valeri, 2006).

The most commonly studied intervention for depressed adolescents is the CBT-based course Coping with Depression for Adolescents (CWD-A), a group-administered structured program that includes psychoeducation, pleasant activity scheduling, social skills training, problem-solving and cognitive

BDI, Beck Depression Inventory; CBT, Cognitive–behavioral therapy; CBTP, CBT – parent design; CDI, Children’s Depression Inventory; CDRS-R, Children’s Depression Rating Scale – Revised; CES-D, Center for Epidemiological Studies, Depression; CGI-I, Clinical Global Impression-Improvement; IPT-A, Interpersonal psychotherapy for depressed adolescents; MFQ-P, Mood and Feelings Questionnaire, Parent; NNT, Number needed to treat; School TAU, school counseling services.

To date, there have been four studies to test the efficacy of CBT in clinically referred depressed adolescents. Vostanis, Feehan, Grattan et al. (1996) compared CBT to supportive treatment and found no difference between treatment groups (86% versus 75% no longer depressed). Treatment was very brief (around six sessions) and was offered over an extended time frame (1–5 months). In contrast, Wood, Harrington, and Moore (1996), who used a similar but more concentrated treatment model (5–8 sessions of CBT over 12 weeks), found that brief CBT was superior to relaxation therapy in depressed adolescents; improvements were also noted in functional impairment, anxiety and dimensional measures of depression. Upon follow-up, there was a tendency for those treated with CBT to relapse so that differences were no longer statistically significant.

Brent, Holder, Kolko et al. (1997) compared 12–16 sessions of CBT that was an adaptation of Beck’s approach (Beck et
al., 1979) with family therapy and with supportive treatment, all delivered by therapists who were trained in and adherents of their treatment model. At post-treatment, CBT produced outcomes superior to the alternative intervention, with regard to decline in depressive symptoms, achievement of remission and speed of response. Upon 2-year follow-up, there were no statistically significant differences among the three randomized groups (Birmaher, Brent, Kolko et al., 2000a).

The final CBT efficacy trial in a diagnosed sample is the Treatment of Adolescents with Depression Study (TADS; March, Silva, Petrucki et al., 2004). TADS is the only published study to compare CBT, fluoxetine, their combination and placebo. In this large well-powered investigation, CBT (43% significantly improved) was not superior to placebo (35%), whereas both combination of CBT and fluoxetine (71%) and fluoxetine alone (61%) were markedly superior to both CBT and to placebo.

Given the generally positive effects of CBT in other investigations, why did CBT fail to outperform placebo in TADS? The authors posit that CBT was less efficacious because of severity, comorbidity and economic disadvantage of the sample. However, other studies found stronger effects for CBT in poorer samples that had comparable severity and comorbidity, with comorbid anxiety actually being a positive prognostic indicator (Brent, Holder, Kolko et al., 1997, 1998; Rohde, Clarke, Lewinsohn et al., 2001). TADS subjects did have greater duration of depression than was reported in other studies, which, in turn, was associated with poorer response to treatment in the TADS study and one meta-analysis of all antidepressant trials for depression (Bridge, Iyengar, Salary et al., 2007; Curry, Rohde, Simons et al., 2006). Another possible explanation for the relatively weak performance of CBT in this study could be the type of treatment delivered. The TADS treatment package attempted to deliver, in a relatively brief treatment, a large number of accepted approaches: problem-solving, behavior activation, cognitive restructuring, emotion regulation, relaxation training and parent–child sessions, whereas some of the more successful interventions have mainly focused on cognitive restructuring or on behavior activation and problem-solving. It is possible that in the TADS manual’s attempt to be inclusive of a variety of successful techniques, subjects never received an adequate “dose” of any one of these specific CBT techniques (Hollon, Garber, & Shelton, 2005).

Combined CBT and Medication
In TADS the combination of CBT and fluoxetine was superior to drug alone in the overall sample, and also for the subgroup with mild to moderate depression, with regard to speed and completeness of response (Curry, Rohde, Simons et al., 2006; Kennard, Silva, Vitiello et al., 2006; Vitiello, Rohde, Silva et al., 2006). Overall combination treatment resulted in the best functional outcomes and highest rates of remission (37% versus 20% for placebo). However, the combination treatment was not superior to medication alone for more severely depressed subjects, although the trends favored combination (effect size [ES] 0.84 for combination versus 0.69 for fluoxetine alone; Curry, Rohde, Simons et al., 2006). In addition to the TADS study, there have been two other investigations of the impact of combined CBT and antidepressant management compared with antidepressant alone, which, in aggregate, do not make a strong case for the use of combined treatment, counterintuitive as this seems. Clarke, Debar, Lynch et al. (2005) studied the addition of the CWD-A treatment to antidepressant management in primary care. This combined treatment resulted in some modest improvement in quality of life, but improvement in depressive symptoms never reached statistical significance; moreover, patients in the combined treatment were more likely to stop their antidepressants. A study conducted in the UK compared combination treatment, using the CBT model that had been used successfully by Wood, Harrington, & Moore (1996), with fluoxetine alone, for moderate to severely ill depressed adolescents. CBT did not add to medication alone with regard to global functioning, quality of life or depressive symptomatology (Goodyer, 2006).

Effectiveness
Three published investigations have produced findings relevant to the effectiveness of CBT in practice. As noted above, Clarke, Debar, Lynch et al. (2005) found in their primary care investigation that adding CBT to high-quality medication management provided only modest benefits on measures of symptoms and functioning. However, these very small improvements occurred as youths significantly reduced their use of psychotropic medication in the CBT plus SSRI arm. In another study based in primary care, depressed adolescents were randomized to either clinical monitoring and usual care or clinical monitoring plus on-site specialty mental health care, with the latter consisting of the patient’s choice of CBT, medication, or both (Asarnow, Jaycox, Duan et al., 2005). The quality improvement (QI) arm, which most often consisted of CBT, was superior to treatment as usual in increasing teens’ access to depression care (i.e., number of sessions) and on improving depression symptoms and quality of life, similar to parallel studies in adults (Wells, Sherbourne, Schoenbaum et al., 2000). One benchmarking study compared CBT to an unselected, clinically complicated sample of depressed adolescents with the results of CBT delivered in a research study at the same site (Weersing, Iyengar, Kolko et al., 2006). Results of clinic-based CBT were quite similar to the published effects of CBT, once symptom trajectories in the research subjects were adjusted for the difference in the proportion of subjects who came by advertisement, as the latter tended to respond more favorably to treatment (Brent, Kolko, Birmaher et al., 1998; Weersing, Iyengar, Kolko et al., 2006).

Predictors of Outcome
Greater intake severity, older age of onset, low involvement in pleasurable activities, greater hopelessness and other cognitive distortions, history of sexual abuse and parental depression were found to be predictive of less positive response in CBT clinical trials (Barbe et al., 2004; Brent, Kolko, Birmaher et al., 1998; Clarke, Hops, Lewinsohn et al., 1992;
Clarke, Hornbrook, Lynch et al., 2001; Lewinsohn, Rohde, & Seeley, 1998; Rohde, Clarke, Lewinsohn et al., 2001. Parental depressive symptoms moderated treatment response to CBT in so far as in the absence of maternal depression CBT was superior to alternative treatments whereas in its presence, CBT was no better than the alternatives (Brent, Kolko, Birmaher et al., 1998; Lewinsohn, Rohde, & Seeley, 1998). Family discord and comorbid substance abuse predicted a slower response to treatment overall (Birmaher, Brent, Kolko et al., 2000a; Rohde, Clarke, Lewinsohn et al., 2001). In contrast, referral by advertisement as compared to clinical referral predicted a good response in all conditions, and comorbid anxiety disorder predicted a particularly positive response to CBT (Brent, Kolko, Birmaher et al., 1998; Rohde, Clarke, Lewinsohn et al., 2001). In some studies, changes in cognitive distortions or improvements in involvement in pleasurable activities are associated with improvement (Ackerson, Scogin, McKendree-Smith et al., 1998; Kaufman, Rohde, Seeley et al., 2005; Kolko, Brent, Baugher et al., 2000). Findings from the TADS study were mostly but not completely consistent with the above-noted results. In contradistinction, greater cognitive distortion predicted better response, at least in the combination cell, and source of referral was unrelated to outcome. Higher family income (≥$75,000/year) also predicted better response to CBT, both alone and in combination with medication (Curry, Rohde, Simons et al., 2006).

Prevention of Onset, Relapse or Recurrence

An adaptation of the CWD-A program reduced the risk of onset of major depression in two groups of at-risk adolescents, those with subsyndromal depression (15% in CBT versus 26% control; Clarke, Hawkins, Murphy et al., 1995) and in at-risk adolescent offspring with either subsyndromal depression or a past history of depression or depressed parents (9% CBT versus 28% control; Clarke, Hornbrook, Lynch et al., 2001). A meta-analysis of CBT prevention packages has found that selected or indicated interventions that focus on youth with subsyndromal symptoms show more positive effects than universal programs both at the end of the intervention (ES 0.30 versus 0.12) and upon follow-up (ES 0.31–0.34 versus 0.02), in part because at-risk youth continue to become more symptomatic over time (Horowitz & Garber, 2006).

With regard to the prevention of relapse, CBT does not appear to produce significantly greater benefit than other interventions at intermediate or long-term follow-up after brief acute treatment of depression (Birmaher, Brent, Kolko et al., 2000a; Wood, Harrington, & Moore, 1996). While the addition of up to six individual CBT monthly booster sessions reduced the rate of relapse from 50% to 20%, the addition of 1–2 group or individual booster sessions did not, suggesting a dose effect (Birmaher, Brent, Kolko et al., 2000a; Clarke, Lewinsohn, Rohde et al., 1999; Kroll, Harrington, Jayson et al., 1996). Although several studies highlight the role of family conflict in onset, duration of episode and risk of recurrence, family interventions have not yet been studied with regard to these outcomes.

Interpersonal Therapy

(Table 37.4)

Theory and Techniques

Interpersonal psychotherapy for adolescents (IPT-A) is an adaptation of interpersonal therapy (IPT), a well-established efficacious treatment for adult unipolar depression (Mufson, Weissman, Moreau et al., 1999). IPT-A conceptualizes depression as occurring within an interpersonal matrix, and targets resolution of interpersonal stress that seems to be associated with the adolescent’s depression. IPT-A begins by taking an interpersonal inventory of important relationships in order to determine appropriate treatment targets. The types of problems typically targeted by IPT-A are loss, role disputes, role transitions, interpersonal skills deficits or adjustment to a single-parent family. The goal of treatment is to replace conflictual, unfulfilling relationships with meaningful lower-conflict relationships.

Evidence of IPT Efficacy

Mufson, Weissman, Moreau et al. (1999) conducted the first efficacy trial of IPT-A in a patient population of depressed adolescents. Forty-eight adolescents were randomized to either IPT-A or monthly clinical management. A much higher proportion of adolescents met recovery criteria (Hamilton Depression Scale-Depression ≤6) in the IPT-A group (75% versus 46%). There was a much higher attrition rate in the clinical monitoring group. Analyses of dimensional measures of depressive symptomatology, functional status and social adaptation also favored IPT-A.

In an independent investigation, Rossello and Bernal (1999) compared the efficacy of IPT, “culturally adapted” CBT, with a waitlist control condition in a sample of depressed Puerto Rican adolescents. There was a high rate of attrition, as only 68% and 52% of IPT and CBT-treated subjects completed the 12-session intervention. Using a clinical cut-off on the CDI in completer analyses, 59% of those in the CBT condition and 82% of those treated with IPT achieved a clinically significant improvement by post-treatment. Thus, on some measures of depression and functional status, IPT was superior to CBT.

Effectiveness

Mufson, Dorta, Wickramaratne et al. (2004) tested IPT-A versus usual care in school-based mental health clinics with school social workers delivering both interventions. Those in the IPT-A arm had a brief training in IPT-A and weekly supervision. IPT-A was superior to usual care on dimensional measures of depression, global function, social adjustment and global clinical status (50% versus 33% symptomatically improved). This strongly supports the transportability of IPT-A into community sites.

Predictors of Response and Adverse Events

Mufson, Weissman, Moreau et al. (1999) found that IPT-A was differentiated from clinical monitoring only in those sub-

600
jects who had moderate or severe depression. Improvements in depression were also associated with improvements in social functioning and problem-solving in IPT-A treatment (Mufson, Weissman, Moreau et al., 1999, 2004). In a follow-up analysis of the school-based effectiveness study, comorbid anxiety was found to result in a poorer overall outcome with regard to depression. In the subgroup with comorbid anxiety, the effect size for IPT-A did appear to be larger than the effect size for usual care, although this escaped statistical significance (Young, Mufson, & Davies, 2006), similar to CBT trial results (Brent, Kolko, Birmaher et al., 1998; Rohde, Clarke, Lewinsohn et al., 2001). In one trial, the rate of suicidal events was similar in IPT-A and clinical management (Mufson, Weissman, Moreau et al., 1999).

Prevention of Onset, Relapse or Recurrence

Thus far, there have been no prevention or continuation studies conducted, but one open study showed a high rate of sustained recovery 1 year after receipt of IPT-A (Mufson & Fairbanks, 1996).

Other Available Interventions

The involvement of family factors in the pathogenesis and recurrence of early-onset depression suggests that targeted family interventions aimed at reducing criticism, facilitating treatment of parental depression and increasing protective factors such as support and time spent together may prove to be efficacious. One study did not demonstrate superior efficacy of a systemic behavioral family therapy over supportive therapy (Brent, Holder, Kolko et al., 1997). One small randomized treatment study found that a family intervention that focused on interpersonal attachment, when compared with a minimal contact waitlist control, resulted in a reduction in both depression and anxiety, with sustained improvement on 6-month follow-up (Diamond, Reis, Diamond et al., 2002). One study piloted the additive benefit of “family psychoeducation” to treatment as usual for depressed adolescents (Sanford, Boyle, McCleary et al., 2006). The treatment consisted of 12 90-minute sessions, and provided education about depression and its treatment, enhanced communication skills, family problem-solving,
increasing support and decreased unproductive interactions.
The family treatment resulted in improved social functioning
in the adolescent, improved quality of parent-child relation-
ship and a trend towards greater improvement in adolescent
depressive symptoms.

An open trial of a new psychosocial treatment, Contextual
Emotion-Regulation Therapy (CERT) was reported in 20
chronically depressed prepubertal children (Kovacs, Sherril,
George et al., 2006). CERT focuses on improving the depressed
child’s emotion regulation and coping skills, helping the child
to identify triggers for mood dysregulation, and development
of adaptive coping and problem-solving strategies to improve
mood and overall functioning. Parents are involved as an
“assistant coach,” which also serves to strengthen the parent-
child relationship. In open treatment, which consisted of 30
sessions delivered over 10 months, a very high proportion of
children achieved remission of their depression (80%) and
dysthymia (92%).

Beardslee, Gladstone, Wright et al. (2003) compared clinician-
facilitated 6–11-sessions family psychoeducation with a didactic
intervention for families with a depressed parent and non-
depressed children aged 8–15. Both interventions aimed at
demystifying depression, decreasing guilt and blame, and
building resilience, with the clinician-facilitated intervention
individualizing the intervention to the particular circumstances
of each family. The children in both groups had a decrease
in emotional disturbance, although there were no between-group
differences (Beardslee et al., 2003).

With regard to non-medication somatic treatments, light
therapy has been shown to be beneficial for pediatric seasonal
affective disorder (Swedo, Allen, Glod et al., 1997). One small
randomized trial of depressed children aged 6–12 found that
treatment with omega-3 fatty acids (eicosapentanoic acid and
docosahexanenoic acid) resulted in significant improvement
in depressive symptoms, with effects comparable to those for
SSRIs (Nemets, Nemets, Apter et al., 2006). Although electro-
convulsive therapy (ECT) has not been rigorously studied in
adolescent depression, there is general clinical consensus that
it has a role in the management of early-onset depression that
is refractory to pharmacological and psychosocial management,
particularly for adolescents without significant personality
disorder traits (Walter & Rey, 2003).

Recommendations for Current Best Practice Treatment

Because there is a relatively high response rate to placebo
or brief supportive treatment and education in many of the
published treatment studies, the first approach for mild depres-
sion should be family education, supportive counseling, case
management and problem-solving (Birmaher & Brent, 2007;
Bridge, Iyengar, Salary et al., 2007; Goodyer, 2006; NICE,
2005; Renaud, Brent, Baugher et al., 1998). For more persistent
or severe depression, one of the three empirically validated
treatments, SSRI medication, CBT or IPT, is indicated. Current
US guidelines recommend initial treatment with any of the three
treatments for moderate depression, with the choice informed
primarily by patient preference and the availability of local
expertise. The British guidelines vary slightly in so far as they
recommend use of an indicated psychotherapy for moderate
to severe depression for 3 months prior to initiation of an
antidepressant medication. They also emphasize that medica-
tion should not be given without concomitant psychotherapy.

Both sets of guidelines recommend continuing a given
 treatment for at least 6–8 weeks, assessing response to treat-
ment and, if the patient is not responding, consider combi-
nation of psychotherapy and medication, a dose adjustment
or switch in medication, or a medication augmentation strat-
egy (Birmaher & Brent, 2007; NICE, 2005).

The extant evidence suggests that more generic psychother-
apies practiced in the community may not be helpful in the
treatment of youth depression (Brent, Holder, Kolko et al.,
1997; Weersing & Weisz, 2002; Weisz, McCarty, & Valeri,
2006; Wood, Harrington, & Moore, 1996). In the absence
of available specialized psychotherapy, or in the face of a
patient’s disinclination to engage in psychotherapy, use of an
antidepressant as a first-line intervention is indicated. Some
evidence suggests that for more severely depressed adolescents,
particularly those with difficulties with motivation, concentra-
tion, sleep and appetite, medication should be a first-line
 treatment (Curry, Rohde, Simons et al., 2006; Goodyer, 2006).
In adults, combination of psychotherapy and medication is
superior to either monotherapy in chronic and severe depres-
sion, although the support for the use of combined treatment
in younger populations is more modest (Clarke, Debar, Lynch
et al., 2005; Goodyer, 2006; Keller, McCullough, Klein et al.,
2000; March, Silva, Petrycki et al., 2004; Thase, Greenhouse,
Frank et al., 1997). Relative contraindications for use of
antidepressant medication are a history of mania or hypomania,
when mood stabilization should be undertaken prior to the
use of antidepressants, and for those with a strong family his-
tory of bipolar disorder, for whom it may be safer to begin
with psychotherapy for the same reasons.

Given that the most evidence for efficacy exists for fluoxet-
ine, this should be a first-line medication. For those who have
failed to respond to fluoxetine, cannot tolerate it or for some
reason do not wish to take it, use of one of the other SSRIs
for which there is some evidence of efficacy is warranted.
Current clinical recommendations are to begin with half the
usual initial target dose (e.g., 10 mg fluoxetine) for 1 week, to
determine if the patient can tolerate the medication, and then
increase to 20 mg for the next 3 weeks. If the patient is still
depressed, then one can continue to increase the dosage around
every 4 weeks because it takes around that amount of time to
tell if an increase is going to be helpful (Nierenberg, McLean,
Alpert et al., 1995). Most patients who respond to fluoxetine
achieve symptomatic relief at 20–80 mg fluoxetine. Once symp-
tomatic relief has been achieved, treatment should continue
for a minimum of 6–12 months in order to prevent relapse.

If a patient fails to respond to a fluoxetine at an adequate
dose and duration (i.e., around 40–80 mg), then it is reasonable
to switch to another SSRI. However, it is important to rule out reasons for continued depression such as rapid drug metabolism, non-compliance, severe family conflict, parental depression, covert substance abuse or the influence of other comorbid conditions, such as OCD, ADHD or anxiety, an undiagnosed mixed state, psychosis, or medical illness, such as hypothyroidism. There are no empirical studies in adolescents to guide clinicians for patients who have failed to respond to an SSRI, although clinical guidelines based upon expert consensus exist (Birmaher & Brent, 2007; Hughes, Emslie, Crismon et al., 1999). However, based on clinical consensus and some studies in adults, if one has obtained a partial response, it is reasonable to augment with lithium, another anti-depressant such as amfebutamone, or one of the empirically supported psychotherapies. If one has obtained no response, a reasonable second step is to switch to a second SSRI, or to add psychotherapy. If after treatment with a second SSRI there is still complete non-response, most clinicians recommend using a different class of medication, such as venlafaxine, amfebutamone or lamotrigine (Birmaher & Brent, 2007).

**Future Clinical and Research Challenges**

Depression in childhood and adolescence is a complex and debilitating disease that frequently has a lifelong chronic recurrent course. In this concluding section, we focus on the unknowns of youth depression and suggest several key areas for future investigation.

**Genetic and Environmental Determinants of Unipolar Depression**

Adolescent depressive symptomatology is highly familial, with genetic and non-shared environmental factors each contributing half of the variance for familial occurrence. Future work should focus on identification of clinical endophenotypes (chronic depression, anxiety plus depression, “neuroticism”) and those determined by laboratory measures (e.g., neurocognitive measures of emotional information processing and brain correlates thereof) that may help to more precisely map genes onto behavior. Moreover, it is critical that future research recognizes the importance of gene × environmental interactions, including seemingly environmental factors (e.g., life events) that in fact are genetically influenced. With a greater understanding of genetics, we can identify youth at risk, and use our knowledge of environment and gene × environment interaction to attenuate familial transmission.

**Neurobiology of Depression**

Functional neuroimaging shows promise of being able to delineate brain regions and circuitry most closely implicated in depressive onset and recovery, thereby helping to clarify both the clinical phenotype and potential targets for prevention and treatment. Neuroimaging studies of youth at high risk for depression may help to better identify the biological and genetic factors involved in the onset of depressive illness. Genetic neuroimaging, in which functional MRI (fMRI) tests the effects of genotype in moderating response to a specific probe, may be a particularly promising approach (Hariri, Mattay, Tessitore et al., 2002). Moreover, neurobiological effects may not only be genetic, but be caused by early adversity or continued stress, including continued depression.

**Matching Patients to Treatments**

The approach to the treatment of pediatric depression is currently determined more by the comfort and expertise of the clinician than the patient profile, in part because of the lack of knowledge about how patient characteristics should inform treatment approach. Future studies should attempt to take what is known about treatment response to see if addressing those issues (e.g., comorbidity, parental depression) can actually improve treatment outcome. Remarkably, no studies have examined the relationship of drug level and metabolites to treatment outcome in any pharmacological clinical trial, which means that non-response and non-compliance cannot be distinguished. One possible promising measure for SSRI action is a measurement of platelet receptor serotonin reuptake inhibition. Moreover, future investigations should harness advances in genetics and neuroscience to predict individual differences in treatment response. More specifically, future studies should examine the relationship between candidate gene polymorphisms and treatment response, controlling for pharmacokinetic factors. Both pharmacological and psychotherapy studies should examine the impact of treatment on neurocognitive and neuroimaging measures, which may help elucidate mechanisms of action and also provide some clues as to how to further boost outcome.

**Incomplete Symptomatic and Functional Recovery**

In the TADS study, as is true in other pharmacological and psychotherapy trials, a very high rate of continued depressive symptoms and functional impairment was reported at the end of 12 weeks of treatment across treatments (Brent, Holder, Kolko et al., 1997; Emslie, Rush, Weinberg et al., 1997; Kennard, Silva, Vitiello et al., 2006; Vitiello, Rohde, Silva et al., 2006). While patients may continue to improve with time, the rate of incomplete recovery is high, which in turn increases the risk for another depressive episode, as well as interpersonal difficulties, educational underachievement, substance abuse, suicidal behavior and other health risk behaviors. There appear to be some common family and social factors that protect against most of these outcomes. Can a parsimonious treatment package such as “Well-Being Therapy” used by Fava in adults, be developed to improve overall functional outcome for depressed youth that increases these protective factors (Fava, Ruini, Rafanelli et al., 2005)?

**Management and Prevention of Suicidal Behavior**

The most serious correlates of depressive disorder are suicidal ideation and behavior, which in depressed patients are associated with greater severity, chronicity and comorbidity (Lewinsohn, Rohde, & Seeley, 1996, 1998). It is an open question as to
whether treatment of depression is sufficient to prevent suicidality or whether additional types of interventions are required, because reductions in depression and in suicidality do not always occur together (Harrington, Kerfoot, Dyer et al., 1998b; Wood, Trainor, Rothwell, Moore et al., 2001). However, patients with serious suicidality are often excluded from clinical trials, and suicidal outcomes are not often reported. Interventions, including those that involve the treatment of depression, can only be evaluated with regard to their impact on suicidal risk if patients at high suicidal risk are admitted to such studies. The design of studies that meet human subject standards is an important step to addressing this pressing issue. Our ability to predict and influence suicidality is particularly salient, given current concerns about suicidal adverse events in SSRI treatment. It is important to better understand the clinical, pharmacokinetic, pharmacogenetic and neurocognitive predictors of suicidal adverse events in youth treated with SSRIs.

**Treatment of Prepubertal Depression**

Currently, there are no established psychological approaches to prepubertal depression. Moreover, because in some studies the response to medication in pre-adolescent children was less vigorous than in adolescents, the role of antidepressants and psychological treatments needs focused evaluation in younger children.

**Treatment of Bipolar Depression, and Youth At Risk for Bipolar Disorder**

The pharmacological management of depression in youth at risk for bipolar disorder carries with it a risk for inducing a mixed or manic state, yet, at the same time, depressive symptoms are a considerable source of the morbidity of this condition. Research should address pharmacological and psychosocial approaches to the management of depression in those at risk for bipolar disorder, including identification of clinical, genetic and neurocognitive predictors of manic switch.

**Early Intervention and Public Health Interventions**

Convergent evidence supports the view that the more chronic the depression, the more difficult it becomes to treat. Yet tertiary care mental health is not equipped to facilitate early identification and intervention, because of inadequate capacity and other barriers to access such as stigma. Consequently, capacity for treatment of children at earlier stages of risk and disorder needs to be developed in other sectors, such as primary care and school-based mental health services. The cost-effectiveness of interventions delivered in alternative settings should be studied.

Another key factor in reducing the public health burden of depression likely will be the efficient dissemination of our best practice models to the youth health and education systems. As discussed on p. 593, there are still very few data on the effectiveness of SSRIs, CBT and IPT when delivered in actual practice settings. The data that are available on CBT and IPT are promising, suggesting that bringing these research-based psychosocial interventions to the community may substantially improve on current models of depression care. Similar data are not available for the SSRIs, despite the fact that SSRI prescriptions are dramatically more prevalent and are more available in community settings than either of the empirically based psychosocial interventions. In the adult literature, there is a growing evidence base on the efficacy and cost-effectiveness of relatively brief psychosocial, antidepressant and combined treatments for mild to moderate depression, delivered in settings such as primary care, that may serve as models for future investigations in younger populations (Katon, Unutzer, & Simon, 2004).

**Decreasing the Public Burden of Depression**

Two extreme views with regard to decreasing the public health burden of early-onset depression are well articulated by Harrington and Clarke (1998): on the one hand, focus the bulk of resources on the relatively small number with moderate to severe disease, or, alternatively, provide preventive intervention to those who are at risk or mildly depressed. From a public health point of view, the impairment burden on the population is mostly from “subsyndromal depression,” so that a small reduction in depressive symptoms in a large number of people may indeed benefit more people. Horowitz and Garber (2006), in their meta-analysis, found much greater effect sizes for indicated and selective interventions, but acknowledged that the appropriate metric is really the cost per effect, which may be comparable with a cheaper, less selective intervention that does not involve the costs of screening. Harrington and Clarke (1998) argued that a universal approach that enhances protective factors such as problem-solving, interpersonal skills, family connection and school connection may be more acceptable and have broader impact. Research on the relative utility of these different approaches to prevention on the overall public mental health of youth is warranted.

CHAPTER 37

CHAPTER 37

CHAPTER 37

Bipolar Disorder in Children and Adolescents

Ellen Leibenluft and Daniel P. Dickstein

There has been a recent marked upsurge in interest in pediatric bipolar disorder (PBD), with almost twice as many articles published on the subject in the past 5 years as in the entire previous decade. Several factors may be contributing to this trend. First, while it is clear that relatively few children have a classic adult-like presentation of bipolar disorder (BD), the number of US children being considered for the diagnosis has expanded. Second, studies of children with either classic BD symptoms or the “broad phenotype” suggest that PBD is both markedly impairing and treatment-resistant, increasing the demand for relevant information and research (Biederman, Faraone, Wozniak et al., 2005a; Geller, Williams, Zimerman et al., 2004b; Kowatch, Youngstrom, Danielyan et al., 2005b). Finally, because of increased interest in developmental psychopathology research generally, and the advent of safe and non-invasive techniques for studying brain function in children, PBD is one of several illnesses that have become the focus of pathophysiological research (Rich, Vinton, Roberson-Nay et al., 2006).

We begin by reviewing the available data concerning the clinical presentation of PBD, including its phenomenology and course, and by providing guidelines for the assessment of children who may have PBD. We then describe research on associated illnesses, prodromes and age of onset. Next, we describe pathophysiological studies, including those using behavioral testing, neuroimaging and genetic/familial techniques. Finally, we conclude with a review of the pharmacological and psychotherapeutic treatment of PBD.

Clinical Presentation

Diagnosis, Phenomenology and Course

Most investigators outside the USA, and some inside, use unmodified DSM-IV-TR diagnostic criteria and assessment techniques to assess bipolar disorder in children. These techniques ascertain whether distinct well-defined episodes of mania or hypomania are present. Using such techniques, researchers in Britain find that pre-adolescent mania is exceptionally rare (Harrington & Myatt, 2003). In the USA, researchers have recruited sizable samples of children meeting strict DSM-IV-TR criteria. For example, the Course of Bipolar Youth (COBY) study in the USA recruited 263 children with clearly episodic bipolar illness (Axelson, Birmaher, Strober et al., 2006; Birmaher, Axelson, Strober et al., 2006). Of the children in the COBY study, 92% had euphoria and 84% had irritability, indicating that most youth with PBD have both symptoms. Over 2-year follow-up, patients (n = 152) had mixed mania or rapid cycling 29% of weeks, significantly more than BD adults (Birmaher, Axelson, Strober et al., 2006). In another sample of 90 children with clearly episodic BD, 86% had elevated mood, while 92% had irritability; also, 50% had a rapid cycling course, and periods of euthymia were identifiable but brief (Findling, Gracious, McNamara et al., 2001).

However, in the USA, some recent PBD research has been shaped by case descriptions suggesting that BD presents differently in children than in adults. For example, in response to reports that children with PBD may have very rapid and complex mood cycles, Geller et al. developed a new semistructured interview for PBD (WASH-U-KSADS; Geller, Warner, Williams et al., 1998b; Geller, Williams, Zimerman et al., 1998c), and new conventions for describing cycling patterns. The WASH-U KSADS defines an episode as the entire duration of illness (rather than, as in DSM-IV-TR, a distinct symptomatic period) and defines cycles as mood changes lasting a minimum of 4 hours (Geller, Tillman, Craney et al., 2004b; Tillman & Geller, 2003). Also, given the overlap between symptoms of mania and attention deficit/hyperactivity disorder (ADHD), Geller et al. require that children with mania exhibit either elevated mood or grandiosity (Geller, Warner, Williams et al., 1998b,c). Using these techniques, Geller et al. described a BD sample (n = 86) in which most had mixed mania (88%), irritability (98%), elated mood (90%) and grandiosity (86%) as well as daily cycling (78%) and a mean of 3.5 ± 2.0 cycles/day.

Similarly, Biederman and collaborators were influenced by case series suggesting that children with BD have irritability rather than euphoria, and that the severity of the irritability in PBD differentiates it from other illnesses. Thus, when assessing irritability, these investigators inquire about extremely
imparing and severe irritability (“super angry, grouchy, or cranky”). If such irritability is endorsed, then they consider the DSM-IV-TR episodicity criterion to be met, even if the irritability does not represent a distinct change from the patient’s usual level of function (Mick, Spencer, Wozniak et al., 2005). Using these techniques, Biederman et al. found that only 33% of children (n = 129) had euphoria while manic (considerably fewer than in the COBY study or Findling, Gracious, McNamara et al., 2001), while 92% had irritability (Biederman, Faraone, Wozniak et al., 2005a).

Overall, four conclusions can be drawn from the literature on the phenomenology and course of PBD. First, descriptions of the “typical” bipolar child vary markedly across studies (Kowatch, Youngstrom, Danielyan et al., 2005b), probably because of different assessment techniques. The adoption of standard diagnostic procedures would facilitate future research, allowing comparisons among pediatric studies and, if adult procedures are used, with the rich clinical literature on adult BD. Second, data from the COBY study and Findling, Gracious, McNamara et al. (2001), obtained using diagnostic techniques comparable to those used in adults, contradict frequent statements in the literature that children with BD do not have euphoria, because almost all patients in these studies experienced euphoria, in addition to irritability (Axelson, Birmaher, Strober et al., 2006; Findling, Gracious, McNamara et al., 2001). On the other hand, several studies indicate that mixed states may be more common in youth versus adults with BD (Birmaher, Axelson, Strober et al., 2006; McElroy, Strakowski, West et al., 1997; Patel, DelBello, Keck et al., 2006). This developmental difference may reflect reporting bias (i.e., when assessing children, parents are also interviewed; irritability is more salient to others than to the patient him/herself), or the fact that children are unable to use coping strategies that hypomanic or manic adults often employ to avoid having their manic goals thwarted (e.g., skipping work/school, not going to bed).

Third, studies support the contention that early-onset BD is associated with high episode frequency (Birmaher, Axelson, Strober et al., 2006; Findling, Gracious, McNamara et al., 2001; Lin, McInnis, Potash et al., 2006; Perlis, Miyahara, Marangell et al., 2004). However, the data do not indicate that children with BD have a non-episodic illness, because several investigators have recruited sizable samples of children with clearly defined episodes meeting DSM-IV duration criteria (Birmaher, Axelson, Strober et al., 2006; Dickstein, Nelson, McClure et al., 2007; Findling, Gracious, McNamara et al., 2001). Finally, consistent with the observation that children tend to cycle more frequently than adults with BD, all studies agree that PBD is a very impairing illness, leaving affected children symptomatic most of the time.

Assessment and Differential Diagnosis
Whereas investigators use a variety of techniques to diagnose PBD, there are advantages to using those that parallel the adult literature, albeit with developmentally appropriate thresholds. Thus, the interviewer should ask child and parent to identify episodes, lasting at least several days, during which the child had a distinct change in mood and became either euphoric, markedly irritable or depressed. Importantly, even an adult with classic euphoric mania is not euphoric 24 hours a day; therefore, symptoms present most of the day should be considered to be at threshold.

Once episodes are identified, the interviewer should inquire whether the DSM-IV-TR “B” symptoms of mania or depression (e.g., sleep and activity changes, increased distractibility) occurred concurrent with mood changes. If the family cannot identify distinct episodes, then the appropriateness of the diagnosis of BD is called into question. Euphoria should exceed that which a typically developing child would experience in a very exciting situation, such as going to Disneyland, and true grandiosity should be distinguished from developmentally appropriate fantasy or oppositional behavior. Grandiosity or euphoria should represent a distinct change from the child’s usual level of function, and should occur at the same time as other symptoms of mania (e.g., decreased need for sleep, increased goal-directed activity). Decreased need for sleep should be differentiated from more typical insomnia, in which youth would prefer to sleep and may nap during the day.

When manic symptoms are occurring, it is best for caretakers to bring the child to the clinic, to allow clinicians to observe behaviors first-hand. While the DSM-IV-TR diagnosis of Bipolar Disorder Not Otherwise Specified (BP-NOS) has been used in a number of clinical situations, it is best reserved for children who have distinct episodes that fail to meet the criteria for a manic episode because they are shorter than 4 days (see p. 615; Birmaher, Axelson, Strober et al., 2006).

When assessing associated illnesses, clinicians should diagnose such illnesses only if symptoms are present when the patient is not in an acute mood episode (Axelson, Birmaher, Strober et al., 2006; Dickstein, Rich, Binstock et al., 2005b). For example, a child with BD should be diagnosed with ADHD only if ADHD symptoms are present when he or she is euthymic or subsyndromally ill. Conversely, for a symptom such as distractibility to count toward the diagnosis of mania in a child with ADHD, the distractibility must worsen significantly during the putative manic episode.

Attempting to differentiate unipolar from bipolar depression is extremely important, because the treatment for the two conditions in adults differs. Careful interviewing to ascertain possible past hypomanic or manic symptoms is therefore essential. While a family history of BD is contributory, children should be treated on the basis of their own clinical presentation, not solely on the basis of family history. ADHD can be distinguished from mania in that children with ADHD alone do not have distinct episodes of mood change accompanied by DSM-IV-TR “B” criteria of mania. Similarly, BD youth with associated ADHD and oppositional defiant disorder (ODD) may have severe irritability, but irritability resulting from ADHD or ODD is distinct from manic irritability in that only the latter occurs, or worsens, during distinct time periods that last days or weeks and during which “B” mania criteria also occur. Therefore, using these techniques, the
of narrow and broad phenotypes of PBD may differ (Rich, Cohen, Gorrindo)

depressive disorder (MDD) in early adulthood (Leibenluft, Cohen, Gorrindo)
resembling those of mania. Substance abuse disorders have received little attention, although one study found that 32% of adolescents with BD (n = 57) also had a substance use disorder (Wilens, Biederman, Kwon et al., 2004).

 Associated Illnesses
In all studies of PBD, associated illnesses are common, especially ADHD, anxiety disorders and ODD. Distractibility, hyperactivity and restlessness are symptoms of both ADHD and mania, and investigators consistently report that more than 70% of children with PBD also have ADHD (Axelson, Birmaher, Strober et al., 2006; Dickstein, Rich, Binstock et al., 2005b; Findling, Gracious, McNamara et al., 2001; Geller, Tillman, Craney et al., 2004b; Wozniak, Biederman, Kiely et al., 1995). It has been suggested that there is a familial association between ADHD and early-onset BD (Faraone, Biederman, Mennin et al., 1997). Rates of other associated illnesses in PBD vary widely. Those of ODD range from 46% (Axelson, Birmaher, Strober et al., 2006) to over 80% (Biederman, Faraone, Wozniak et al., 2005a), while those of conduct disorder (CD) range from 12% (Axelson, Birmaher, Strober et al., 2006) to 41% (Biederman, Faraone, Chu et al., 1999); higher rates are reported by investigators who view irritability as particularly characteristic of PBD. Rates of anxiety disorders range from 14% (Findling, Gracious, McNamara et al., 2001) to 76% (Harpol, Wozniak, Kwon et al., 2005). Substance abuse disorders have received little attention, although one study found that 32% of adolescents with BD (n = 57) also had a substance use disorder (Wilens, Biederman, Kwon et al., 2004).

Age of Onset
Two large epidemiological studies of BD adults report a median onset age of 18 (Christie, Burke, Regier et al., 1988) or 25 years (Kessler, Chiu, Demler et al., 2005). However, studies indicate that BD age of onset is not distributed normally, with two recent studies (Bellivier, Golmard, Rietschel et al., 2003; Lin, McInnis, Potash et al., 2006) each reporting three peaks of onset age. Early onset may be familial (Leboyer, Bellivier, McKeon et al., 1998; Lin, McInnis, Potash et al., 2006) and/or associated with a strong family history of BD (Bellivier, Golmard, Henry et al., 2001; Chongappa, Kuper, Frank et al., 2003; Johnson, Cohen, & Brook, 2000; Kennedy, Everitt, Boydell et al., 2005).

Clinical Prodromes/Risk Factors
Several longitudinal community-based studies have queried which childhood or adolescent diagnoses are associated with increased risk for later BD. One found that anxiety disorder at age 14 or 16 was associated with BD at age 22 (odds ratio [OR] 5.76; 95% confidence interval [CI], 1.44–22.95; Johnson, Cohen, Brook et al., 2000). Another found that mania at age 26 was associated with depression (OR 3.3; 95% CI, 1.2–9.2) and CD/ODD (OR 2.5; 95% CI, 1.1–5.4) at age 11–15, but not with ADHD (Kim-Cohen, Caspi, Moffitt et al., 2003); the association between adult mania and childhood anxiety was a statistical trend (OR 2.1; 95% CI, 0.9–4.8). Thus, epidemiological samples do not support the contention that ADHD is a risk factor for subsequent BD, although anxiety, depression and CD/ODD may be. Clinical-based follow-up studies of children with ADHD give somewhat more mixed results, although the bulk of the evidence is consistent with the epidemiological data (Biederman, Monuteaux, Mick et al., 2006; Hazell, Carr, Lewin et al., 2003; Mannuzza, Klein, Bessler et al., 1998).

All eight clinical studies (n = 28–83) that followed depressed children into late adolescence or early adulthood find that prepubertal MDD is associated with increased risk for BD (Geller, Zimerman, Williams et al., 2001; Harrington, Fudge, Rutter et al., 1990; Kovalcak, Akiskal, Gatosins et al., 1994; McCauley, Myers, Mitchell et al., 1993; Rao, Ryan, Birmaher et al., 1995; Strober & Carlson, 1982; Strober, Lampert, Schmidt et al., 1993; Weissman, Wolk, Winkramar et al., 1997).
1999). However, the prevalence of BD ranged widely, perhaps because of small sample sizes. Positive family history, psychosis and rapid symptom onset may predict BD (Akiskal, Walker, Pazantian et al., 1983; Geller, Fox, & Clark, 1994; Strober & Carlson, 1982; Strober, Lampert, Schmidt et al., 1993).

Preschoolers

Controversy has surrounded recent American reports suggesting that BD may occur in preschool children (Dilsaver & Akiskal, 2004; Scheffer & Niskala Apps, 2004; Tumuluru, Feller, Fristad et al., 2003; Wilens, Biederman, Brown et al., 2002, 2003). These reports are of particular interest given data indicating a rapid rise in the percentage of US preschoolers receiving psychotropic medication (Zito, Safer, dosReis et al., 2000).

The two largest samples of preschoolers diagnosed with BD (n = 44, Wilens, Biederman, Forkner et al., 2003; n = 31, Scheffer & Niskala Apps, 2004) report very high rates of ADHD (80–95%) and mixed states (i.e., co-occurring manic and depressive symptoms) in approximately 80%. Severe, impairing irritability is ubiquitous in preschoolers diagnosed with BD, and elated mood and grandiosity are also reported, with the caveat that the boundaries of these symptoms in controls or typical preschoolers with ADHD are not well defined, and many case descriptions of preschool mania do not identify the presence of distinct mood episodes. Preschoolers diagnosed with BD tend to have strongly positive family histories (e.g., 70%). Longitudinal follow-up of these children is essential to ascertain the extent to which they meet DSM-IV-TR criteria for BD in adolescence and adulthood.

Clinical Presentation: Summary

The burgeoning research on BD in youth permits some preliminary conclusions about clinical presentation. Research groups who use adult assessment techniques find that children with BD have definable (albeit frequent) episodes that are typically characterized by euphoria mixed with irritability. Research groups using other techniques find either that euphoria is relatively rare, or that distinct episodes cannot be identified. Longitudinal studies will determine whether children ascertained using these alternative techniques develop into adults who fit neatly into the DSM-IV-TR category of BD, have bipolar spectrum illness, exhibit symptoms of another psychiatric illness or have a healthy outcome. As the number of genetic cases ascertained using these alternative techniques develop into adults who fit neatly into the DSM-IV-TR category of BD, have bipolar spectrum illness, exhibit symptoms of another psychiatric illness or have a healthy outcome. As the number of genetic cases ascertained using these alternative techniques develop into adults who fit neatly into the DSM-IV-TR category of BD, have bipolar spectrum illness, exhibit symptoms of another psychiatric illness or have a healthy outcome. As the number of genetic cases who meet DSM-IV-TR criteria for BD in adolescence and adulthood.

Pathophysiology

Behavioral Data

Some behavioral paradigms assess traditional neuropsychological domains to determine a patient’s level of cognitive function or gain clues to pathophysiology. Such data indicate that youth with BD, like BD adults, have trait-related deficits in verbal memory and sustained attention (Doyle, Wilens, Kwon et al., 2005; McCarthy, Arrese, McGlashan et al., 2004; McClure, Trelad, Snow et al., 2005a; Pavuluri, Schenkel, Aryal et al., 2006), although there are some negative studies of sustained attention (DelBello, Zimmerman, Mills et al., 2004b; McCarthy, Arrese, McGlashan et al., 2004; Robertson, Kutcher, & Lagace, 2003). Deficits have also been identified in working memory (Doyle, Wilens, Kwon et al., 2005; Pavuluri, Schenkel, Aryal et al., 2006) and mathematical skill (Lagace, Kutcher, & Robertson, 2003).

Other behavioral studies are aimed at elucidating the neural circuitry mediating PBD. These paradigms assess emotional function (e.g., by measuring responses to reward, punishment or emotional faces) and find three specific deficits in BD youth. First, they have difficulty adapting their behavior to changes in reward contingencies (i.e., selecting a novel stimulus when the previously rewarded one begins to lose, rather than win, points; Dickstein, Trelad, Snow et al., 2004; Gorrindo, Blair, Budhathi et al., 2005; McClure, Trelad, Snow et al., 2005b). This deficit is reminiscent of parents’ complaints that patients will not stop one activity and switch to another when appropriate. Deficits in response flexibility may be relevant to the pathophysiology of BD in that response inflexibility, present during euthymia, may be a forme fruste of the more marked response inflexibility seen when bipolar patients are acutely ill. That is, when patients with BD are depressed or manic, they have marked deficits in their ability to respond appropriately to emotional rewarding stimuli, as evidenced by the anhedonia present during depression and the hyperhedonia characteristic of mania.

Prevalence

Cross-national epidemiological studies of adults find a lifetime prevalence rate of 1–3% for BD (Kessler, Chiu, Demler et al., 2005; Lasch, Weissman, Wickramaratne et al., 1990; ten Have, Vollebergh, Bijl et al., 2002; Weissman, Bland, Canino et al., 1996). In youth, community-based studies find low rates of BD. Lewinsohn et al. found that 1.1% of adolescents (n = 1507) met the criteria for BD, while 2.1% of a subset reassessed at age 24 (n = 893) did so (Lewinsohn, Klein, & Seeley, 1995, 2000; Lewinsohn, Seeley, Buckley et al., 2002). A second study (n = 1015, 9–13 years) found no manic cases and a 3-month prevalence of 0.10 ± 0.06% for hypomania (Costello, Angold, Burns et al., 1996), while a third (n = 717) found that the 12-month prevalence of BD was 1.9% in patients assessed at ages 14 ± 3 years and 16 ± 3 years (Johnson, Cohen, & Brook, 2000). Finally, a twin sample enriched for ADHD (n = 1610, 7–18 years), found a BD prevalence of 0.2% (Reich, Neuman, Volk et al., 2005).
et al., 2005). In patients with BD, the adverse impact of emotion on attention may contribute to their inability to label emotions properly. Future study will elucidate the neural circuitry of these deficits and possible associations between abnormal processing of emotional stimuli and core features of BD, such as switching mood states.

**Neuroimaging**

**Structural Magnetic Resonance Imaging**

By far the most replicated structural magnetic resonance imaging (MRI) finding in PBD is significantly decreased amygdala volume compared to controls (Blumberg, Kaufman, Martin et al., 2003; Chang, Karchemsky, Barnea-Goraly et al., 2005; DelBello, Zimmerman, Mills et al., 2004b; Dickstein, Milham, Nugent et al., 2005a). Because structural MRI studies of BD adults have reported both increased and unchanged amygdala volume (Altshuler, Bartzokis, Grieder et al., 1998; Altshuler, Bartzokis, Grieder et al., 2000; Brambilla, Harenki, Nicoletti et al., 2003; Pearlson, Barta, Powers et al., 1997; Strakowski, DelBello, Sax et al., 1999), decreased amygdala volume may represent a marker of childhood-onset BD, although further work is needed to determine the effects of development, gender, medications and comorbidity on amygdala size. Individual studies suggest possible differences between patients with PBD and controls in other brain regions (e.g., prefrontal cortex and striatum), but the literature is less consistent (for reviews see Blumberg, Charney, & Krystal, 2002; Pakrasi, Milham, Nugent et al., 2005a). Because structural MRI studies of BD adults have reported both increased and unchanged amygdala volume (Altshuler, Bartzokis, Grieder et al., 1998; Altshuler, Bartzokis, Grieder et al., 2000; Brambilla, Harenki, Nicoletti et al., 2003; Pearlson, Barta, Powers et al., 1997; Strakowski, DelBello, Sax et al., 1999), decreased amygdala volume may represent a marker of childhood-onset BD, although further work is needed to determine the effects of development, gender, medications and comorbidity on amygdala size. Individual studies suggest possible differences between patients with PBD and controls in other brain regions (e.g., prefrontal cortex and striatum), but the literature is less consistent (for reviews see Blumberg, Charney, & Krystal, 2002; Pakrasi, Milham, Nugent et al., 2005a).

**Functional Magnetic Resonance Imaging**

Functional MRI (fMRI) allows investigators to quantitatively assess neural activation while subjects perform tasks engaging specific psychological processes. For example, investigators study the neural mechanisms mediating patients’ impulsivity and attention by using fMRI tasks requiring motor inhibition or the ability to direct one’s attention away from distracting stimuli. These studies indicate striatal dysfunction in PBD. For example, Blumberg, Kaufman, Martin et al. (2003) found increased striatal activation in BD adolescents, compared to controls, during a Stroop paradigm of cognitive interference. Using a motor inhibition task, Leibenluft, Rich, Vinton et al. (2007) found that, compared to controls, PBD subjects had a reduced striatal “error signal” during failed motor inhibition (Leibenluft, Rich, Vinton et al., 2007), a deficit that might contribute to the patients’ inability to inhibit effectively.

In an fMRI study building on the finding that children with PBD have face emotion identification deficits (McClure, Trelain, Snow et al., 2005a), Rich, Vinton, Roberson-Nay et al. (2006) found that PBD subjects viewed neutral faces as more hostile and feared these faces more than did controls, and that these between-group differences in ratings were associated with increased amygdala and striatal activation in PBD versus control youth (Rich, Vinton, Roberson-Nay et al., 2006). Interestingly, whereas both children with PBD and those with anxiety disorders exhibit amygdala dysfunction during this fMRI task (relative to controls), the precise nature of that dysfunction varies among diagnoses (McClure, Monk, Nelson et al., 2007). It will be important for future work to compare the pathophysiology of PBD with that of other mood disorders, as well as with ADHD.

**Magnetic Resonance Spectroscopy**

Magnetic resonance spectroscopy (MRS) research in BD has focused on N-acetyl aspartate (NAA), an intraneuronal marker whose levels are decreased in neuropathology, and myo-inositol (mI), an intracellular second messenger, thought to be overabundant in mania, whose levels are decreased by lithium (Moore, Bebcuk, Parrish et al., 1999; Silverstone, Wu, O’Donnell et al., 2002). Youth with familial BD (Chang, Adleman, Dienes et al., 2003), and adults with BD (Winsberg, Sachs, Tate et al., 2000), have significantly decreased NAA in the dorsolateral prefrontal cortex compared to controls and, in one study, lithium treatment was associated with increased NAA in a sample of adult controls and BP patients (Manji, Moore, & Chen, 2000; Moore, Bebcuk, Hasanan et al., 2000). In BD youth, olanzapine treatment resulted in significantly greater medial ventral prefrontal cortex NAA in remitters (n = 11, 58%) versus non-remitters (n = 8, 42%); DelBello, Cecil, Adler et al., 2006). Studies also indicate that PBD subjects have increased anterior cingulate cortex (ACC) mI compared to healthy controls or youth with intermittent explosive disorder (Davanzo, Yue, Thomas et al., 2003). Moreover, 7 days of lithium treatment significantly decreased mI in the ACC, and this decrease was more prominent in lithium responders than in non-responders (Davanzo, Thomas, Yue et al., 2001). Together, these MRS studies suggest that PBD may be characterized by specific neurochemical alterations that respond to psychopharmacological treatment; future work in this area may ultimately inform such treatment.

**Diffusion Tensor Imaging**

Diffusion tensor imaging (DTI) is an emerging neuroimaging technique used to study the integrity of white matter tracts. A DTI study found that adolescents experiencing their first manic episode have less fractional anisotropy in the prefrontal cortex than controls, indicating disruption of white matter tracts (Adler, Adams, DelBello et al., 2006). Future DTI studies, in combination with MRS and structural and functional MRI studies, may allow investigators to define more precisely the causes of neural dysfunction in youth with PBD.

**Familial Risk and Genetics**

**Children At Risk for Bipolar Disorder**

Compared to children without a first-degree relative with BD, those with such a relative are at an approximately 10-fold increased risk for BD (Hodgins, Faucher, Zarac et al., 2003; Kelsoe, 2003; Smoller & Finn, 2003). Twin studies suggest that the heritability of BD in adults is greater than 60%, with greater concordance for BD in monozygotic (60–70%) than dizygotic twins (20–30%) (Bertelsen, Harvald, & Hauge, 1977; Smoller & Finn, 2003).
CHAPTER 38

The clinical status and neurocognitive function of children with a first-degree relative with BD are of considerable interest. Six studies with n > 50 have assessed children recruited through their parents with BD (Carlson & Weintraub, 1993; Chang, Steiner, & Ketter, 2000; Grigoroiu-Serbanescu, Christodorescu, Jipescu et al., 1989; Henin, Biederman, Mick et al., 2005; Hillegers, Reichart, Wals et al., 2005; Wals, Hillegers, Reichart et al., 2001). All find very high rates of psychopathology in these youth, with 44–63% meeting criteria for at least one DSM-IV-TR diagnosis, including ADHD, anxiety disorder, MDD and/or PBD.

Molecular Genetics

Currently, much research aims to identify genetic mechanisms underlying the increased familial risk for BD. Studies implicate a number of genetic regions in the transmission of adult BD (Hayden & Nurnberger, 2006; Kelsoe, 2003), with a focus on 6q21–q25 having perhaps the strongest evidence (McQueen, Devlin, Faroane et al., 2005). Candidate gene studies implicate the genes coding for brain-derived neurotrophic factor (BDNF) perhaps especially in rapid-cycling BD (Green, Raybould, Maggregor et al., 2006) and DAOA(G72)/G30. However, it is clear that all conclusions must be considered tentative in the absence of replication, because the genetics of BD are complex, with multiple genes involved and no one gene of main effect (Kelsoe, 2003). In addition, recent research indicates that there may be significant overlap between the genes conferring risk for BD and those implicated in schizophrenia (Cradock & Forty, 2006; Kelsoe, Spence, Loetscher et al., 2001). Other studies implicating dopaminergic genes (e.g., the dopamine transporter gene [DAT] on chromosome 5p; Keikhaee, Fadai, Sargolzaee et al., 2005) in both ADHD and BD may be of particular interest in PBD, given the strong association between ADHD and early-onset BD (Geller, Williams, Zimerman et al., 1998c; Wilens, Biederman, Forkner et al., 2003). In PBD, three genetic studies have been conducted, with one finding that the val66 allele of the BDNF gene on chromosome 11p was preferentially transmitted in PBD (n = 53 trios; Geller, Badner, Tillman et al., 2004a).

Treatment

Clinicians attempting to prescribe evidence-based treatment for PBD are confronted by a dearth of randomized placebo-controlled trials (RCTs) that precludes designating any psychopharmacological or psychotherapeutic treatment as having "strong" evidentiary support. RCTs are essential because placebo response rates range 10–50% in both acute and maintenance treatment trials of adult mania (Keck, Welge, McElroy et al., 2000a,b). In fact, fewer than 10 published placebo-controlled RCTs have been conducted in pediatric BD. Given the paucity of pediatric data, clinicians often rely on data from adult BD; hence, we summarize briefly the most relevant adult data. However, caution is urged in basing treatment on adult data, because youth sometimes respond differently from adults, as in major depression (Hazell, O’Connell, Heathcote et al., 1995).

We discuss both psychopharmacological and psychotherapeutic approaches to PBD. Again, the lack of systematic data precludes firm recommendations as to how these two modalities should be prioritized, although it is likely that both modalities will ultimately prove to be important in the treatment of PBD. Our discussion focuses on children clearly meeting DSM-IV-TR criteria for bipolar disorder who, like adults with the illness, are typically too severely impaired to benefit from psychotherapeutic approaches. Without initial stabilization with pharmacotherapy, this is the population that is generally targeted in RCTs of medications. In children exhibiting the "broad phenotype" of PBD (see p. 615), whose major presenting problem is non-episodic irritability, psycho-social approaches, including interventions with the child, family and school environment, may be particularly important.

Generally, clinicians should focus treatment on the most acute and disabling aspects of BD (e.g., acute mania, depression, psychosis, substance abuse, suicidality; Fig. 38.1). Later treatment addresses other problems (e.g., comorbid anxiety, ADHD, substance abuse, deficient social skills). Treatment decisions require collaboration among physicians, patients and families to identify target symptoms, educate about side-effects, and evaluate each treatment’s efficacy. Daily ratings of target symptoms by parents and/or patients allow treatment to be based upon prospective, rather than retrospective, data.

Ideally, medication trials should be at least 6–8 weeks long, with only one new agent added at a time. However, this approach may not be feasible in acutely manic or psychotic patients. Physicians should assess continuously the need for each medication to determine whether any can be discontinued. Moreover, as noted above, symptoms do not typically resolve on medication alone; rather, comprehensive treatment usually requires both psychopharmacology and psychotherapy. Finally, treatment must develop in synchrony with a child’s illness, because acute and maintenance interventions differ.

Psychopharmacology for Pediatric Bipolar Disorder

Pharmacotherapy of Mania

Mania should be the initial treatment focus in BD, because antimanic medications not only reduce manic symptoms but may also prevent activation secondary to antidepressants or psychostimulants. Currently available antimanic medications include:

1 Lithium;
2 Antiepileptic medications (AEDs, e.g. valproate and carbamazepine); and
3 Atypical antipsychotic medications (Fig. 38.1).

In general, relatively weak support exists concerning the efficacy of any of these agents in PBD. This complicates efforts to select any one agent as a first-line treatment and again emphasizes the importance of thorough discussions with patients and their families concerning the available data on each agent’s efficacy and safety. In our discussion of each medication, we focus
on efficacy in BD, and only mention side-effects of particular interest; readers are also referred to other references for dosing guidelines and a more thorough discussion of side-effects (Correll, Penzner, Parikh et al., 2006; Kowatch, Fristad, Birmaher et al., 2005a).

Lithium
Support for lithium’s utility in PBD is mixed. Among the three categories of medications typically used in PBD, efficacy data are stronger for lithium than for the AEDs but weaker than for the atypical antipsychotics. Similarly, in terms of safety data, lithium should probably also be placed in an intermediate category relative to these two other treatments.

While lithium is the only medication with a US Food and Drug Administration (FDA) indication for the treatment of mania in patients as young as 12 years, this indication was granted at a time when FDA decisions for children were based largely on adult data. If lithium efficacy data were reviewed today, an FDA indication would not be granted because of the lack of two large placebo-controlled RCTs to demonstrate efficacy. Nevertheless, given the data from open trials, small studies, etc., and the extensive efficacy data in adults with BD, it is reasonable to prescribe lithium for youth with PBD.

One small parallel-group placebo-controlled RCT examined the use of lithium in a heterogeneous group of 25 patients with substance abuse and either DSM-III-R BD, or MDD plus at least one feature associated with elevated risk for BD (e.g., BD in a first-degree relative; Geller, Cooper, Sun et al., 1998a).

On global response ratings, 46.2% of patients responded to lithium versus 8.3% to placebo, but lithium had no specific benefit for mood symptoms (Geller, Cooper, Sun et al., 1998a). Another study (Kafantaris, Coletti, Dicker et al., 2004) used a discontinuation design, whereby acutely manic adolescents (n = 108) were treated with lithium openly before randomization to either continued lithium treatment or placebo. Consistent with other trials (Findling, Gracious, McNamara et al., 2001; Kafantaris, Coletti, Dicker et al., 2003; Kowatch, Suppes, Carmody et al., 2000), 42% of patients responded to open lithium treatment. However, the blinded discontinuation trial found no difference between lithium and placebo, with a relapse rate greater than 50% in both groups.

In adults, there is robust evidence for the efficacy of lithium in adult acute mania (Bowden, Brugger, Swann et al., 1994, 2005; Small, Klapper, Milstein et al., 1991) and long-term prophylaxis (Bowden, Calabrese, Sachs et al., 2003). Longterm lithium treatment also appears to reduce suicide risk in adult BD (Cipriani, Pretty, Hawton et al., 2005; Goodwin, Fireman, Simon et al., 2003).

Adult studies suggest that optimal lithium levels are between 0.6 and 1.0 mEq/L for acute mania and down to 0.4 mEq/L for maintenance treatment, but this has not been tested rigorously in youth (Gelenberg, Kane, Keller et al., 1989; Keller, Lavoi, Kane et al., 1992; Stokes, Shamoian, Stoll et al., 1971). Of note, an MRS study showed that PBD youth (n = 9) had lower brain/serum lithium concentrations than BD adults (n = 18; Moore, Demopoulos, Henry et al., 2002), suggesting that PBD

Fig. 38.1 Pediatric bipolar disorder psychopharmacology algorithm. After Kowatch et al. (2005a).
patients, compared to adults with the illness, may require higher doses of lithium to achieve the same brain concentration of lithium. However, the clinical implications of this finding have not been studied systematically.

**Antiepileptic Drugs**
Relative to lithium or atypical antipsychotic medication, support for the therapeutic efficacy of the AEDs in PBD is weakest. However, because many AEDs are used in pediatric epilepsy, considerable data exist concerning long-term effects in children (de Silva, MacArdle, McGowan et al., 1996). The safety data for AEDs is generally strong, with the exception of questions regarding acute hepatic or pancreatic failure and possible adverse effects on female gonadal function (see below).

Data from RCTs fail to demonstrate the benefits of AEDs in pediatric BPD. First, DelBello, Findling, Kushner et al. (2005) found no difference in reduction of manic symptoms in patients treated with topiramate (n = 29) versus placebo (n = 27), although secondary measures provided some suggestion of greater benefit from topiramate. Second, Wagner, Weller, Carlson et al. (2002) found no difference in efficacy between oxacarbazepine and placebo in more than 300 youth with PBD. While open-label trials, most of them small, document some evidence of benefit for carbamazepine, valproate or lamotrigine, in the absence of a placebo control these studies can provide only weak support for efficacy (Chang, Saxena, & Howe, 2006; Findling, McNamara, Youngstrom et al., 2005; Kowatch, Suppes, Carmody et al., 2000; Wagner, Weller, Carlson et al., 2002).

In adult BD, acute antimanic efficacy has been demonstrated for valproate and a long-acting form of carbamazepine, leading to FDA indications for both in BD (Pope, McElroy, Keck et al., 1991, Weisler, Keck, Swann et al., 2005). Lamotrigine is another AED with an FDA indication for BD, although data suggest that it is more effective as a maintenance treatment, preventing depressive and manic relapse, than for acute mania (Bowden, Calabrese, Sachs et al., 2003; Bowden & Karren, 2006; Goodwin, Bowden, Calabrese et al., 2004; Ichim, Berk, & Brook, 2000).

Valproate has a black-box FDA warning because of the possibility of acute life-threatening hepatic failure and pancreatitis (Grauso-Eby, Goldfarb, Feldman-Winter et al., 2003). Therefore, any patient taking valproate who develops the acute onset of nausea, vomiting or acute abdominal pain should have a prompt medical evaluation. In addition, irregular menses and polycystic ovary syndrome (i.e., polycystic ovarian morphology, increased serum testosterone or leutening hormone and irregular menses) may be associated with valproate use (McIntyre, Mancini, McCann et al., 2003).

Regarding lamotrigine, the FDA issued a black-box warning for use in children younger than 16 because of the association between lamotrigine use and the development of two potentially life-threatening rashes, Stephens–Johnson syndrome and toxic epidermal necrolysis (TEN). More benign rashes are common, and a meta-analysis found that increased risk for such rashes was associated with patient age less than 12 years or co-

administration of medications that inhibit hepatic metabolism (e.g., valproate; Calabrese, Sullivan, Bowden et al., 2002). Experts suggest that the risk of rash can be minimized by increasing the dose extremely slowly. If a rash occurs, the patient should be seen urgently by a physician to rule out Stephens–Johnson syndrome or TEN.

**Antipsychotic Medications**
Atypical antipsychotic agents have the strongest efficacy data in PBD; however, given the small number of trials, even here the evidence is moderate at best. Moreover, there are more safety concerns regarding this class of medications versus AEDs and probably also versus lithium.

At present, two RCTs evaluate efficacy of quetiapine in PBD. First, a small 6-week double-blind placebo-controlled RCT in manic/mixed BD adolescents found that valproate plus quetiapine (n = 15) was significantly more effective than valproate plus placebo (n = 15) (DelBello, Schwiers, Rosenberg et al., 2002). The second showed similar efficacy for quetiapine (n = 25) versus valproate monotherapy (n = 25) (DelBello, Kowatch, Adler et al., 2006c), although quetiapine had advantages on secondary outcome measures. Additional open trials of atypical antipsychotics, including olanzapine, risperidone and aripiprazole, suggest efficacy (Barzman DelBello, Kowatch et al., 2004; Biederman, Mick, Hammerness et al., 2005b,c; Frazier, Meyer, Biederman et al., 1999, 2001; Pavuluri, Henry, Carbray et al., 2004b). Atypical antipsychotic medications that are FDA approved for the treatment of mania in adults include aripiprazole, olanzapine, quetiapine, risperidone and ziprasidone (Bowden, Grunze, Mullen et al., 2005; Calabrese, Keck, Macfadden et al., 2005; Hirschfeld, Keck, Kramer et al., 2004; Keck, Marcus, Tourkodimitris et al., 2003a,b; Khanna, Vieta, Lyons et al., 2005; McIntyre, Brecher, Paulsson et al., 2005; Tohen, Greil, Calabrese et al., 2005; Vieta, Bourin, Sanchez et al., 2005).

A particular concern is the association of atypical antipsychotic medication with “metabolic syndrome” (i.e., extreme and rapid weight gain and endocrine abnormalities, including diabetes mellitus; Caballero, 2003). For example, BD youth gained an average of 5 kg in 8 weeks in an open-label study of olanzapine (Frazier, Biederman, Tohen et al., 2001). Patients should be monitored routinely for weight, height and body mass index, and possibly every 6 months for fasting glucose and lipid panel (Correll, Penzner, Parikh et al., 2006; Straker, Correll, Kramer-Ginsberg et al., 2005). Finally, for atypical antipsychotics, firm conclusions on the risk of tardive dyskinesia are not possible because of the lack of long-term data (Ghaemi, Hsu, Rosenquist et al., 2006).

**Pharmacotherapy of Depression or ADHD in PBD**
No RCT has targeted bipolar depression in children or adolescents. RCTs in adult bipolar depression demonstrate efficacy for lamotrigine, quetiapine and the combination of olanzapine plus fluoxetine (Alshuler, Suppes, Black et al., 2003; Calabrese, Bowden, Sachs et al., 1999, 2005; Tohen, Greil, Calabrese et al., 2005; Zornberg & Pope, 1993). Studies give conflicting
results as to whether selective serotonin reuptake inhibitor (SSRI) antidepressants or lithium are preferable in the treatment of adult bipolar depression (Amsterdam, Garcia-Espana, Fawcett et al., 1998; Nemeroff, Evans, Gyulai et al., 2001). No RCTs address this issue in youth. Of note, some evidence suggests that the risk of antidepressant-induced mania is higher in pre-pubertal children than in older adolescents or adults (Martin, Young, Leckman et al., 2004; Rey & Martin, 2006).

One double-blind crossover RCT in children with PBD and ADHD found that, once mania remitted on valproate, the addition of amphetamine salts to valproate was more effective in reducing ADHD symptoms than was placebo plus valproate, and amphetamine salts did not exacerbate manic symptoms \( n = 30 \) (Scheffer, Kowatch, Carmody et al., 2005). Thus, clinicians treating youth with BD and comorbid ADHD should treat the patient’s mania, and then consider psychostimulant treatment.

**Psychotherapy for Pediatric Bipolar Disorder**

While there are few trials of psychotherapy in youth or adults with BD, preliminary data suggest that any one of three types of psychotherapy, in combination with psychopharmacology, may reduce morbidity in BD. First, in families with BD offspring \( n = 35 \), multifamily psycho-educational groups are associated with increased knowledge about BD and ability to obtain appropriate services (Fristad, Gavazzi, & Mackinaw-Koons, 2003). Second, in BD youth, open cognitive-behavioral therapy \( n = 34 \) with family involvement was associated with significant symptom reduction (Pavuluri, Graczyk, Henry et al., 2004a). Third, in family-focused psycho-educational therapy (FFT), families participate in psycho-education, communication enhancement and problem-solving skills training. In PBD adolescents \( n = 20 \), FFT resulted in a 12-month reduction of depression (38% improvement) and mania (46% improvement) ratings (Miklowitz, George, Axelson et al., 2004).

In sum, these data suggest that the combination of psychotherapy plus psycho-pharmacotherapy may reduce the morbidity of BD in youth. However, there is a clear need for RCTs to document efficacy definitively.

**Conclusions**

We now know much more about PBD than we did as recently as a decade ago. Several conclusions can be drawn. BD occurs in children and adolescents, and when it does it tends to be severely impairing. Several studies implicate depression and anxiety as risk factors for PBD. The prevalence of BD in children and adolescents is 1% or less. BD is associated with several neurocognitive deficits, consistent with functional and structural neuroimaging data implicating prefrontal cortex–amygdala–striatal circuitry in its pathophysiology. BD is clearly heritable, with high rates of psychopathology in the offspring of adults with BD. The hunt for susceptibility genes for BD is on, although the clearest findings at this time are that the genetics of the illness are likely to be complex, and there are likely to be susceptibility genes involved in the pathogenesis of both BD and schizophrenia.

Finally, interest in the clinical presentation and pathophysiology of PBD has been accompanied by similar interest in its treatment. However, the rarity of the disease, the fact that the children tend to be severely impaired and the scarcity of trained investigators conspire to create a paucity of double-blind placebo-controlled treatment trials. Because of the woefully limited data, strong recommendations cannot be made for any treatment. In the meantime, clinicians must strive to stay current with the literature while also extrapolating from the latest treatment research in adults with BD, bearing in mind that PBD patients do not respond to therapeutic interventions “like adults.” Furthermore, the applicability of the adult treatment data is greatest to those children who have been assessed using techniques similar to those used in adults. It is to be hoped that the near future will bring great advances in the knowledge base about the treatment of PBD, just as the recent past has brought significant advances in the literature about the phenomenology and short-term course of the illness.

Bipolar Disorder

CHAPTER 38

for bipolar disorder (STEP-BD). Biological Psychiatry, 55, 875–881.

The current chapter reviews five anxiety disorders: phobic disorders, separation anxiety disorder, social anxiety disorder, generalized anxiety disorder and panic disorder. It is organized around four themes. The first section focuses on diagnosis, nosology and assessment. The second summarizes data on prevalence, risk factors and outcome. The third reviews research on family genetics and psychobiology. Treatment is summarized in the final section.

Clinical Presentation of Childhood Anxiety Disorders

Diagnosis
For phenomena that fall on a continuum, extremes have been viewed alternatively as severe expressions of continuously distributed traits or as distinct pathological entities. Controversy remains regarding the relative advantages and disadvantages in conceptualizing pediatric anxiety as a continuous or categorical phenomenon. A key reason for categorizing children presenting in the clinic as affected by anxiety disorders is to allocate services for those anxious children most in need. However, categorization of one or another group of children does not imply distinct etiology.

Distinguishing normal anxiety from pathological anxiety can be problematic because childhood anxieties are not only common, but may be adaptive. Diagnostically, anxiety may be considered pathological at any age if it limits developmentally appropriate behavior and thus causes functional limitation. However, anxiety may be considered pathological even when the child’s activities are not affected if there is significant distress. Classification of disorders with little or no manifest impairment and only distress is often difficult, because the threshold for considering distress as clinically significant varies according to many factors, such as the child’s age, life circumstances or cultural background. Another guide for diagnosis is the child’s ability to recover from anxiety. As such, failure to adapt represents a hallmark of pathology.

Disagreements on definitional boundaries between normal and pathological anxiety are likely to persist as long as clinical descriptors remain the exclusive basis for diagnosis. Other data may shed light, leading to nosological changes by identifying which syndromes carry long-term significance. As with definitions of hypertension, the definition of “abnormal” anxiety could change as longitudinal data identify factors that contribute to excessive long-term risk (Pine, Cohen, Gurley et al., 1998; Pine, Cohen, & Brook, 2001). Eventually, advances in genetics or neuroscience also may impact on nosology. However, considerable progress is needed before such approaches can provide clinical utility.

Nosology of Childhood Anxiety Disorders
Delimitating specific syndromes that facilitate communication among professionals is not a trivial accomplishment, but it represents a minimal standard for a useful nomenclature. While DSM-IV and ICD-10 meet this minimal goal, questions concerning the distinctiveness of anxiety disorders persist. These questions emerge as a result of comorbidity among anxiety disorders, coupled with inconsistent findings of distinct natural histories and factors used to validate diagnosis. The ICD-10 and DSM-IV have similar diagnoses for childhood anxiety disorders. The major difference concerns the handling of comorbidity: ICD-10 provides a single diagnosis for co-occurring anxiety and behavior disorders, whereas the DSM-IV requires separate diagnoses for each condition. In addition, obsessive compulsive disorder (OCD) and post-traumatic stress disorder (PTSD) are classified as anxiety disorders in the DSM-IV, but not in ICD-10 (these are not considered in this chapter because they are clinically distinct from the disorders examined here). Finally, some differences exist in the definitions of childhood anxiety disorders between ICD-10 and DSM-IV (Klein, 1994); however, this chapter focuses on common clinical features.

Presentation of Specific Anxiety Disorders
Phobic Disorder
Phobic disorder is defined by marked unreasonable fear of a specific object that is not intrinsically dangerous, such as animals, or a situation, such as heights. The level of fear is considered extreme, and exposure invariably elicits extreme fear. In addition, the phobia must either cause clinically significant distress or impair the person’s well-being by leading to interference with ordinary activities because of avoidance. Phobic disorders may begin at any age, but typical onset is in childhood (Fyer, 1998; Pine, Cohen, Gurley et al., 1998).
Phobias can be classified based on the nature of the feared object: animals, natural environments, blood injection; or specific situations, such as elevators. Most children with phobic disorders share a limited number of feared situations. Attempts to differentiate among phobias on pathophysiological grounds have not yielded divergent features, except for blood injury phobia (Fyer, 1998), whose distinct physiological signature consists of a sudden drop in blood pressure and heart rate, and fainting.

**Separation Anxiety Disorder**

Separation anxiety disorder represents the only anxiety diagnosis that must begin in childhood. In ICD-10, onset must be in early childhood, whereas in the DSM-IV, onset must occur any time before age 18. The onset is frequently in late childhood, before adolescence, and decreases as children mature into adolescence. As the name connotes, the disorder reflects anxiety at separation from home or caregivers that causes impairment by leading to avoidance. The terms “schoolobia” and “school refusal” have been used to describe a pattern of school avoidance (Egger, Costello, & Angold, 2003). In preadolescents, refusal to attend school because of fears is most often related to separation anxiety disorder. Feared separations situations often seem illogical. For example, a child may have no difficulty going to school, but be highly anxious while visiting familiar friends’ homes. Difficulty sleeping alone is especially salient in children with separation anxiety disorder. As reviewed below, some evidence suggests relationships between childhood separation anxiety disorder and adult panic disorder.

**Social Phobia/Social Anxiety Disorder**

Social anxiety disorder is characterized by anxiety in a range of social situations because of fear of scrutiny, ridicule, humiliation, or embarrassment. Some children may not articulate these concerns but feel uncomfortable in social settings. Children must experience discomfort with peers, not only with adults, and anxiety cannot be caused by impaired capacity for socialization, as evidenced by the fact that the children interact satisfactorily with those who are familiar to them. The diagnostic distinction between severe social anxiety disorder and mild pervasive developmental disorder can be problematic. Chronic avoidance of social interactions might limit development of social competence, contributing to similarities with mild pervasive developmental disorder. However, in general, children and adolescents with social anxiety desire social contacts, whereas those with pervasive developmental disorder typically lack interest in reciprocal relationships.

The diagnostic qualifier, generalized social phobia, denotes anxiety in multiple social settings. There are no standard definitions for distinguishing it from the non-generalized form, leading to divergent interpretations. Some apply the non-generalized label to individuals who experience social anxiety in only one or two situations, such as parties; others use the diagnosis for individuals who experience only performance anxiety, such as public speaking, eating in front of people, as well as test anxiety, but who do not have anxiety during social interactions. Performance anxiety may occur without significant anxiety in social situations, but the reverse is unusual.

Epidemiological evidence supports the distinction between generalized and non-generalized social anxiety disorder. The generalized form has been reported to have earlier onsets, more chronicity, more comorbidity and more psychopathology in relatives (Wittchen, Stein, & Kessler, 1999). This work exemplifies how epidemiological studies can inform diagnostic validity.

**Generalized Anxiety Disorder**

Generalized anxiety disorder encompasses multiple worries about a variety of life circumstances, such as school work, one’s appearance or future. The age of onset is poorly understood, but typically it is not in early childhood. Prior to the DSM-IV, “overanxious disorder” was used for children and adolescents with multiple worries. It remains unclear to what degree the outdated diagnosis of overanxious disorder overlaps with generalized anxiety disorder (Pine, Cohen, Gurley et al., 1998). Generalized anxiety disorder is the only anxiety disorder that requires somatic symptoms. However, there is no documentation that these occur preferentially in this anxiety disorder.

Relative to other anxiety disorders, generalized anxiety disorder has very high rates of comorbidity, and it rarely presents on its own in clinic patients. Beyond comorbidity with other anxiety disorders, it has a strong relationship with major depressive disorder (Costello, Pine, Hammen et al., 2002; Kessler, Andrade, Bijl et al., 2002). This high comorbidity raises questions about whether the diagnosis identifies a unique syndrome as opposed to a complication of other associated disorders. Because the symptoms consist mostly of worries, the disorder is not usually characterized by avoidant behavior, although there are exceptions. For example, children with extreme worries about academic performance may miss school on testing days.

**Panic Disorder**

The essential clinical feature of panic disorder is the repeated experience of unprovoked spontaneous panic attacks, which may lead to limited independent travel or agoraphobia. The panic attacks are characterized by intense fear of impending doom, accompanied by physical symptoms, such as rapid heartbeat, shortness of breath, choking sensation, sweating, depersonalization or derealization. To some extent, these symptoms identify meaningful subtypes of panic disorder patients. Thus, patients who present with respiratory symptoms have been reported to differ from other panic disorder patients in treatment response and familial aggregation (Briggs, Stretch, & Brandon, 1993; Horwath, Adams, Wickramaratne et al., 1997). Usual onset begins with spontaneous panic attacks, typically during adolescence. Progression to full-blown panic disorder occurs in a minority, typically during early adulthood (Pine, Cohen, Gurley et al., 1998).

Diagnostic confusion arises concerning panic disorder because panic reactions can occur in many anxiety states, including in various phobias during exposure to feared situations. The key
distinction is that, in panic disorder, panic attacks occur without cues, as prototypically exemplified by nocturnal panic attacks. Moreover, young children may display panic reactions, but whether they experience spontaneous, unprovoked panic attacks, the hallmark of panic disorder, remains controversial. Whether panic disorder occurs in pre-adolescents is still an unresolved issue, but if it does, it must be very rare (Costello, Egger, & Angold, 2004). This scarcity has limited systematic study.

It has been suggested that, in keeping with the cognitive model of anxiety, children lack the cognitive resources for misinterpreting somatic experiences in a catastrophic fashion, and therefore do not have panic attacks. This conjecture seems unlikely, because panic reactions associated with terror occur in children. It is the sudden unprovoked aspect of panic that seems to be missing in childhood, not the catastrophic reaction. At the same time, it is possible that true panic attacks have age-related clinical variants.

Comorbidity of Childhood Anxiety Disorders

Comorbidity is an important clinical feature because it entails greater dysfunction than either condition alone. Two forms of diagnostic overlap are considered: comorbidity among anxiety disorders, and anxiety disorders with other disorders.

Anxiety Comorbidity

Children referred for treatment exhibit especially high comorbidity among anxiety disorders (Costello, Egger, & Angold, 2004). Such patterns likely reflect ascertainment biases. In a large treatment study, social anxiety, separation anxiety and generalized anxiety disorders were each diagnosed in about 60% of children (RUPP, 2001). Comorbidity was particularly elevated in children with generalized anxiety disorder who, in 90% of cases, also had another anxiety disorder. Clearly, comorbidity is less marked in community than clinical samples, but strong comorbidity across anxiety disorders, especially for generalized anxiety or overanxious disorder, is also found in population studies (Anderson, Williams, McGee et al., 1987; Bird, Canino, Rubio-Stipec et al., 1988; Essau, Conradt, & Petermann, 1999; Fergusson, Horwood, & Lynskey, 1993; McGee, Feehan, Williams et al., 1990; Verhulst, van der Ende, Ferdinand et al., 1997). This high comorbidity has raised questions regarding the diagnostic separation of these three disorders.

Non-Anxiety Disorders

There is unanimous agreement that major depression is highly comorbid with anxiety disorders. The strength of this relationship rivals virtually all others in developmental psychopathology (Angold, Costello, & Erkanli, 1999; Costello, 2004; Costello, Pine, Hammaren et al., 2002). Because depression is rarer than anxiety disorders, especially in pre-adolescents, it follows that among those with anxiety the overlap with depression is not as striking as when one selects those with depression, and that this comorbidity increases with age. Although some clinical reports indicate comorbidity between anxiety and attention deficit hyperactivity disorder (ADHD), population-based studies find weak relationships (Angold, Costello, & Erkanli, 1999). There is some evidence of comorbidity between anxiety disorders and substance abuse or conduct disorder (Kaplow, Curran, Angold et al., 2001; Rutter, Maughan, & Kim-Cohen, 2006).

Assessment

The assessment of pediatric anxiety has benefitted from a proliferation of instruments. They include paper-and-pencil rating scales for children, parents and teachers, clinician-rated scales, as well as child and parent interviews. Several reviews have appeared of self, parent and teacher rated anxiety scales for children (Brooks & Kutch, 2003; Seligman, Olendick, Langley et al., 2004; Silverman & Olendick, 2005). Therefore, only an overview is provided.

Rating Scales

Rating scales serve diverse purposes. They may screen large groups to identify children most in need of assistance or to implement prevention programs. Scales may be used for economic reasons, as they provide an economical way for assessments in epidemiological or behavioral genetic studies (Topolski, Hewitt, Eaves et al., 1999). In clinical studies, scales may serve as indices of severity (RUPP, 2003).

Rating scales that antecedent DSM-III and ICD-10 were not designed to reflect the current classification. They comprised factors such as worry, physiological anxiety and fear of bodily harm, as in the Revised Children’s Manifest Anxiety Scale (RCMA; Reynolds & Richmond, 1985), the State-Trait Anxiety Inventory for Children (STAIC; Spielberger, 1973) and the Revised Fear Survey Schedule for Children (FSSC-R; Olendick, Yang, King et al., 1996). The widely used Children’s Behaviour Checklist (CBCL; Achenbach, 1991) generates a nonspecific factor of emotional disturbance, called “internalizing” factor. In general, these scales assess constructs distinct from those generated by newer scales.

An important clinical challenge is to differentiate between anxiety and depression, a challenge reflected by the fact that a single unitary factor of the CBCL encompasses both dysfunctions. Many other scales that purport to differentiate anxiety from depression fail to do so (Klein, 1994). The meaning of scale ratings of anxiety is further complicated by the poor agreement between parent or child ratings with information obtained from clinical interviews (RUPP, 2003). It is beyond the purview of this chapter to provide comprehensive discussion of psychometric requirements for diagnostic indices.

Growing interest spurred the development of more diagnostically relevant measures of childhood anxiety. Recent efforts reflect shifts in the classification of anxiety disorders, with greater relevance given to diagnostic groupings. Standardized scales include the Multidimensional Anxiety Scale for Children (MASC; March, Parker, Sullivan et al., 1997; March & Sullivan, 1999) and the Self Report for Child Anxiety Related Disorders (SCARED; Birmaher, Khetarpal, Brent et al., 1997). The MASC and SCARED stand out as promising clinically
relevant indices. Both measures demonstrate adequate test–
retest reliability, divergent validity from depression measures,
reasonable correlations with clinical ratings of anxiety severity,
and sensitivity to treatment effects.

Several anxiety scales are designed for clinicians. The
Hamilton Anxiety Scale (HAS; Hamilton, 1969) developed
for adults has had limited application in younger populations.
In a controlled treatment study, it performed less well than
another clinician-rated index, the Pediatric Anxiety Rating Scale
(PARS), which taps diagnostic criteria and has good psychomo-
metric properties (RUPP, 2003).

Diagnostic Interviews

Diagnostic interviews serve different purposes. The highly
structured DISC was developed for epidemiological studies, to
be administered by individuals without clinical training or by
computer (Shaffer, Fisher, Lucas et al., 2000). Support for the
clinical utility of the DISC is mixed. Fair agreement between
DISC diagnoses and clinical interviews conducted by the
same clinicians led to the claim that the DISC had a role in
clinical settings (Schwab-Stone, Shaffer, Dulcan et al., 1996).
However, other data do not support the claim. For example,
diagnostic rates are high in epidemiological studies using
the DISC (Table 39.1). Moreover, other findings question the
validity of anxiety diagnoses generated by the DISC (March,
Swanson, Arnold et al., 2000).

The Child and Adolescent Psychiatric Assessment (CAPA;
Angold & Costello, 2000), highly structured and administered
by non-clinicians, is also used in epidemiological studies.
Relative to the DISC, the CAPA requires more training and
more closely resembles the clinical interview. While CAPA
appears promising, the unavailability of data concerning treat-
ment sensitivity precludes endorsement of clinical relevance.

The key issue is whether anxiety disorders generated by struc-
tured interviews are valid. Some evidence from longitudinal,
family-based and imaging studies points towards validity.
However, inconsistent findings concerning the predictive signi-
ficance of childhood anxiety disorders among girls and boys
studied epidemiologically (Costello, Angold, & Keeler, 1999;
McGee, Feehan, Williams et al., 1992; Pine, Cohen, Gurley
et al., 1998) raise questions about the validity of anxiety diag-
oses in community samples.

The Kiddie-Schedule for Affective Disorder and Schizoph-
renia (K-SADS) was developed for use by clinicians and
allows full latitude of inquiry. Multiple versions exist, includ-
ing a highly structured version administered by lay inter-
viewers (Kaufman, Birmaher, Brent et al., 1997, 2000). The Diagnostic
Interview for Children and Adolescents (DICA; Reich, 2000),
also highly structured, has been used in semistructured for-
mat. The Anxiety Disorders Interview Schedule for Children
(ADIS) allows full clinical inquiry (Silverman, Saavedra, & Pina,
2001). As with other clinically based semistructured interviews,
the quality of data depends highly on interviewers’ training
and qualifications.

There is little to guide the selection of one instrument over
another, in terms of better reliability or validity. All have
demonstrated modest to adequate test–retest reliability, with
anxiety disorders faring no better than mood disorders and
slightly worse than behavioral disorders. The major factor
informing selection concerns the availability of skilled clinicians
for implementation. Although conceived for research purposes,
diagnostic interviews may be useful to clinicians because they
provide comprehensive coverage of symptomatic status (see
chapter 19), and represent excellent teaching tools for train-
ing in clinical diagnosis.

Epidemiology of Pediatric Anxiety
Disorders

Across several continents, well-executed epidemiological studies
delineate key features of anxiety disorders, including preval-
ence, risk factors and longitudinal outcomes. These studies
have the great advantage of avoiding clinical biases introduced
by clinical samples.

Prevalence of Childhood Anxiety Disorders

Prevalence studies that have relied on interviews with parents
and/or children are presented in Table 39.1. Most report the
prevalence of broadly conceptualized anxiety disorders. Ongo-
ing epidemiological studies are obtaining DSM-IV and ICD-10
diagnoses. However, most anxiety diagnoses have remained
virtually unchanged, so that previous studies are relevant to
the current nomenclature.

Most epidemiological studies at all ages find anxiety dis-
orders to be the most common mental disorders. The few
population-based studies of panic disorder have found very
low rates in children and adolescents, below 1% for lifetime
and lower frequencies for the past 6 or 12 months (Pine, Cohen,
Gurley et al., 1998; Reed & Wittchen, 1998; Verhulst, van
der Ende, Ferdinand et al., 1997; Whitaker, Johnson, Shaffer
et al., 1990). In pre-adolescents, separation anxiety disorder
is probably the most prevalent diagnosis (Anderson, Williams,
McGee et al., 1987; Costello, Angold, Burns et al., 1996, 1999;
Costello, Egger, & Angold, 2005; Pine, Cohen, Brook et al.,
1998), whereas social anxiety disorder, generalized anxiety dis-
order and what was previously termed overanxious disorder
increase in adolescence (Fergusson, Horwood, & Lynskey,
1993; McGee, Feehan, Williams et al., 1990; Pine, Cohen,
Gurley et al., 1998; Verhulst, van der Ende, Ferdinand et al.,
1997). All longitudinal epidemiological studies (Anderson,
Williams, McGee et al., 1987; Costello, Angold & Keeler 1999;
Kim-Cohen, Caspi, Moffitt et al., 2003; McGee, Feehan,
Williams et al., 1992; Pine, Cohen, Gurley et al., 1998) find
an increment in social phobia during adolescence, confirming
that the disorder often emerges in adolescence.

Rates of any anxiety disorder within the past 6 or 12 months
range widely, from 1.8% in New Zealand (Anderson, Williams,
McGee et al., 1987) to 23.5% in Holland (Verhulst, van der
Ende, Ferdinand et al., 1997). Variation may reflect true dif-
ferences as a result of cultural influences. However, disparate
rates emerge even when site differences seem minimal. For
### Table 39.1 Prevalence (%) of anxiety disorders in children, adolescents, and adults followed prospectively.

C-GAS, children’s global assessment scale; GAD, generalized anxiety disorder; OAD, overanxious disorder; P/C, parent/child; PD, panic disorder; SAD, separation anxiety disorder; SiPh, simple phobia; SoPh, social phobia.

<sup>a</sup> Rates calculated from papers.

<sup>b</sup> Adolescents in primary care clinics.

<sup>c</sup> Same cohort within site.

<sup>d</sup> DISC-C and DISC-P, Diagnostic Interview Schedule for Children, Child and Parent Versions (Costello et al., 1984).

<sup>e</sup> Rates vary depending on diagnostic criteria based on DISC-C, and parent and teacher ratings, e.g., diagnostic criteria met: (1) by two of three sources or by one source and symptoms confirmed by at least one other source; (2) by one source but no other source confirms symptoms; (3) by combining symptoms from all three sources.

<sup>f</sup> Percentage meeting diagnostic criteria applying same standards as at age 15 in McGee et al. (1992).

<sup>g</sup> Per cent meeting criteria based on DISC-C plus parent ratings.

<sup>h</sup> Interview by Graham & Rutter (1968).

<sup>i</sup> Includes anxiety and mood disorders.

<sup>j</sup> M-CIDI, Munich modification of CIDI (Wittchen et al., 1999).

<sup>k</sup> Diagnosis based on interview with adolescent.

<sup>l</sup> K-SADS, Kiddie Schedule for Affective Disorders and Schizophrenia (Ambrosini et al., 1989).

<sup>m</sup> Two stage study: N in stage 2/N in Stage 1.

<sup>n</sup> Percent meeting diagnostic criteria based on interview with parent or child.

<sup>o</sup> Top line: percentage meeting diagnostic criteria on parent or child interview and had a C-GAS <61 (Shaffer et al., 1983).

<sup>p</sup> Bottom line: percentage meeting diagnostic criteria on parent or child interview and had a C-GAS of 61–70.

<sup>q</sup> DISC, Diagnostic Interview Schedule for Children and Adolescents (Herjanic & Reich, 1982).

<sup>r</sup> CIDR, Composite International Diagnostic Interview (Wittchen, 1994).

<sup>s</sup> CAPA, Child and Adolescent Psychiatric Assessment (Angold & Costello, 2000).

<sup>t</sup> DISC Version 2.3 (Shaffer et al., 1996).

<sup>u</sup> Percentage meeting diagnostic criteria only for symptom number, age of onset and duration.

<sup>v</sup> Percentage meeting diagnostic criteria and impairment linked to the specific disorder.

<sup>w</sup> Top line: percentage meeting diagnostic criteria.

<sup>x</sup> Bottom line: percentage meeting diagnostic criteria and impairment criteria.

Example, two well-executed studies of adolescents, using similar interviews and both conducted in urban sites in Germany, Bremen (Essau, Conradt, & Petermann, 1999) and Munich (Wittchen, Stein, & Kessler, 1999), report lifetime rates for social phobia of 1.6% and 4%, respectively. As is evident in Table 39.1, another case in point are the New Zealand studies from Dunedin (McGee, Feehan, Williams et al., 1990) and Christchurch (Fergusson, Horwood, & Lynskey, 1993). No anxiety disorder is spared discrepancies in prevalence, even when diagnostic definitions are identical and sites appear indistinguishable.

Table 39.1 illustrates clearly that diagnostic rates are reduced sharply if diagnoses are made irrespective of the “extreme distress” criterion, when only impairment is present. Not surprisingly, the one study that compared prevalence as a function of impairment (Shaffer, Fisher, Dulcan et al., 1996) found that applying an impairment criterion led to a dramatic lowering of prevalence estimates.

Could secular changes affect rates of anxiety disorders? This possibility cannot be ruled out, but does not seem to account for discrepancies across studies, because results do not
suggest time-dependent rates of anxiety disorders (Table 39.1). Similarly, could methods for combining informant information contribute to cross-study differences? The low rate of informant agreement in most studies makes this a reasonable possibility. Depending on their age, children contribute varyingly valuable levels of information, and prevalence of anxiety disorders varies as a function of the reporting source (Table 39.1).

It is generally agreed that the answer regarding optimal approach to diagnosis will come from studies that examine the relative accuracy of diagnostic conventions in predicting course, as well as other features such as genetics and biological markers. One study reported that childhood anxiety disorders without impairment are not predictive of difficulties in adolescence, whereas the same is not true for disorders with impairment (Costello, Angold, & Keeler, 1999). However, these findings were not supported by another study (Pine, Cohen, & Brook, 2001). Further complicating diagnosis, impairment may occur in subthreshold syndromes (Reed & Wittchen, 1998).

In conclusion, a fair estimate of current prevalence for any pediatric anxiety disorder accompanied by impairment appears to be 5–10%. Additionally, epidemiological studies have been important in confirming that child and adolescent anxiety disorders are associated with significant impairment in multiple functional domains.

**Risk Factors**

As a result of the impact of referral biases in clinical samples, epidemiological studies provide more precise identification of risk factors. The current section reviews a range of potential risk factors, including demographic factors, various forms of environmental insult or stress, pre-diagnostic manifestations and medical conditions. Because of inconsistent findings and very small numbers of anxiety disorder cases in epidemiological samples, we also review data from clinically based studies.

Gender emerges as the most consistent risk factor for anxiety. Higher rates of most anxiety disorders have been found in females relative to males as early as age 6 (Lewinsohn, Gotlib, Lewinsohn et al., 1998). Anxiety in girls may also have greater predictive impact than in boys for later anxiety (Costello, Angold, & Keeler, 1999; McGee, Feehan, Williams et al., 1992), but findings are not unanimous (Pine, Cohen, Gurley et al., 1998).

Little consensus exists regarding socio-environmental risk factors. Anxiety has been linked to various features, including economic disadvantage, school failure, stressful life events, family dysfunction, single home households, parental emotional problems and low parental education, but no consistent pattern has emerged. Using a quasi-experimental design, Costello, Compton, Keeler et al. (2003) did not find that changes in social welfare were associated with changes in rates of anxiety. Negative findings may reflect limitations of epidemiological studies. Although they have the advantage of minimizing referral biases, they typically study relatively small numbers of affected children, often with relatively mild disorders. For example, among 1035 adolescents in one study (Essau, Conradt, & Petermann, 1999), only 17 had social phobia.

Inconsistent associations for socio-environmental risk factors also emerge in clinical or family-based studies. For example, a recent meta-analysis identified an association between pediatric anxiety and parenting behaviors (Wood, McLeod, Sigman et al., 2003). However, these are non-specific correlates of psychopathology that occur in multiple childhood disorders. Interest in the relationship between pediatric anxiety disorders and adverse social experiences emerges from at least two sets of findings. First, as reviewed below, rodents and non-human primates display developmental plasticity in behavioral and neural responses to threats (Gross & Hen, 2004), as shown by findings that alterations in social experiences produce long-term alterations in stress responses. These data generate questions concerning the degree to which adverse social experiences might shape humans' responses to threats during childhood. Second, children who experienced trauma exhibited marked increases in various anxiety disorders, not exclusively PTSD (Pine & Cohen, 2002; Steinberg & Avenevoli, 2000).

Associations between adverse life events and pediatric anxiety have not been found consistently (Eley & Stevenson, 2000; Hankin & Abramson, 2001; Williamson, Birmaher, Dahl et al., 2005). Because most studies are cross-sectional, it remains unclear whether life events represent correlates, as opposed to causes, of anxiety. However, in a longitudinal study, adverse life events in adolescence predicted incidence of future anxiety, with a particularly strong risk in females for generalized anxiety disorder (Pine, Cohen, Johnson et al., 2002). Similar associations have been found among adults, in that the same varieties of psychosocial risk exhibit associations with pediatric and adult anxiety disorders.

Subclinical elevations on anxiety rating scales and personality style questionnaires, such as the Children’s Anxiety Sensitivity Index (CASI), have been considered risk factors for anxiety disorders (Pine, Cohen, & Brook, 2001). Whether such measures reflect current anxiety, as opposed to risk factors, remains controversial (Mannuzza, Klein, Moulton et al., 2002). So far, no data document an association between such scale ratings and future anxiety.

Finally, risks associated with medical conditions have been reported. In the perinatal period, various adversities have been linked to risk for anxiety. These include neurological injury, febrile seizures, low birth weight, exposure to toxins and minor neurological findings (Breslau, 1995; Breslau & Chilcoat, 2000; Breslau, Chilcoat, Johnson et al., 2000; Shaffer, Schonfeld, O’Connor et al., 1985; Vasa, Gerring, Grados et al., 2002; Whitaker, Van Rossem, Feldman et al., 1997). However, as with other risk factors, no consistent findings emerge.

The strongest medical risk factor appears to be respiratory dysregulation. Circumstances that produce recurrent dyspnea predict risk for pediatric anxiety disorders (Goodwin, Pine, & Hoven, 2003; Slattery, Klein, Pine et al., 2002); associations are particularly strong with asthma, which confers risk
for separation anxiety disorder and panic attacks. Cigarette smoking during adolescence also incurs risk for future panic attacks, but not for social anxiety disorder (Johnson, Cohen, Pine et al., 2000). Similar associations have not been found for illicit substances (Rutter, Maughan, & Kim-Cohen, 2006). Findings are consistent with other work implicating respiratory dysfunction in separation anxiety disorder and panic disorder.

Kagan, Snidman, McManis et al. (2001) noted a relationship between what has been designated as inhibited childhood temperament and later anxiety disorders. Children with inhibited temperament are defined as high reactive during infancy, behaviorally inhibited and reacting with apprehension to novelty during toddlerhood. They are defined as in the top 15% in delay to speak and smile in novel settings.

Altogether, associations between inhibition and psychopathology have been examined in thousands of children. Findings by Kagan (1994) suggest an association between behavioral inhibition and later anxiety, with distinct associations at different developmental periods. During school-age years, increased risk occurs for various anxiety disorders, including separation anxiety disorder and phobias. Others find that inhibition at age 3 predicts risk for depression but not anxiety at age 21 (Casp, Moffitt, Newman et al., 1996).

Associations with anxiety vary in strength, and correlations between inhibition and anxiety ratings cross-sectionally, let alone over time, are rarely greater than 0.20–0.40. Hence, the magnitude of associations is at best moderate. However, some evidence suggests particularly strong associations for measures of social anxiety in adolescence (Hayward, Killen, Kraemer et al., 1998; Schwartz, Snidman, & Kagan, 1999). Comparable associations also emerge with shyness in early childhood, and with anxiety in early adolescence, with odds ratios in the moderate range (Prior, Smart, Sanson et al., 2000), as well as for teacher or parent measures of anxious/withdrawn behavior in childhood and anxiety disorders in adulthood (Goodwin, Fergusson, & Horwood, 2004).

**Longitudinal Outcome**

The long-term consequences of childhood anxiety disorders take on special importance given the high proportion of affected children. The study of diagnostic stability has used community cases, high-risk children and clinic patients, using retrospective and prospective designs.

Seven community-based studies have examined the course of specific anxiety disorders. The first, from Dunedin (Anderson, Williams, McGee et al., 1987), provides indirect evidence on outcome for individual anxiety disorders (Feen, McGee, & Williams, 1993; Kim-Cohen, Caspi, Moffitt et al., 2003; McGee, Feen, Williams et al., 1992; Poulton, Pine, & Harrington, in press). In the initial follow-up, from age 11 to 15, a composite index of any mood or anxiety disorder predicted later anxiety for girls, but not boys (McGee, Feen, Williams et al., 1992). This sex difference was obtained in two other prospective studies (Costello, Angold, & Keeler, 1999; Rueter, Scaramella, Wallace et al., 1999). The latter also found that emotional symptoms predicted major depression. Further follow-up documents longitudinal associations in anxiety disorders, with little relationship between specific child and adult anxiety disorders. The results from two other community-based studies provide similar evidence of non-specific risk for adult anxiety disorders among adolescents with a range of anxiety disorders (Bittner, Goodwin, Wittchen et al., 2004; Lewinsohn, Zinbarg, Seeley et al., 1997).

Thus, five studies found that anxiety disorders during childhood or adolescence predicted risk for an array of mood or anxiety disorders during adulthood. None documented diagnostic specificity in outcome. Two other studies found evidence of specificity. A school-based study found specificity in the course of social phobia but not separation anxiety disorder across adolescence (Hayward, Killen, Kraemer et al., 1998). Perhaps the strongest evidence of longitudinal specificity derives from the New York longitudinal study (Pine, Cohen, Gurley et al., 1998). From childhood or adolescence to adulthood, specific phobias predicted specific phobias exclusively. Similarly, social phobia was predictive of social phobia exclusively. Separation anxiety disorder predicted no specific disorder, but tended to predict panic attacks, and overanxious disorder was associated with an array of adult disorders including anxiety disorders, but not overanxious disorder, and major depression.

Beyond these community-based studies, evidence of specificity in course also emerged from a prospective high-risk study that followed children of parents with either major depression or panic disorder. Phobias and overanxious disorder, but not separation anxiety disorder, carried a two- to four-fold increase of major depression at follow-up (Weissman, Warner, Wickramaratne et al., 1997). The course of childhood anxiety disorders has also been reported for clinic samples. Two studies ascertained children with school refusal and prominent anxiety symptoms prior to the nosological system introduced in the early 1980s (Berg & Jackson, 1985; Flakerska-Praquin, Lindstrom, & Gillberg, 1997). The majority of children experienced relatively benign clinical courses into adulthood. Three other clinical studies (Aschenbrand, Kendall, Webb et al., 2003; Klein, 1995; Last, Hansen, & Franco, 1997) confirm a relatively low rate of later anxiety disorders in children with anxiety disorders. In the study by Klein (1995), separation anxiety disorder coupled with school phobia predicted panic disorder, as well as major depression, although panic disorder was not a frequent outcome (7% versus 0% in non-anxious comparisons). Another short-term follow-up found an elevated rate of panic disorder only among clinic children with “primary” separation anxiety disorder (Aschenbrand, Kendall, Webb et al., 2003).

In conclusion, data from outcome studies support several observations. Although childhood anxiety disorders show considerable stability, most children with anxiety disorders do not have anxiety disorders or depression in adulthood. However, most adults with anxiety or mood disorders are likely to have a childhood history of anxiety. Evidence of specific risk for adult mood and anxiety disorders is not strong.
**Pathophysiology**

**Family Genetics**

Familial aggregation studies have relied on multiple designs, summarized below.

**Family Studies**

During the past 25 years, more than 20 studies have reported an association between various forms of parental psychopathology and childhood anxiety (Beidel & Turner, 1997; McClure, Brennan, Hammen et al., 2001; Merikangas, Avenevoli, Dierker et al., 1999; Middeldorp, Cath, Van Dyke et al., 2005; Rende, Wickramaratne, Warner et al., 1995; Turner, Beidel, & Costello, 1987; Warner, Mufson, & Weissman, 1995; Weissman, Leckman, Merikangas et al., 1984). These studies include so-called “top-down” studies, which evaluate children of parents with anxiety or depressive disorders, as well as a handful of so-called “bottom-up” studies, which ascertain parents of children with anxiety disorders. Multiple studies reported higher rates of anxiety disorders in children of parents with anxiety disorders, relative to children of non-ill parents, as shown in Table 39.2. Questions arising from these studies concern the specificity of parent-child concordance for anxiety disorders versus depression, and specificity of aggregation for distinct anxiety disorders (Middeldorp, Cath, Van Dyck et al., 2005). The weight of evidence from the studies in Table 39.2 suggests non-specificity in the associations between offspring anxiety disorders and parental anxiety and depression. Some work provides evidence of specificity for parent-child anxiety disorders aggregation. An association between panic disorder in parents and separation anxiety disorder in offspring is the most consistent finding (Biederman, Faraone, Hirshfeld-Becker et al., 2001, 2004; Capps, Sigman, Sena et al., 1996). Coupled with data implicating respiratory dysfunction in the two conditions, these data suggest that panic disorder and separation anxiety disorder share an underlying diathesis (Klein, 1993). An association between parental depression and separation anxiety disorder in offspring has also been noted (Biederman, Monuteaux, Faraone et al., 2004). Other data suggest that parental depression is associated with offspring social anxiety disorder, phobias and generalized anxiety disorder, but not separation anxiety disorder (Lieb, Imsneee, Hoffer et al. 2002; Merikangas, Avenevoli, Dierker et al., 1999). Finally, late adolescent rather than adult onset panic disorder may be particularly heritable (Goldstein, Wickramaratne, Horwath et al., 1997).

**Genetic Studies**

In the light of consistent cross-generational transmission, attempts have been made to decompose familial transmission into environmental and genetic components. Few studies have been conducted in pediatric anxiety, none using an adoption design and most relying on symptom scales.

Among adults, a growing literature suggests that genetic factors account for approximately 40% of the variability in risk for anxiety, with most of the remaining variance attributed to non-shared environmental factors (Hettema, Neale, & Kendler, 2001; Hettema, Prescott, Myers et al., 2005). These studies provide evidence of both unique and shared liabilities across distinct adult disorders. Generalized anxiety disorder and major depressive disorder appear to share a genetic substrate, and differ largely in contributions from non-shared environmental factors (Hettema, Neale, & Kendler, 2001). Studies in adolescents suggest similar genetic patterns, with common genes predisposing towards anxiety before puberty and depression after puberty (Silberg, Pickles, Rutter et al., 1999; Silberg, Rutter, & Eaves, 2001). Other anxiety disorders appear to have more disorder-specific genetic risk. For example, genetic risk for panic disorder appears distinct from the risk for phobias, generalized anxiety disorder and major depression (Hettema, Prescott, Myers et al., 2005). While not all twin data support specificity, the weight of evidence indicates that adult anxiety disorders are influenced by both disorder-specific and disorder-unique liability factors (Middeldorp, Cath, Van Dyck et al., 2005).

Genetic influences on anxiety comorbidity have been examined in a large twin study (Hettema, Prescott, Myers et al., 2005). The study found genetic influences to separate two groups of anxiety disorders. One consisted of panic disorder and generalized anxiety disorder, the other of specific phobias. Based on these genetic findings, comorbidity between panic disorder and generalized anxiety disorder is to be expected. Other work in this sample suggests that shared liability to a range of anxiety states may be expressed through underlying personality factors, such as neuroticism (Hettema, Neale, Myers et al., 2006). Extending the search for possible explanations of comorbidity across anxiety disorders, the twin sample was used to test the contribution of neuroticism to the genetic variance in anxiety disorders (Hettema, Neale, Myers et al., 2006).

In children, divergent estimates of heritability emerge from studies using scale scores (Bolton, Eley, O’Connor et al., 2006; Eley, Bolton, O’Connor et al., 2003; Eley & Stevenson, 1999; Eley, Stirling, Ehlers et al., 2004; Topolski, Hewitt, Eaves et al., 1999). Similar assessment methods have yielded divergent estimates for parent and child rated anxiety scales. Twin data in children are consistent in suggesting a modest genetic component to most forms of childhood anxiety, with heritabilities generally accounting for less than 40% of the variance. These relatively low heritabilities across the age range have led to the suggestion that genes confer a broad diathesis towards anxiety as opposed to a predilection for one or another specific disorder. Consistent with this possibility, heritabilities for temperamental factors, such as behavioral inhibition, have been somewhat higher than those for specific anxiety symptoms or disorders (Goldsmith & Lemery, 2000). Non-shared environmental factors account for much of the remaining variance in child-based twin studies of anxiety symptoms, much as they do in adults. Results in children show variability in genetic and environmental contributions to anxiety. This variability, which may reflect distinct genetic and environmental effects across age, sex and specific forms

Parental diagnoses: AGO, agoraphobia; MDD, major depression; OCD, obsessive compulsive disorder; PD, panic disorder.
Offspring diagnoses: AD, anxiety disorder including PD, OCD or social phobia; GAD, generalized anxiety disorder; OAD, overanxious disorder; SAD, separation anxiety disorder. T1, time one; T2, 2-year follow-up.

* 95% Confidence interval of odds ratio excludes 1.0 (i.e., statistically significant at $P \leq 0.05$).
of anxiety, complicates clear interpretation of the nature of transmission.

As noted in chapter 23, the identification of genes will contribute greatly to our understanding of causal factors. No genomic studies have been conducted in childhood anxiety disorder. In adults, panic disorder, which has been shown to be familial, has been examined for influential genes. Replications have failed. Some suggest that it is futile to expect nosological clarity in psychiatry from genetic findings (Kendler & Greenspan, 2006). It is unlikely that the search for genes in childhood anxiety disorders will fare better than it has for adult anxiety disorders. This failure will limit definitive statements regarding the exact nature of genetic influences, but it will not alter the need to rely on other informative clinical and biological strategies to determine the nosological validity of childhood anxiety disorders.

Endophenotypes
Research has begun to move beyond examination of familial aggregation in anxiety symptoms to the study of underlying mechanisms. Anxiety is viewed as a downstream manifestation of genetically based perturbations in neural function that do not directly map on to diagnostic categories. Rather, they cause abnormalities in information processing that lead to psychopathology.

The term “endophenotype” has been used to describe heritable abnormalities in neural function and associated information-processing capacities (Gottesman & Gould, 2003). Endophenotypes show independent associations with psychiatric disorders and with their risk factors. Strong evidence for potential endophenotypes is scarce; working memory abnormalities in schizophrenia probably represent the most compelling example in psychiatry.

Three lines of work provide preliminary data on potential endophenotypes in pediatric anxiety disorders. First, behavioral inhibition has been conceptualized as an endophenotype. Longitudinal studies note associations with anxiety disorders, and family studies with parental panic disorder (Kagan, Snidman, McManis et al., 2001). This work views temperament and anxiety as alternative manifestations of perturbations in the brain’s fear circuit. However, because behavioral inhibition may also be associated with parental depression, there may not be diagnostic specificity in this relationship (Caspì, Moffitt, Newman et al., 1996; Rosenbaum, Biederman, Biederman, Hirshfeld-Becker et al., 2000). In addition, some suggest that behavioral inhibition represents manifest psychopathology, as opposed to a risk factor or endophenotype. An intervention study found stronger treatment effects on anxiety symptoms than on behavioral inhibition (Rapee, Kennedy, Ingram et al., 2005), supporting the endophenotype perspective for behavioral inhibition.

Second, some work implicates enhanced autonomic reactivity in risk for anxiety (Grillon, Dierker, & Merikangas, 1997; Merikangas, Avenevoli, Dierker et al., 1999). As with behavioral inhibition, reactivity-based endophenotypes are presumed to result from perturbations in fear-circuit function. Particular interest has focused on measures of hypothalamic–pituitary–adrenal (HPA) axis activity, although such findings in pediatric anxiety disorders are inconsistent (Terlep, Klein, Roberson-Nay et al., 2006). Third, information-based approaches suggest that abnormal attention regulation during threat exposure may represent an endophenotype (Pine, Klein, Roberson-Nay et al., 2005b). Attention-processing abnormality to threat, also presumed to result from fear-circuit dysfunction, has been linked to both pediatric anxiety disorders and parental panic disorder.

Molecular Genetics
Studies of molecular genetic correlates have extended the modern view of psychopathology as the result of circuitry-based perturbations in information processing. Perspectives on psychiatric genetics have advanced considerably in the past 10 years, to the point where most common forms of psychopathology, including pediatric anxiety disorders, are viewed as so-called “complex disorders.” Such conditions are caused by panoplies of genetic and non-genetic factors, each making relatively small contributions to the phenotype.

In anxiety disorders, the most productive research has attempted to link specific genetic polymorphisms to neural and cognitive dysfunction. Virtually all work on anxiety is of adults. Current findings implicate a polymorphism of the serotonin transporter gene in fear-circuitry dysfunction (Hariri, Mattay, Tessitore et al., 2002). Other work, again largely in adults, suggests that such genetically based perturbations predispose to psychopathology through interactions with environmental risk (Caspì, Sugden, Moffitt et al., 2003). Although much of this work examines associations with adult depression, it is relevant to pediatric anxiety disorders, given their associations with adult depression. Two studies have reported a gene–environment interaction with the serotonin transporter gene in pediatric depression (Eley, Stirling, Ehlers et al., 2004; Kaufman, Douglas-Palumberi, Houshyar et al., 2004), and another found such an interaction for behavioral inhibition (Fox, Nichols, Henderson et al., 2005). Behavioral inhibition also has been linked to a polymorphism in the gene for corticotropin-releasing factor (CRF), a key regulator of HPA function (Smoller, Yamaki, Fagerness et al., 2005). Such an association is consistent with data implicating HPA axis function in fear-circuit activity (see p. 639).

Psychobiology
Neural Circuitry in Animals
Advances in basic science have altered theories of anxiety disorders. They are viewed as reflecting individual differences in neural function: pediatric anxiety disorders are hypothesized, by some, to result from abnormalities in physiological systems implicated in animal models of anxiety (Gross & Hen, 2004). This view has led investigators to target various physiological systems in an effort to document psychobiological substrates of anxiety.

Animal models of anxiety benefit from strong cross-species conservation in brain circuitry and pharmacology. Distinct
forms of fear are regulated by inter-related brain systems involving the prefrontal and medial temporal lobes. Perhaps the best understood phenomena are learned fears, which can be modeled by “fear conditioning” experiments, where an aversive stimulus, such as a shock, is paired with a neutral stimulus, such as a light. Following such pairings, an organism exhibits fear of the formerly neutral stimulus. Learned fear depends upon a neural circuit involving the amygdala, a bilateral collection of individual nuclei located within the brain’s medial temporal lobes (LeDoux, 2000). Learning to fear a previously harmless stimulus involves changes in neural function within the basolateral nucleus of the amygdala, and expression of this learning involves output through the central nucleus. Similarly, the process of extinction, whereby a feared stimulus no longer elicits a fear response, requires communication between the amygdala and frontal cortex, and perturbations in extinction reflect aberrant communication between these regions (Quirk & Gehlert, 2003).

Other forms of fear develop without prior learning and are regulated by distinct but related neural circuits. For example, nocturnal organisms such as rodents fear well-lit environments (Davis, 1998). Unlike learned fears, this fear does not extinguish and may actually increase with repeated exposure. Unlearned fear involves the basolateral but not the central nucleus of the amygdala; the two circuits are regulated by distinct neurochemical systems. For example, infusions with CRF may potentiate unlearned fear, but not conditioned fear.

Neural Development and Fear
The mature fear circuit reflects long-term influences of early-life rearing environment. A wealth of investigations with rodents shows that alterations in maternal care produce long-term changes in the threshold for engaging the medial temporal lobe and prefrontal components of the fear circuit (Meaney, 2001). These effects arise through non-genomic influences, involving DNA methylation. Specifically, functional aspects are altered for genes involved in regulation of the medial temporal lobe and frontal cortex. Work in non-human primates demonstrates comparable associations between rearing and threat responses (Suomi, 2003). These influences appear also for indices of HPA axis function, generating interest in the relationship between HPA axis function and pediatric anxiety disorders. Much of the scientific interest in rearing effects was based on the implicit assumption of permanent scarring. However, the influence of early life experiences is complicated. For example, over 900 genes are regulated by maternal care (Weaver, Meaney, & Seyf, 2006). Moreover, some effects of rearing on genes are reversible. Further complicating an understanding of effects of early rearing, Mathew, Coplan, Smith et al. (2002) not only failed to replicate increased cerebrospinal fluid (CSF) corticotropin releasing factor (CRF) in primates raised under stress, but obtained diametrically opposite results (Mathew, Coplan, Smith et al., 2002). In sum, the effects of early maternal behavior and stress on later functions are highly complex, indirect and not regularly irreversible.

Another approach uses anatomic, neurochemical and genetic manipulation to demonstrate developmental plasticity in the fear circuit. Lesion studies in non-human primates find distinct effects of amygdala lesions on fear-related behaviors in mature relative to immature primates (Amaral, 2002). Genetic and chemical manipulations in rodents produce long-term alterations in fear-related behaviors and associated neural circuitry among immature mice, but not in mature mice exposed to the same manipulations (Gross & Hen, 2004). Altogether, animal data suggest that function of the mature fear circuit reflects influences during childhood on fear-circuit development, but the nature of these influences is likely to be highly complex.

Human Physiology and Neural Circuitry
Functional aspects of brain circuits that regulate learned and innate fears can be elicited reliably in lower mammals as well as humans, through changes in physiological indices; of these, the startle reflex has the best understood neuroanatomic circuit. The reflex is augmented by presentations of mildly stressful stimuli. The neural circuit involved in fear conditioning in rodents is thought to mediate augmentation of the reflex in humans.

Adults with various forms of anxiety exhibit startle abnormalities (Grillon, 2002; Grillon & Baas, 2003). Asymptomatic children of parents with anxiety disorders also have been found to have abnormalities in startle regulation (Grillon, Dierker, & Merikangas, 1997, 1998). Problematically, startle abnormalities reported in at-risk offspring have not been found in youth with anxiety disorders. In addition, startle abnormalities occur in offspring at risk for anxiety and for depression as well, raising questions about the specificity of associations between abnormal startle and anxiety (Grillon, Warner, Hille et al., 2005).

Kagan, Snidman, McManis et al. (2001) suggested that behavioral inhibition, a marker of risk, results from abnormalities in the same brain circuits implicated in startle potentiation, based on peripheral physiological profiles, using indices influenced by circuits that regulate fear in mammals. In spite of parallels in neural circuits of fear regulation in humans and animals, there are crucial pharmacological inconsistencies. For example, medications effective in panic disorder do not affect fear conditioning, although they appear to affect certain forms of unlearned fear (Blanchard, Griebel, Henrie et al., 1997; Cassella & Davis, 1985). Moreover, associations between fear conditioning and clinical anxiety disorders are marginal at best (Lissek, Powers, McClure et al., 2005). Accordingly, risk for anxiety disorders has been hypothesized to relate to failures in extinction, or to inherited tendencies to respond to innate unlearned fearful stimuli, rather than to abnormalities in fear-learning per se.

The most developed line of research examines respiratory dysregulation in panic disorder (Klein, 1993, 1996). Much like a well-lit room for a rodent, respiratory stimulants represent unlearned fear-inducing stimuli for air-breathing organisms, including humans. A wealth of evidence suggests that sensitivity to respiratory stimulants identifies individuals with a
diathesis for types of anxiety closely related to spontaneous panic attacks. For example, adults with panic disorder have enhanced responses to respiratory stimulants, such as CO₂, sodium lactate, cholecystokinin or doxapram. Sensitivity to CO₂ has also been found in children with anxiety disorders, specifically separation anxiety disorder, but not those with social anxiety disorder (Pine, Klein, Roberson-Nay et al., 2005a). Syndromes such as subclinical panic disorder that have strong familial associations with panic disorder are also characterized by enhanced responses to respiratory stimulants. Moreover, in adults, signs of respiratory abnormalities, such as enhanced sensitivity to CO₂, occur especially among panic patients with high familial loading (Horwath, Adams, Wickramaratne et al., 1997). In addition, healthy adult first-degree relatives of panic patients also exhibit enhanced responses to respiratory stimuli (Coryell, Fyer, Pine et al., 2001); however, CO₂ sensitivity was not found among offspring at risk for panic disorder (Pine, Klein, Roberson-Nay et al., 2005a).

Cognition and Anxiety
Cognitive processing, specifically memory and attention, is preferentially mobilized by perceived threats, presumably due to the responses’ adaptive value. Brain imaging which has been used to delineate fear-circuit dysfunction in anxiety susceptibility has focused on threats’ abilities to disrupt strategic control of attention or attention orienting (Davis & Whalen, 2001). Two procedures have been common to probe threat-related effects on cognitive processes in humans. One relies on the “emotional Stroop test,” which taps disruption of strategic attention control. Latencies increase when naming colors of “threat” words as opposed to “neutral” words (Williams, Mathews, & McLeod, 1996). Adults with various anxiety disorders show relatively prolonged latencies to name the color of “threat” words, such as “panic,” presumably because of enhanced vigilance to them. The second procedure uses the dot-probe test, which measures attention orienting. Reaction time to a spatial probe is quantified as a function of the proximity of the probe to “threat” words or pictures (Bar-Haim, Lamy, & Pergamin, 2007; Mogg & Bradley 1998). Adults with anxiety show faster reaction times to probes proximal to threatening stimuli, an effect attributed to enhanced vigilance to threats. In both procedures, there are relatively subtle but consistent positive associations between adult anxiety and reaction times to threat presentations. Some evidence suggests similar effects in childhood anxiety disorders (Monk, Nelson, McClure et al., 2006; Pine, Mogg, Bradley et al., 2005c).

Beyond these two procedures, other less frequently used indices quantify attentional resources during self-monitoring of attention states. In adolescents an association has been reported between aberrant anxiety-state monitoring with anxiety disorders as well as panic disorder in their parents (Pine, Klein, Roberson-Nay et al., 2005b). Finally, diagnostic specificity of cognitive biases is in question, because biases have also been found in depression. In addition, cognitive bias for threat does not appear to be a marker of risk because it occurs primarily in symptomatic adults and disappears with treatment (Williams, Mathews, & MacLeod, 1996). Nevertheless, manipulating bias experimentally has been shown to alter adults’ stress responses (MacLeod, Rutherford, Campbell et al., 2002).

Brain Imaging
Two imaging procedures have been used in pediatric anxiety disorders, neuromorphometry, which examines brain structure, and functional magnetic resonance imaging (fMRI), which reflects blood flow changes during cognitive processes.

Two sets of studies have compared brain structure in pediatric anxiety disorders or related states in response to facial photographs. One study found enhanced amygdala activation during the viewing of evocative face-emotion displays (Thomas, Drevets, Dahl et al., 2001). These findings, consistent with those in adults, implicate amygdala hypersensitivity in some forms of anxiety. The second study found no increased amygdala activation in anxious adolescents but observed enhanced activation in the ventral prefrontal cortex, a region implicated in extinction (Monk, Nelson, McClure et al., 2006). Moreover, prefrontal cortex activity correlated negatively with anxiety severity in patients, suggesting that anxiety reflects perturbed functioning in a distributed neural circuit regulated, in part, by the prefrontal cortex. A final study compared amygdala activity in adults classified as inhibited or not inhibited in childhood (Schwartz, Wright, Shin et al., 2003). Enhanced amygdala activity was found in the formerly inhibited individuals, implicating amygdala function in risk for anxiety.

Treatment
Distress and impairment engendered by anxiety disorders and their long-term liability highlight the need for effective treatments. Some interventions, such as cognitive-behavior therapy (CBT), are based on a theoretical model of anxiety; others, such as selective serotonin reuptake inhibitor (SSRI) medications, follow from demonstrated efficacy in adult anxiety disorders. The literature is replete with case studies reporting efficacy of treatments. The review is of systematic controlled trials.

Psychotherapy
CBT is the best-studied intervention. Because CBT is based on the notion that distorted cognitions underlie anxiety symptoms, aspects of many CBT treatments focus on the child’s
thought processes, aiming to replace negative beliefs with more realistic neutral cognitions. Some CBT treatments recruit the family’s active involvement to facilitate exposure. The contribution that parents can make in treatment is likely to vary as a function of the child’s disorder and age.

A major positive feature of CBT is the availability of treatment manuals. CBT has been compared with no-treatment waitlist controls (Kendall, 1994; Kendall, Flannery-Schroeder, Panichelli-Mindel et al., 1997) or a non-specific control intervention (Beidel, Turner, & Morris, 2000; Last, Hansen, & Franco, 1998; Silverman, Kurtines, Ginsburg et al., 1999). While often used in psychotherapy trials, the use of waitlist controls is methodologically problematic when applied to clinic patients. This disposition confirms to patients that they require treatment but it is withheld. Not only might such an intervention fail to help anxiety, it may have a deleterious impact. The most informative studies are those that have relied on a credible comparison treatment. Finally, it is essential that treatment outcome be evaluated by individuals who are not aware of the treatment delivered, rather than by the therapist. In this fashion, one ensures that biases introduced by treatment allegiances do not influence estimates of outcome. These design features are very infrequently met in current studies of psychotherapy in anxiety disorders.

CBT was examined in two systematic studies by Kendall (1994) and Kendall, Flannery-Schroeder, Panichelli-Mindel et al. (1997). Children received CBT for 16 weeks, or were on a waitlist for 8 weeks before then receiving CBT. In both trials, relative to the waitlist, CBT was significantly superior. Moreover, sustained reductions in anxiety continued over several years. Waitlist controls have been used in other studies of CBT; only three studies used “attention” controls (Beidel, Turner, & Morris, 2000; Last, Hansen, & Franco, 1998; Silverman, Kurtines, Ginsburg et al., 1999), with one finding efficacy for CBT in social phobia (Beidel, Turner, & Morris, 2000). Other studies have examined variations in treatment, providing preliminary evidence that either parental involvement (Mendelowitz, Manassis, Bradley et al., 1999) or a group-based format (Barrett, Dadds, & Rapee, 1996) may lead to particularly high rates of response. Finally, on the basis of a systematic trial of group CBT, group family CBT and waitlist control, one study concluded that CBT could be implemented effectively in a group format (Barrett, Duffy, Dadds et al., 2001). While results show that CBT produces significant gains in children with anxiety disorders, considerably more work is needed, particularly with credible control conditions.

A recent comparative efficacy study raises major unanticipated questions on the comparative efficacy of CBT, relative to pill-placebo and SSRI medication, in the treatment of adolescent depression (March, Silva, Petrycki et al., 2004). These findings emphasize the need for a comparable large-scale CBT/SSRI study in anxiety disorders. Such a study in child anxiety disorders is ongoing.

The success of CBT in the treatment of impairing anxiety disorders has raised questions on the role of this treatment for prevention. Attempts to use CBT preventatively have typically relied on what is termed “secondary” prevention, whereby children with mild anxiety receive CBT. While results generally suggest that CBT reduces anxiety symptoms in such groups (Rapee, Kennedy, Ingram et al., 2005), whether results apply to primary prevention is unclear. These interventions have been shown to work in children in the preschool years and onwards. Because children with symptoms are targeted in this work, such interventions might be characterized as therapeutic rather than preventive. Far less work has used alternative approaches, targeting broader portions of the population independently of those with mild symptoms or other risk factors.

**Pharmacotherapy**

SSRIs have documented efficacy in virtually all adult anxiety disorders. Four placebo-controlled trials have been published for SSRIs in pediatric anxiety disorders. The first large multisite 8-week study found that fluvoxamine was superior to placebo in children with either social anxiety, separation anxiety or generalized anxiety disorders (RUPP, 2001). Another large study demonstrated comparable benefit for paroxetine over placebo, in children and adolescents with social anxiety disorder (Wagner, Berard, Stein et al., 2004). Finally, two modest-sized studies demonstrated efficacy for fluoxetine and sertraline, each relative to placebo (Birmaher, Axelson, Monk et al., 2003; Rynn, Siqueland, & Rickels, 2001).

Concern about SSRIs emerged in 2002–2004, following reports that SSRIs were associated with a two-fold increase in suicidal ideation or behavior, relative to placebo treatment (approximately 4% versus approximately 2%). This observation led to cautionary statements from regulatory officials in Europe and the USA, although debate continues concerning the significance of these data (Vasa, Carlino, & Pine, 2006). Diagnosis did not moderate this association, suggesting that concerns might apply equally to anxiety and mood disorders. A previous literature review (Klein & Pine, 2002) indicated that there was inconsistent support for the efficacy of tricyclic antidepressants in children with separation anxiety. Finally, although there have been some reports on the use of benzodiazepines in anxious children (Klein & Pine, 2002), the efficacy and safety profile of the SSRIs weaken consideration of benzodiazepines.

**Conclusions**

Multiple findings have documented the importance of childhood anxiety disorders. These include their elevated prevalence, their associated impairment, the fact that they put children at risk for later depression and their moderate but significant continuity with anxiety disorders in adulthood.

Epidemiological studies have generated divergent rates of current anxiety disorders. The evidence suggests 5–10% point prevalence in the general population, with girls over-represented. Some have found greater stability of anxiety in girls than

641
boys. Childhood anxiety disorders predict adult anxiety and depression, but no other psychopathology.

Knowledge of antecedents would enable identification of children at risk and the development of preventive efforts. Few antecedents have been established. Early inhibited temperament is weakly related to later anxiety, especially social phobia. A modest influence for genetic transmission has been found, with non-shared environmental factors having a greater role. The non-genetic factors in childhood anxiety disorders are poorly understood. As a result, they make little contribution to the clinical management of children with anxiety disorders.

Models of brain circuits that regulate fear in animals, also studied in adults, are being applied to children. Early studies suggest that children show abnormalities in underlying fear circuitry, as measured by startle responses to unconditioned fear stimuli, and information processing of fear-related stimuli. However, it is difficult to determine which is cause and which is effect. Neuroimaging studies have focused on the hypothesis of amygdala involvement in anxiety. At this time, the best-documented biological feature of childhood anxiety is respiratory dysregulation, as indexed by hypersensitivity to CO₂ exposure in children with separation anxiety disorder.

Treatment of anxiety disorders encompasses psychotherapeutic and psychopharmacological interventions. Most treatment studies have included a mixture of anxiety disorders. Most behavioral treatment studies have methodological limitations, but there is evidence of short-term and sustained improvement. SSRIs have been shown to be effective in childhood anxiety disorders. However, it is difficult to determine which is cause and which is effect. Neuroimaging studies have focused on the hypothesis of amygdala involvement in anxiety. At this time, the best-documented biological feature of childhood anxiety is respiratory dysregulation, as indexed by hypersensitivity to CO₂ exposure in children with separation anxiety disorder. Treatment of anxiety disorders encompasses psychotherapeutic and psychopharmacological interventions. Most treatment studies have included a mixture of anxiety disorders. Most behavioral treatment studies have methodological limitations, but there is evidence of short-term and sustained improvement. SSRIs have been shown to be effective in childhood anxiety disorders. Treatments based on empirical evidence can now be offered to children with anxiety disorders.

Suicidal Behavior and Deliberate Self-Harm

Keith Hawton and Sarah Fortune

In this chapter we first address the issue of operational definitions of suicidal phenomena in research and clinical practice, followed by consideration of the variety of motives and intentions associated with acts of self-harm in young people. The rates of suicidal behaviors are presented, in conjunction with a summary of research on risk and protective factors. Clinical assessment issues and possible outcomes following an episode of self-harm are described. Treatment options, including psychological interventions and medication, are reviewed, with particular consideration of the issue of engagement in treatment with young people and their families. Finally, we consider factors that influence help-seeking and outline prevention initiatives.

Range of Suicidal Behaviors Including Suicide Ideation, Deliberate Self-Harm and Suicide

Many young people consider suicide or self-harm at some point in their lives. Some carry out non-suicidal acts of self-injury, while fewer make suicide attempts. A small minority will die, either intentionally or unintentionally. There is a continuum of suicidality but there are also two main points at which discontinuity exists. First, of those who have suicidal ideas only a small proportion engage in some form of deliberate self-harm (DSH). This represents an important behavioral threshold. Second, some people engage in DSH once, never to repeat, while others carry out repeated acts of DSH.

Definitions of Terms

Suicide ideation is defined as thoughts about an act of DSH or suicide, including wishing to kill oneself, making plans of when, where and how to carry out the act, and having thoughts about the impact of one’s self-harm or suicide on others. DSH is defined as any form of non-fatal self-poisoning or self-injury (such as cutting, taking an overdose, hanging, self-strangulation and running into traffic), regardless of motivation or the degree of intention to die. Suicide includes deaths resulting directly from acts of deliberate self-harm. Official verdicts in the UK, and many other countries, are determined by the coroner and are classified using ICD-10 (World Health Organization, 1996). To reach a verdict of suicide a coroner needs to be satisfied that the act was self-inflicted and that death was the intended outcome. However, strict adherence to these criteria may result in underestimation of the true extent of suicide. Operational definitions are the subject of much debate in both suicide research and clinical practice (Beck, Davis, Frederick et al., 1973; Maris, Berman, Maltzberger et al., 1992; O’Carroll, Berman, Maris et al., 1998).

Motives for Suicidal Behaviors and DSH

Acts of self-harm may have a variety of motives or intentions, such as finding one’s thoughts or one’s situation unbearable, wanting to die or needing to communicate to others the extent of current distress (Bancroft & Hawton, 1983; Hjelmeland, Stiles, Bille-Brahe et al., 1998). The patterns of motives for DSH described by people who have self-harmed are relatively consistent across the lifespan (Hjelmeland & Groholt, 2005) and across countries (Hjelmeland, Hawton, Nordvik et al., 2002). There are differences according to the method of DSH. In a school-based survey, adolescents who took overdoses often said they wanted to die, whereas those who cut themselves more often reported self-punishment and escape from a terrible state of mind as motives for their DSH (Rodham, Hawton, & Evans, 2004). Escape from a difficult state of mind is a common motive for DSH in adolescents (Hawton, Cole, O’Grady et al., 1982; Kienhorst, de Wilde, Diekstra, & Wolters, 1995). Depression and hopelessness are related to an expressed desire to die as a reason for DSH (Boergers, Spirito, & Donaldson, 1998).

Some clinicians and researchers have distinguished self-mutilation as having distinctly different motivations compared with other types of deliberate self-harm. Self-mutilation is defined by Favazza (1992) as the deliberate destruction or alteration of body tissue without conscious suicidal intent, most often by cutting. This behavior is thought to reduce anger, tension or dissociative numbness. This definition suggests habitual cutting among adolescents who lack suicidal intent. However, studies of older individuals who had engaged in self-mutilation behavior indicated a significant risk of subsequent suicide (Stanley, Gamaroff, Michelson et al., 2001) and several recent studies have identified high rates of psychiatric morbidity and other risk-taking behaviors among this group of young people (Guertin, Lloyd-Richardson, Spirito et al., 2001; Muehlenkamp & Gutierrez, 2004). On balance it is probably best to consider self-mutilation as part of the continuum of suicidal...
phenomena, given that sometimes it can lead on to both suicide attempts and death by suicide.

Establishing the intent or motives for an episode of DSH can be complicated as adolescents are often ambivalent about their possible suicidality. In addition, fluctuating mood states can make it difficult to get clear information from adolescents, particularly retrospectively. Self-reported intent may also be influenced by the aftermath of the DSH act. The method of DSH is often taken as a proxy measure of intent. This may be problematic for three reasons. First, young people are known to underestimate risks and habitually engage in behaviors that carry high risk (Millestein & Halpern-Felsher, 2002). Thus, they may not intend to die but nevertheless select a method of DSH that is lethal or, conversely, they do intend to die but select a method that is relatively benign. Second, many young people have poor knowledge about the potential lethality of substances taken in overdose (Harris & Myers, 1997). Third, young people may switch between different methods of deliberate self-harm. Presentation with a relatively low lethality method may follow past acts involving more dangerous methods or may be followed by future episodes in which a more lethal method is used (Fortune, 2006).

Introduction to the “Suicidal Process”
Among adolescents, suicidal thinking is relatively common in the community, deliberate self-harm is less common and suicide is a rare event (Evans, Hawton, & Rodham, 2005a). To date there has been little research on the extent to which the spectrum of suicidal behaviors may appear or disappear in the lives of young people. Runeson, Beskow, & Waern (1996) have described the “suicidal process,” which they define as an interaction between the individual and their environment that accumulates in such a way that suicidal ideas become plans, and plans are acted upon. They argue that the suicidal process operates at both conscious and unconscious levels. The person's experience of the process may or may not be communicated to others, but represents increasing vulnerability to acts of DSH and possibly suicide.

Broader Developmental Processes
The development of suicidal phenomena must be considered in the context of the broader developmental challenges faced by children and adolescents in which emerging physical, cognitive and personality characteristics transform the individual from a child to a young adult. Children pass through a series of stages in intellectual development. Some time after the age of 11 years the child begins to break away from tangible objects towards abstract principles and hypothetical possibilities (Piaget, 1968) and become increasingly able to consider abstract ideas such as the meaning of life. Conceptualizations of death reflect these cognitive changes and start with an early realization, around 8 years of age, that everyone dies (Mishara, 2003), through to an existential “choice to live” during adolescence. Erikson (1968) argued that the key developmental task of adolescence is development of identity versus role confusion, with the peer group assuming primacy over the family as part of this process. The exploration of intimate relationships during this developmental phase makes adolescents particularly vulnerable to rejection. At the same time, the desire to fit in with peers makes adolescents vulnerable to the risk of taking on the behaviors of deviant peers. Youth culture may also have impact on the likelihood of suicide. Adolescents in western cultures appear to be less judgmental about suicide compared with their parents and modern youth culture may portray suicide in positive terms (Cantor, 2000). Youth culture also deemphasizes the religious–moral dimension of suicide while simultaneously emphasizing an individual’s right to suicide (Bagley & Ramsay, 1997).

Population Prevalence of Suicide, Suicidal Ideation and DSH
Suicide
Reported rates of suicide deaths among children and adolescents around the world vary considerably as can be seen in Table 40.1. Some of this diversity may reflect differences in definition as outlined above, and the cultural and legal mores that surround this issue. Generally, more males than females die by suicide in all countries for which data are published, with the exception of China (Cantor & Neulinger, 2000). In a recent large population-based study in India suicide rates were also found to be higher among adolescent females compared to adolescent males (Aaron, Joseph, Abraham et al., 2004). These findings are the reverse of those in adolescents who have died by suicide in other countries.

In several countries rates of suicide are higher in indigenous or aboriginal populations, particularly among young people. For example, First Nations people in the USA (US Department of Health and Human Services, Centers for Disease Control and Prevention, & National Center for Health Statistics, 2004); Metis and Inuit in Canada (Kirmayer, Malus, & Boothroyd, 1996), Australian Aborigines (Tatz, 2001) and New Zealand Māori (Ministry of Health, 2005). Historically, the rate of suicide among Black people in the USA has been considerably lower than White people (Bingham, Bennion, Openshaw et al., 1994); however, from 1980 to 1995 there was a dramatic increase in suicide deaths among Black youth (Joe & Kaplan, 2001).

Youth suicide rates in the UK are declining following a period in which rates in young males had been rising alarmingly. It should be noted that official statistics markedly underestimate the true rates of suicide, especially in children and adolescents, with some apparent suicide deaths being recorded as open verdicts, accidents or misadventure (Madge & Harvey, 1999). In the UK, the rate of suicide and undetermined deaths for adolescent males 15–19 years old in 2003 was 6.58 per 100,000 and 2.24 per 100,000 for females of the same age. The rate of suicide and undetermined deaths among children aged 10–14 years was much lower, at 0.62 per 100,000 for males and 0.42 per 100,000 for females (Office of National Statistics, 2004).
Suicidal Ideation and DSH

A recent systematic review on the prevalence of suicidal phenomena in adolescents based on community or school-based studies in several countries demonstrated that suicidal ideation is more common than DSH, which is in turn more common than attempted suicide. Nearly 1 in 5 adolescents had thought about suicide in the previous year. The mean lifetime prevalence of deliberate self-harm was 13%, with 26% reporting deliberate self-harm in the previous year. The mean proportion of adolescents who had attempted suicide was 10%, with 6% making a suicide attempt in the previous 12 months. Rates of suicidal phenomena were higher among females than males (Evans, Hawton, Rodham et al., 2005b).

In the UK, relatively few studies have been conducted on the prevalence of suicidal ideation and self-harm in the community. In a school-based study of 6020 students, 15% reported thoughts of deliberate self-harm (which had not been acted on) in the preceding year. This was much more common among females (22%) than males (9%). DSH in the past year occurred in 7% and was also much more frequent among females (11%) than males (3%; Hawton, Rodham, Evans et al., 2002a). In contrast, in a large national study of suicidal phenomena among children and adolescents 5–15 years old, based on parental report, 1% of 5- to 10-year-olds had ever tried to harm, hurt or kill themselves, rising to 2% among those aged 11–15 years (Melzter, Harrington, Goodman et al., 2001). Parents are often unaware of DSH acts by their offspring (Huey, Henggeler, Rowland et al., 2004; Meltzer, Harrington, Goodman et al., 2001; Sourander, Aromaa, Pihlakoski et al., 2006), especially where self-cutting is involved.

Two studies that used a similar methodology to Hawton, Rodham, Evans et al. (2002a) were conducted in Australia (De Leo & Heller, 2004) and Norway (Ystgaard, Reinholdt, Husby et al., 2003); these suggested that rates of DSH in adolescents in the UK, Australia and Norway are similar. In a comparative study, again using equivalent methodology, rates of DSH were also similar in Belgium, but considerably lower in the Netherlands (Hawton, Rodham, & Evans, 2006).

There appear to be some differences between rates of non-fatal suicidal behavior in children and adolescents of different ethnic groups. In the USA, for example, several studies have indicated that Hispanic youth, particularly females, experience higher rates of suicide ideation, DSH and hopelessness than their White and Black peers (for review see Canino & Roberts, 2001). In New Zealand, a large national health study found that Māori youth reported significantly higher rates of depression, suicide ideation and suicide attempts in the last year than European/Pakeha students (Adolescent Health Research Group, 2005).

There have been a small number of studies of DSH among ethnic minority children and adolescents in the UK which have produced somewhat conflicting results. The most robust data come from the school-based study described above, in which DSH was less common among Asian (7%) and Black (7%)
boys (50%) than girls (37%; Lalwani, Sharma, Kabra et al., 2005). More recent studies have reported similar (Bhugra, Thompson, Singh et al., 2003) or lower rates of DSH among Asian youth (Bhugra, Thompson, Singh et al., 2004). This issue is reviewed in Bhugra and Bhui (2007).

Methods of Suicide and DSH by Gender and International Differences

There is significant variation among cultures in the methods most commonly used for suicide. The preferred methods of suicide in any given country may have an impact on suicide rates, given that some methods are potentially more lethal than others. In addition, deaths involving a certain method may increase or decrease depending on the availability of that method (Grossman & Kruesi, 2000; Hawton, 2005). For example, in the USA firearms are the most common method of suicide among both Black and White young people, but account for a relatively small number of deaths in the UK, New Zealand and Australia. The substitution of method relies on both the acceptability and availability of alternative methods; the increasing rate of hanging in young people suggests that it has become an increasingly acceptable method of suicide (Centers for Disease Control, 2004). It is also extremely accessible as well as having a high rate of lethality. The reason for the spread in acceptability of hanging as a method of suicide is not known.

The globalization of information has already resulted in rapid transmission of previously unknown and very lethal methods of suicide; for example, the spread of the use of charcoal burning from Hong Kong to Taiwan and Japan and the rapid rise in the popularity of this method. The mechanisms underlying the apparent increased acceptability, cultural meaning and preference for methods of suicide such as this require further research, including the likely role of the media, including the Internet, in influencing this trend.

In India, in contrast with other countries, hanging is a slightly more frequent method of suicide in girls (57%) than boys (50%), whereas poisoning is slightly more common in boys (50%) than girls (37%; Lalwani, Sharma, Kabra et al., 2004). The use of toxic pesticides in agrarian communities such as in China, India (Prasad, Abraham, Minz et al., 2006) and Sri Lanka (Eddleston, Gunnell, Karunaratne et al., 2005b) means that a similar method (self-poisoning) is associated with much higher mortality in these countries than in countries where analgesics and other medications are the most frequently used substances for self-poisoning. The medical management of organophosphate poisoning is difficult and a lack of adequate medical services and distances to hospitals in developing countries may elevate death rates (Eddleston, Eyer, Worek et al., 2005a).

At the community level the most common methods of DSH in the UK and many other countries are cutting and overdose. Hawton, Rodham, Evans et al. (2002a) found that cutting (65%) and overdose (31%) were the main methods of DSH among adolescents in the community. Studies using the same methodology showed similar rates of cutting in Australia (59%; De Leo & Heller, 2004) but higher rates in Norway (74%; Ystgaard, Reinholdt, Husby et al., 2003). However, only a minority of young people engaging in DSH in the community go to hospital, with those taking overdoses most likely to do so (Hawton, Rodham, Evans et al., 2002a). In studies based on presentations to general hospitals in the UK, the majority of adolescents had harmed themselves by taking an overdose, self-poisoning with analgesics being particularly common (Hawton, Hall, Simkin et al., 2003).

Risk Factors Associated with Suicidal Phenomena in Children and Adolescents

An overall model of suicide behavior can help the clinician or researcher conceptualize the main contributory factors identified in a wide range of research studies. This can also provide a framework to support formulations and treatment planning. In such a model (Beautrais, 2000) suicidal behaviors are viewed as the endpoint of adverse life events in which multiple risk factors combine to encourage the development of suicidal behaviors (Fig. 40.1). This essentially represents a stress–diathesis model (Schotte & Clum, 1982), which suggests that temperamental and genetic factors and early experiences may make some young people particularly vulnerable to subsequent internal or external stressors.

There are a number of comprehensive reviews of the research literature on risk factors associated with fatal and non-fatal suicide behaviors among children and adolescents to which the reader is directed (Beautrais, 2000; Brent, 1995; Bridge, Goldstein, & Brent, 2006; Evans, Hawton, & Rodham, 2004; Gould, Greenberg, Velting et al., 2003). Below we highlight contributory factors for which there is at least reasonably strong evidence.

Genetic and Neurobiological Aspects of Suicidal Behavior in Young People

Suicidal behavior runs in families (Brent, Bridge, Johnson et al., 1996a). However, the risk in these families is not entirely accounted for by the increased rates of psychiatric disorder. The heritability of impulsive aggression also appears to be important (for a review see Brent & Mann, 2005). Twin studies have shown that the concordance for fatal and non-fatal suicidal behavior is higher among monozygotic than dizygotic twins (Roy, 1993). The clustering of suicidal behavior in families cannot be explained entirely by behavioral imitation (Brent & Mann, 2005). Importantly, adoption studies have shown elevated rates of suicide among the biological relatives of adoptees who die by suicide compared with those of non-suicidal adoptees (Roy, Rylander, & Sarchiapone, 1997).

Genetic factors may affect the risk of suicide behaviors by their influence on neurobiology and much of this work
has arisen from the investigation of genetic factors in depression (for review see Levinson, 2006). The relationship between genetics and depression is dealt with in more detail in chapter 37. Deviations in the serotonin system are one of the most robust neurobiological findings associated with suicidal behavior (Asberg & Forslund, 2000). The relationship between serotonin dysregulation and suicide behavior may reflect poor impulse control, which is observed in suicidal, violent and impulsive behaviors. Earlier studies examined serotonin metabolites in cerebrospinal fluid and found lower than average levels of 5-hydroxytryptamine (serotonin 5-HT) and the metabolite 5-hydroxyindoleacetic acid (5-HIAA) in suicide victims (Arango, Underwood, Gubbi et al., 1995), and people at risk of repetition of suicide attempts and suicide (Nordstrom, Samuelsson, Asberg et al., 1994). More sophisticated neuroanatomical studies have identified a reduced density of serotonin 1A receptors and serotonin transporter receptors in the prefrontal cortex and brainstem of those who have died by suicide (Arango, Underwood, Gubbi et al., 1995), and people at risk of repetition of suicide attempts and suicide (Nordstrom, Samuelsson, Asberg et al., 1994). More sophisticated neuroanatomical studies have identified a reduced density of serotonin 1A receptors and serotonin transporter receptors in the prefrontal cortex and brainstem of those who have died by suicide (Arango, Underwood, Boldrini et al., 2001; Mann, Huang, Underwood et al., 2000). Dysregulation of serotonin function may predispose a person experiencing stressful events to react impulsively (Mann, Brent, & Arango, 2001). There is less evidence for other neurobiological markers for suicidal behaviors such as dopamine, noradrenaline, cortisol and serum cholesterol (Asberg & Forslund, 2000; Bondy, Buettner, & Zill, 2006).

The main focus of interest in the genetic studies of suicidal behavior has been on three gene types: tryptophan hydroxylase (TPH), serotonin transporter (SERT), located on chromosome 17, and serotonin A receptor genes (Arango, Underwood, Boldrini et al., 2001). Serotonin transporter polymorphisms, particularly the “short” allele of the 5HTTLPR genotype, are associated with suicidal behavior in adults with psychiatric disorder and in particular violent attempts (Lin & Tsai, 2004). More recent studies in adults have explored the role of cannabinoids in the model of anxiety and stress responses underpinning suicidal behavior, in particular cannabinoid receptors (CB1), corticotropin-releasing hormone (CRH) and γ-aminobutyric acid (GABA) (Bondy, Buettner, & Zill, 2006). Despite the interest in this area to date, there are relatively few replicated findings or meta-analyses, particularly in children and adolescents.

**Psychological and Cognitive Characteristics**

Psychological characteristics associated with suicidal behavior include hopelessness (Evans, Hawton, & Rodham, 2004), dichotomous (all or nothing) thinking, negative biases in future judgment (Pfeffer, 2000; Williams & Pollock, 2000) and an external locus of control, or the belief that “things happen to you” because of forces outside your own control (Kienhorst, de Wilde, Diekstra et al., 1992). Impaired problem-solving may be another contributory factor (Speckens & Hawton, 2005). This appears to be related to overgeneralized autobiographical memory (Williams & Pollock, 2000), although this phenomenon is not specific to suicidal behavior (Evans, Hawton, & Rodham, 2004).
Certain personality characteristics such as impulsivity, aggression, neuroticism and trait anxiety may act as intermediate factors that are relatively independent from major psychiatric disorders (Bridge, Goldstein, & Brent, 2006). Irritability and impulsivity have also been strongly associated with suicide in young men (Conner, Meldrum, Wieczorek et al., 2004) and non-fatal acts in both genders (Bridge, Goldstein, & Brent, 2006). Aggression is also associated with DSH (Sourander, Aromaa, Pihlakoski & Brent, 2006). A review of the associations between attention deficit/hyperactivity disorder (ADHD) and suicidal behavior concluded that they are modest, with elevated risk for fatal and non-fatal suicidal behavior, particularly in males, mediated by comorbid conditions, notably depression, conduct disorder and substance abuse, with the risk considerably elevated in young people with all three conditions (James, Lai, & Dahl, 2004).

**Psychiatric Disorders Associated with DSH and Suicide**

Many studies have demonstrated high rates of mental illness in adolescents engaging in both fatal and non-fatal suicidal behavior (for review see Evans, Hawton, & Rodham, 2004). In this section we highlight strong and recent findings about the relationship between mental illness and suicidal phenomena which have been investigated prospectively through longitudinal studies, retrospectively through psychological autopsy studies, and smaller cross-sectional and clinical population studies (which often provide less robust findings). Although mental illness is present in many children and adolescents who engage in suicidal behaviors, clearly not all people who experience mental illness engage in suicidal behavior, so it may be a strong precursor but not a complete explanation.

In a systematic review of psychological autopsy studies (Cavanagh, Carson, Sharpe et al., 2003, p. 400) results of seven studies of adolescents or young adults suggested that 47–74% of suicides examined were attributable to a mental disorder, of which affective disorders made the greatest contribution. This review also highlighted that comorbidity, particularly comorbidity of mental disorder and substance abuse, made a strong contribution to the risk of suicide. An earlier review (Marttunen, Aro, & Lonnqvist, 1993) indicated that antisocial behavior was present in 43–73% of suicide deaths in adolescents, often in combination with depressive symptoms and/or substance abuse. Several more recent psychological autopsy studies (Fortune, Stewart, Yadav et al., 2007; Houston, Hawton, & Sheppard, 2001; Portzky, Audenaert, & van Heeringen, 2005; Shaffer, Gould, Fisher et al., 1996) and non-fatal suicidal behaviors (Evans, Hawton, & Rodham, 2004). Hopelessness is an important mediating variable between depression and suicidal behavior (Thompson, Mazza, Herting et al., 2005). There is also a link between suicide ideation and depression, with increasing severity of depression associated with increasing likelihood of suicide ideation (Allison, Roeger, Martin et al., 2001). The course of depression across adolescence also appears to influence suicidality. In a longitudinal study of 193 children and adolescents, persistent depression was associated with significantly higher rates of suicidal ideation and suicide attempts. Depressed females were more likely to experience recurrent episodes, while males tended to experience persistent mental illness (Dunn & Goodyer, 2006).

Whereas most studies have concerned adolescents with an overt mood disorder, in a recent longitudinal study of 10- to 17-year-olds from a birth cohort, those presenting with subthreshold mood disorders (i.e., those with some symptoms but not meeting the criteria for a diagnosis) had an increased risk of later development of depression, anxiety, suicidal ideation and DSH. The risk, in terms of suicide ideation, associated with subthreshold depression was similar to that of major depressive disorder (Fergusson, Horwood, Riddel et al., 2005).

Bipolar disorder has also been associated with elevated rates of suicide attempts, with the lifetime prevalence ranging from 20% (Strober, Schmidtlaeckner, Freeman et al., 1995) to 44% (Lewinsohn, Seeley, & Klein, 2003). Case–control studies suggest that bipolar disorder in young people is associated with elevated risk of suicide (Brent, Perper, & Moritz, 1993).

**Anxiety**

Anxiety, particularly when comorbid with depression, has
been identified as increasing the risk of fatal and non-fatal acts, although this does not appear to be a direct association (Bridge, Goldstein, & Brent, 2006; Evans, Hawton, & Rodham, 2004). In a case–control study anxiety was more strongly associated with suicide attempts than suicide deaths (Beautrais, 2001). Panic attacks have been associated with increased risk of suicidal ideation and DSH (Gould, King, Greenwald et al., 1998). Young adult females who reported multiple suicide attempts had higher rates of childhood anxiety disorders than ideators and those who had made a single suicide attempt (Rudd, Joiner, & Rumzek, 2004).

Substance Abuse
Substance abuse disorders, including cigarette smoking, are associated with increased risk of suicide attempts (Evans, Hawton, & Rodham, 2004) and suicide deaths (Beautrais, 2000). Several reviews (Esposito-Smythers & Spirito, 2004; Gould, King, Greenwald et al., 1998; Gould, Greenberg, Velting et al., 2003) have shown that substance abuse is more strongly correlated with suicide attempts than ideation and that the relationship is likely to be direct (Evans, Hawton, & Rodham, 2004). Suicide risk is highest among young men and older adolescents with substance abuse (Bridge, Goldstein, & Brent, 2006). Clinically, it can be difficult to establish if substance abuse precedes or follows the mental health difficulties and suicidal phenomena. Up to one-third of young people presenting to hospital following an episode of deliberate self-harm have consumed alcohol around the time of the act (Hawton, Hall, Simkin et al., 2003), and alcohol abuse is associated with increased rates of repetition (Vajda & Steinbeck, 2000).

Psychosis
Approximately 5% of patients of all ages diagnosed with schizophrenia die by suicide, with young people and those early in the course of illness being most likely to kill themselves (Palmer, Pankratz, & Bostwick, 2005). However, psychotic disorders make a relatively small contribution to the overall youth suicide rate (Beautrais, 2000). Suicide risk is increased among young people with psychotic disorders where there were higher levels of premorbid functioning, better insight, higher intelligence and preservation of cognitive function (Apter & Freudenstein, 2000; Pompili, Mancinelli, Girardi et al., 2004). A recent systematic review of risk factors for suicide among those with schizophrenia identified depression, previous suicide attempts, drug abuse, agitation, fear of mental disintegration, poor engagement with treatment and recent loss as important, whereas specific psychotic symptoms had less predictive value than the factors associated with general psychosocial functioning and affective disturbance (Hawton, Sutton, Haw et al., 2005). Many adolescents with schizophrenia also abuse drugs and alcohol, thus exacerbating the risk for DSH and death by suicide (Apter & Freudenstein, 2000).

Conduct Disorder/Antisocial Behavior
Antisocial behavior is a risk factor for DSH among females although, perhaps surprisingly, the relationship is less clear for males (Evans, Hawton, & Rodham, 2004). Many of the risk factors for conduct disorder are also risk factors for DSH, including family disruption, childhood abuse, personal and familial substance abuse and negative life events (Apter & Freudenstein, 2000). There are higher than average rates of DSH (Coffey, Wolfe, Lovett et al., 2004; Morgan & Hawton, 2004) and suicide among imprisoned youth (Coffey, Wolfe, Lovett et al., 2004; Shaw, Baker, Hunt et al., 2004). Antisocial behaviors are prominent among young men who die by suicide (Gould, Greenberg, Velting et al., 2003; Marttunen, Aro, & Lonnqvist, 1993) and those with comorbid antisocial and substance abuse disorders (Bridge, Goldstein, & Brent, 2006).

Eating Disorders
Poor body image and disordered eating are associated with suicidal phenomena and some consider starvation to be a form of suicidal behavior that obviates the need for other methods of DSH. Suicide risk in anorexia nervosa has been estimated to be 2–15% and 0.4–2% for bulimia nervosa, with higher rates among adolescent males than females with eating disorders (Dancyger & Fornari, 2005).

Poor Physical Health Related to Psychological Problems
The relationship between physical illness and suicide in young people has received less attention than in adult populations. However, psychosomatic and physical presentations among suicidal children and adolescents are important for two reasons. First, although some adolescents with depression may present with similar symptoms to adults, they also commonly present with psychosomatic complaints such as headaches, loss of energy, chest pain, abdominal pain or other physical symptoms (McPherson, 2005). Second, poor physical health and many chronic illnesses are associated with increased risk for suicide ideation (Suris, Parera, & Puig, 1996) and DSH (Evans, Hawton, & Rodham, 2005a), independent of psychiatric disorder (Goodwin, Marusic, & Hoven, 2003; Vajda & Steinbeck, 2000).

Environmental Factors Including Biopsychosocial Stressors

Family Factors Including Parental Psychiatric Disorders, Violence, Abuse
Longitudinal community studies have shown that difficulties in parent–child relationships, including those related to early attachment problems, perceived low levels of parental caring and communication are related to increased risk of suicide and suicide attempts among children and adolescents (Ackard, Neumark-Sztainer, Story et al., 2006; Fergusson & Lynskey, 1995b; Fergusson, Woodward, & Horwood, 2000); similar observations have been made in clinical samples (Lessard & Moretti, 1998; Pfeffer, 2000).

CHAPTER 40
Several reviews have concluded that adolescents from families that have experienced parental separation or divorce are at increased risk of suicide behavior, particularly among females (e.g., Beautrais, 2000; Brent, Perper, Moritz et al., 1994a; Gould, Fisher, Parides et al., 1996). It seems that conflict between parents, both before and after their relationship ends, has a detrimental impact on children.

**Family History of Suicide Behavior**

Research consistently indicates that a family history of suicidal behavior is associated with increased risk for suicide deaths (Agerbo, Nordenstoft, & Mortensen, 2002; Brent, Perper, Moritz et al., 1994a; Brent, Oquendo, Goldstein et al., 1988; Gould, Fisher, Parides et al., 1996) and non-fatal DSH behavior by adolescents (Hawton, Rodham, Evans et al., 2002a; Johnson, Brent, Bridge et al., 1998; Roy, Rylander, & Sarchiapone, 1997). Similarly, exposure to fatal and non-fatal suicidal behavior in the family increases suicidal ideation in adolescents (Cerel & Roberts, 2005) and has been associated with more violent suicide attempts (Bridge, Goldstein, & Brent, 2006; Roy, Rylander, & Sarchiapone, 1997).

Having a suicidal family member may model to adolescents that suicide is a possible solution to overwhelming psychological pain (Roy, Rylander, & Sarchiapone, 1997), although the detrimental effects of living with a parent who has undiagnosed or undertreated mental health problems are also significant (Agerbo, Nordenstoft, & Mortensen, 2002). More work is required to clarify the extent to which suicidal behavior can be considered as a construct that is transmitted through families independently of the established association with familial risk of depression, impulsivity and other psychopathology (Brent & Mann, 2005).

**Parental Mental Health Disorders**

Parental mental health disorders are associated with increased risk of their children dying by suicide, particularly parental depression and substance abuse (Brent, Perper, Moritz et al., 1994a). Several authors have found an association between poor parental mental health and both suicide ideation and non-fatal suicide behavior (Fergusson & Lynskay, 1995a; Meltzer, Harrington, Goodman et al., 2001; Sourander, Aromaa, Pihlakoski et al., 2006).

**Childhood Physical and Sexual Abuse**

A strong and direct association exists between suicide attempts and both childhood sexual abuse and physical abuse (Beautrais, 2000; Evans, Hawton, & Rodham, 2005a). Parental history of childhood sexual abuse is also associated with an increased risk of suicide attempts among offspring (Brent, Oquendo, Birmaher et al., 2002). Bullying is associated with poor mental health, suicide ideation and attempts (Coggan, Bennett, Hooper et al., 2003; Kaltiala-Heino, Rimpela, Marttunen et al., 1999; Sourander, Aromaa, Pihlakoski et al., 2006). There has been recent concern about suicide by young people allegedly bullied by peers using mobile telephones and via the Internet (Smith, 2004).

**Peers, Including the Influence of Peer Suicidal Behaviors and Suicide Clusters**

The importance of peer relationships and suicidal behaviors among groups of friends is becoming increasingly apparent. Having a friend who attempted suicide in the previous year increased rates of suicide ideation and attempts among both girls and boys (Evans, Hawton, & Rodham, 2004). The relative risk of suicide among those exposed to an index suicide has been shown to be 2–4 times higher in 15- to 19-year-olds, with contagion less salient among those aged over 25 years (Gould, Greenberg, Velting et al., 2003). In a large study in the USA, socially isolated girls were more likely to experience suicide ideation and both boys and girls with dense social networks were less likely to attempt suicide (Bearman & Moody, 2004).

Clusters of suicidal acts in adolescents sometimes occur, particularly in institutional settings such as schools and in-patient psychiatric units. This may reflect modeling of the behavior and exposure to similar stressors (Gould, Wallenstein, & Davidson, 1989). Suicide clusters are relatively unusual and account for only 5% of all youth suicides. Subsequent suicide behavior is more likely among young people who were already experiencing mental health difficulties (Beautrais, 2000).

**Sexual Orientation**

Gay, lesbian and bisexual young people are at increased risk of engaging in DSH (Remafedi, French, Story et al., 1998; Russell & Joyner, 2001), with estimates of risk ranging 2–6 times that of heterosexual young people (Gould, Greenberg, Velting et al., 2003). In one of the relatively few studies in this area, 59% of males in New York who had made a suicide attempt reported it was related to their sexual orientation and 38% of females who had made an attempt attributed this to issues relating to their sexuality (D’Augeli, Grossman, Salter et al., 2005). No study has yet documented increased rates of death by suicide related to sexual orientation (Gould, Greenberg, Velting et al., 2003). However, gay, lesbian and bisexual youth are more likely to experience risk factors associated with suicide (Shaffer & Pfeffer, 2001), particularly mental health difficulties (Fergusson, Horwood, & Beautrais, 1999).

**School**

Several reviews of studies of young suicide attempters (Beautrais, Joyce, & Mulder, 1996a; Evans, Hawton, & Rodham, 2004) and those who die by suicide (Gould, Fisher, Parides et al., 1996) have indicated that more have had school-based difficulties and/or have dropped out of school than have non-suicidal adolescents. Dropping out of school has been shown to be a risk factor for medically serious suicide attempts, in addition to the socio-economic disadvantages that are associated with having few educational qualifications (Donald, Dower, Correa-Velez et al., 2006). Children and adolescents who remain in school but have special educational needs appear to have higher rates of suicidal phenomena than their
peers without such needs (Denny, Clark, & Watson, 2003; Meltzer, Harrington, Goodman et al., 2001).

Proximal Risk Factors/Life Stressors

Both psychological autopsy (Marttunen, Aro, & Lonnqvist, 1993) and case-controlled studies (Beautrais, 2000) suggest that, compared with controls, young people who die by suicide experience higher rates of exposure to recent stressful life events such as rejection, conflict or loss following the break-up of a relationship (Brent, Moritz, & Liotus, 1996a; Donald, Dower, Correa-Velez et al., 2006), disciplinary or legal crises (Marttunen, Henriksson, Isometsä et al., 1998). Life stressors are also associated with DSH (Hawton, Hall, Simkin et al., 2003). The nature of the stressors seems to vary according to age. For example, children and younger adolescents describe familial stress, whereas older adolescents typically describe peer-related stressors (Gould, Greenberg, Velting et al., 2003; Hawton, Hall, Simkin et al., 2003). Becoming intoxicated is a short-term solution that many adolescents engage in following crises. Intoxication leads to impaired judgment and decreased inhibition, and can facilitate suicidal behavior (Apter & Freudenstein, 2000).

Refugees and asylum seekers face particular psychosocial stressors that are likely to have an impact on young people and their families. Unemployment, social isolation and the difficulties involved in applying for asylum experienced by parents are factors that, together with the high rates of depression, anxiety and post-traumatic stress disorder (PTSD) in this population, may lead to suicidal behavior (Fazel, Wheeler, & Danesh, 2005; Keller, Rosenfeld, Trinh-Shevrin et al., 2003; Sultan & O’Sullivan, 2001).

Exposure to Suicide in the Media, Music and the Internet

The accumulated evidence suggests that certain types of media reports and portrayals of suicide and attempted suicide can increase the risk of suicidal behavior (for reviews see Hawton & Williams, 2005; Pirkis, Francis, Blood et al., 2002; Schmidtke & Schaller, 2000). The greatest influence is probably on methods used for suicide and deliberate self-harm and seems to be particularly marked in young people (Phillips & Carstensen, 1988; Stack, 1991). It appears that such effects are more likely where media reporting or portrayal is dramatic, features details of a specific method of suicide, is on television and is repeated (Pirkis & Blood, 2001; Pirkis, Burgess, Francis et al., 2006b; Stack, 2003).

Many children appear to learn about suicide from television (Mishara, 1999; Pirkis & Blood, 2001). Some people may respond quickly to media presentations of suicide, acting impulsively or putting previous thoughts about suicide into action, while others may make a more considered response (Schmidtke & Häfner, 1988). Thus, in addition to potential immediate changes in suicidal behavior, media influences may also have longer-term effects, by changing attitudes, providing information about methods of suicidal behavior or planting the idea that suicide is an appropriate response to problems.

While concern has been raised about the possible influence of music (especially certain types of popular music) on suicidal phenomena among children and adolescents, this has received very limited attention in the research literature (Martin, Clarke, & Pearce, 1993).

Recently, concern has been raised about Internet sites dealing with suicide and their potential negative influence on adolescent suicidal behavior (Gould, Munfakh, Lubell et al., 2002). The provision of interactive experiences and the development of “online communities” mean that the Internet may have a unique role in influencing suicidal behavior and/or providing peer support and possibly helping prevent suicidal behavior. It is not known if technology-based communication has implications for the consideration of contagion in young people, or what role cyber-bullying (i.e., bullying via Internet, email and text messaging) is a stressor among young people who engage in suicide behaviors.

Few studies have been conducted in this area. In a large community study, depressed young people, especially boys, were heavier users of the Internet, more likely to access the Internet at school and more likely to use chat-rooms and interact with peers they saw infrequently in person, and also strangers (Ybarra, Alexander, & Mitchell, 2005). A study of online postings to message boards focusing on self-injurious behavior by young people aged 12–20 years suggested that online interactions provide important social support to users, but that these interactions may also normalize or encourage self-injurious behavior (Whitlock, Powers, & Eckenrode, 2006). The Internet may also provide opportunities for suicide prevention. For example, 6 months after a school-based presentation promoting the use of a website for young people experiencing emotional difficulties, 45% of students said they had visited the website (Nicholas, Oliver, Lee et al., 2004).

Availability of Means for DSH/Suicide

The preferred method of DSH has an impact on suicide rates, given that some methods are potentially more lethal than others. In the UK, self-laceration and overdose are the most commonly used methods of DSH among children and adolescents (Hawton, Rodham, & Evans, 2006). Children and adolescents who die by suicide in the UK are most likely to have used hanging, self-poisoning, carbon monoxide poisoning or drowning (Hawton, Houston, & Sheppard, 1999a).

Deaths involving a certain method may increase or decrease depending on the availability of that method (Grossman & Kruesi, 2000; Hawton, 2005). For example, in the USA firearms are the most common method of suicide (Stack & Wasserman, 2005), but account for a relatively small number of deaths in the UK, New Zealand and Australia. The substitution of one method for another relies on both the acceptability and availability of alternative methods. For example, a decrease in the use of firearms and self-poisoning among young people in the USA was accompanied by an increase in deaths by suffocation, mostly hanging (Centers for Disease Control, 2004). Rates of hanging have also increased among
young people of both genders in the UK (Gunnell, Bennewith, Hawton et al., 2005). The increasing rate of hanging suggests that this has become an increasingly acceptable method of suicide (Centers for Disease Control, 2004). Hanging is also extremely accessible as well as having a high rate of lethality. The reasons for the spread in acceptability of hanging and the increased use of this method among young females as a method of suicide are not known.

The ready availability of pesticides in agrarian communities such as in China and Sri Lanka is associated with the use of these for self-poisoning. Because of their high lethality, suicide rates in young people are relatively high compared with those in developed countries (Eddleston, Gunnell, Karunaratne et al., 2005b).

### Protective Factors

Compared with the volume of research on risk factors, relatively little work has been conducted on factors that protect against the development of suicide behavior in adolescents. The concepts of adversity and resilience are dealt with in chapters 25 and 26. In summary, factors that protect against mental illness associated with suicidal phenomena include good social skills, problem-solving abilities and an internal locus of control (Merry, McDowell, Hetrick et al., 2002). Factors thought to protect against the risk of suicide include enjoyment and involvement with school (Dexheimer Pharris, Resnick, & Blum, 1997), playing sports (Tomori & Zalar, 2000), family cohesiveness (Rubenstein, Halton, Kasten et al., 1998), religious affiliation and a commitment to life-affirming beliefs (Neeleman, Halpern, Leon et al., 1997; Stack, 2000).

### Impact of Suicide on Peers, School and Relatives

Suicide by a peer has a significant impact on their friends, family, school and community. In a series of studies on peers of children and adolescents who died by suicide, Brent, Perper, Moritz et al. (1994b) found worsening of depression among those who were already depressed at the time of their peer’s death and elevated rates of depression (Brent, Perper, Moritz et al., 1992), anxiety and PTSD, particularly in the first 6 months after the death (Brent, Moritz, Bridge et al., 1996b).

The siblings and parents of adolescents who died by suicide showed elevated levels of grief over a prolonged period of time, with an increased risk of recurrence of maternal depression (Brent, Moritz, Bridge et al., 1996a). Traumatic grief reactions, distinct from depression or PTSD, have also been identified in friends (Melhem, Day, Shear et al., 2004a,b).

A small group of adolescents who have lost a peer by suicide may witness the effects of the suicide on the community and “may find themselves wishing that they too could create the same effects” (Rivers, 1995, p. 15). This issue is a particular challenge for postvention among school peers. However, as noted earlier, clusters of suicides do occur in adolescents, they are relatively unusual (Beautrais, 2000).

There has been little research into the effects of DSH on parents. In the USA, Wagner, Aiken, Mullaley et al. (2000) showed that parents react to DSH may be influenced by factors such as the nature of the previous relationship with their son or daughter, the degree of suicidal intent involved in the act and whether the DSH act was a first episode or a repeat (Wagner, Aiken, Mullaley et al., 2000). The types of motives attributed to the act by parents, including whether the parents interpret the DSH as an act of manipulation, a sign of distress or a definite attempt to die, may also be important (James & Hawton, 1985).

### Outcome Following DSH

#### Single Episode of DSH Compared With Those Who Repeat

Some young people who harm themselves do so on only one occasion, whereas others repeat the behavior. Conceptually, the first act of self-harm is different from all those that follow it, and each act falls somewhere on the spectrum of suicidality in so far as many acts of self-harm have death as a possible outcome (either psychologically or medically). A history of previous suicidal behavior increases the risk of future attempts in both clinical and general populations (Evans, Hawton, & Rodham, 2004; Gould, Greenberg, Velting et al., 2003). The greatest risk of repetition is in the first year following DSH.

The estimates of risk of repetition are 5–15% per year (Bridge, Goldstein, & Brent, 2006), although this may be much higher where repetition that does not come to clinical attention is considered (Hawton, Rodham, & Evans, 2006). The risk of repetition remains high for many years after an episode of DSH. For example, in a 10-year follow-up, Gibb, Beautrais, and Fergusson (2005) reported that 28% of those admitted for a suicide attempt had been readmitted, with the highest risk in the first 2 years. In a study of 450 adolescents who had taken overdoses, 12% re-presented to hospital with further overdoses within 5 years. Repetition is associated with substance abuse, psychotic illness and personality disorder (Reith, Whyte, & Carter, 2003). There are mixed findings on whether repetition rates are higher in one gender or the other (Gibb, Beautrais, & Fergusson, 2005; Goldacre & Hawton, 1985).

Once an adolescent has actually engaged in DSH they cross a behavioral threshold. Repeat DSH may be more likely if the act resulted in the adolescent receiving relief from undesirable affect or if an earlier attempt prompted a desirable change in
their lives as a result of the responses of others. These factors plus further exposure to stressful life events and problems combine to place them at increased risk for engaging in DSH when facing similar situations; following the initial episode DSH becomes an additional tool in their behavioral repertoire where it did not exist previously (Goldston, Sergent Daniel, Reboussin et al., 1999). Depression is a key factor associated with repetition of DSH in adolescents (Hawton, Kingsbury, Steinhardt et al., 1999b).

Similarly, self-reported DSH at age 12 years predicts suicidal ideation and DSH at 15 years (Sourander, Aromaa, Phlakoski et al., 2006). A recent study by Harrington, Pickles, Aghan et al. (2006) showed that in most cases deliberate self-harm by adolescents ceased within 3 years. However, those who continued to self-harm into adulthood were characterized by higher rates of psychopathology and adversity in both childhood and adulthood; and, in another study, by anxiety, at least for females (Rudd, Joiner, & Rumzek, 2004).

Emergence of Personality Disorders

To date there has been little research on the prevalence and morbidity associated with personality disorders among adolescents. Borderline personality disorder (BPD) has long been associated with non-fatal DSH among adults, and some argue it takes a similar form in adolescents as seen with adults (Bradley, Conklin, & Westen, 2003). The use of this diagnosis in those under the age of 18 years is somewhat contentious (Vito, Ladame, & Orlandini, 1999).

Worthlessness, guilt, hopelessness and anger are associated with both BPD and suicide (Apter & Freudenberg, 2000; Brodsky, Malone, Ellis et al., 1997) and may place young people at risk of poor psychosocial outcomes. In a community-based longitudinal study, adolescents with personality disorders had significantly higher rates of major psychiatric disorder and suicidal ideation in early adulthood, after controlling for comorbid mental disorders and suicidality during adolescence (Johnson, Cohen, Skodol et al., 1999). Rudd, Joiner, & Rumzek (2004) suggested that the frequency and chronicity of suicide attempts in adulthood are related to childhood anxiety disorders through the emergence of personality psychopathology, with different patterns for males and females. The authors highlighted histrionic and paranoid traits in females and schizoid, avoidant, dependent, aggressive and borderline traits in males.

Suicide Following DSH: Risk and Timing

A history of past suicide attempts is one of the most powerful and clinically relevant predictors of eventual suicide. Most studies find elevated risk of overall mortality following DSH (Carter, Reith, Whyte et al., 2005; Gibb, Beauvais, & Ferguson, 2005; Goldacre & Hawton, 1985; Suominen, Isometsa, Suokas et al., 2004). In one follow-up study of 15- to 24-year-olds who had presented to hospital following an episode of DSH, the overall number of deaths from all causes was 3%, four times higher than expected. This was mainly because of an excess number of suicides (2%), which were 10 times more frequent than expected. The main risk factors for suicide were male gender, previous DSH, prior psychiatric history and high suicide intent (Hawton & Harriss, 2007).

Clinical Assessment

Clinicians should conduct risk assessments when young people express suicidal thoughts or behaviors. Both the purpose and the process of such assessments need to be given careful consideration. A significant issue is establishing the purpose of the assessment, particularly suicide prediction compared with risk assessment (Bryan & Rudd, 2006). It is extremely difficult for clinicians to predict accurately the risk of their patient dying by suicide or of engaging in non-fatal suicidal behavior. An assessment should form the basis of future clinical management and establishing treatment goals. In adults, having a psychosocial assessment has been associated with reduced rates of repetition (Kapur, House, Dodgson et al., 2002). The fact that many adolescents spend very little, if any, time planning their deliberate self-harm (Rodham, Hawton, & Evans, 2004), and that being intoxicated is often associated with many such acts, compounds this issue (Esposito-Smythers & Spirito, 2004). A core task of a risk assessment is to establish an interactive and dynamic relationship; to be part of a response to the young person’s distress that offers some hope for a better future.

Assessment following DSH

Improved assessment and management of deliberate self-harm are highlighted in a number of published guidelines (American Academy of Child and Adolescent Psychiatry, 1999; National Institute for Clinical Excellence, 2004; Royal Australian and New Zealand College of Psychiatrists, 2004). The assessment of children and adolescents following DSH is influenced by a range of process and service issues. At a process level, the assessment of adolescents can present particular challenges, as young people are often ambivalent about their suicidality and fluctuating mood states can make it difficult to get clear information, particularly retrospectively. Current guidelines emphasize standards of care and note that several studies have suggested that some staff responsible for medical care have, or are perceived by DSH patients as having, negative attitudes towards those who deliberately harm themselves (Herron, Tichhurst, Appleby et al., 2001; Hopkins, 2002) and may not recognize the complex relationships between DSH and mental illness (Friedman, Newton, Coggan et al., 2006). Poor continuity of care requiring frequent repetition of their “story” (Dower, Donald, Kelly et al., 2000) and negative expectations about post-discharge therapy (Rotheram-Borus, Piacentini, Van Rossem et al., 1996) contribute to dissatisfaction among some adolescents who have self-harmed. In a study of adolescent DSH patients, those who were more satisfied with hospital management and subsequent therapy appeared to have better therapeutic outcomes (Burgess, Hawton, & Loveday, 1998).
Screening and Case Identification Procedures

Some schools have tried to detect young people at high risk of suicide through screening programs. Case-finding strategies have been employed in schools in an effort to reduce suicide by early detection of young people at high risk. This approach has particularly been pursued in the USA (Gould, Greenberg, Velting et al., 2003). Although these methods are increasingly sensitive to detecting young people with problems, engagement in treatment following identification remains a significant issue (Shaffer & Craft, 1999; Shaffer & Pfeffer, 2001; Shaffer, Scott, Wilcox et al., 2004). Data from the Colombia Teen Screen program indicates that 19% of “at risk” young people refused a referral, 25% did not attend the first appointment and 17% attended one session only (Shaffer, 2003).

There are also difficulties with some schools accepting this approach for various reasons, including lack of staff resources and concerns that asking students about suicide will give them ideas about harming themselves. However, in a recent randomized controlled trial, depressed adolescents and previous attempters reported lower levels of distress and suicidality following a screening questionnaire that included specific questions about suicidal behaviors compared with their counterparts who were not asked those questions. This study also demonstrated that asking about suicide does not “put the idea into a young person’s head” for those who would not ordinarily be thinking about this issue (Gould, Marrocco, Kleinman et al., 2005).

Treatment Following DSH

A range of treatment studies have been conducted with adults following DSH, but few interventions with children and adolescents who have harmed themselves have been evaluated.

Cognitive–Behavior Therapy and Problem-Solving

Cognitive–behavior therapy (CBT) is the principal treatment for adolescent depression and affective disorders (Harrington, Whittaker, & Shoebridge, 1998; Merry, McDowell, Hetrick et al., 2002) and targets depressive thoughts and behavior patterns (see chapter 63). In a large randomized controlled trial, 439 patients aged 12–17 years with major depressive disorder (MDD) were randomly allocated to one of four treatment conditions, each lasting 12 weeks:

1. Fluoxetine alone;
2. CBT alone;
3. CBT with fluoxetine; or
4. Placebo.

The CBT treatment consisted of 15 1-hour sessions. Patients treated in all conditions showed a reduction in suicide ideation across the trial, those treated with CBT plus fluoxetine showing the greatest improvement (Treatment of Adolescent Depression Study Team, 2004).

Problem-solving therapy, in which patients are assisted to identify problems and enhance their strategies for addressing them, has been noted in three recent systematic reviews of treatments for DSH to offer a promising area for further investigation (Gaynes, West, Ford et al., 2004; Hawton, Townsend, Arensman et al., 2000; Townsend, Hawton, Altman et al., 2001). However, there have been no evaluations of problem-solving therapy with younger patients.

Family Therapy

Family therapy is a mechanism of intervening with suicide behavior among adolescents, given that family issues are implicated in the etiology of suicide behavior (Spirito & Boerger, 1997). Family therapy focuses on the relationships, roles and communication patterns between family members (see chapter 65). In a treatment study of depressed adolescents who were randomly allocated to CBT, systemic behavioral family therapy (SBFT) or non-directive supportive therapy (NST), those who were currently or previously suicidal were more depressed at the start of therapy and were significantly less likely to complete it. In addition, NST did not appear to ameliorate the MDD of these adolescents (Barbe, Bridge, Birmaher et al., 2004).

Rotheram-Borus, Piacentini, Miller et al. (1994) developed brief CBT in a family context. Kerfoot, Harrington, and Dyer (1995) implemented a brief structured home-based intervention with suicidal adolescents and their families. Non-depressed adolescents in the home-based group had less suicidal ideation than controls, but the home-based intervention was no more effective for depressed adolescents (Harrington, Kerfoot, Dyer et al., 2000).

Group Therapy

Group therapy approaches are often used in child and adolescent mental health services, although there are few well-designed studies of this approach with suicidal adolescents. Wood, Trainor, Rothwell et al. (2001) randomly assigned 63 adolescents with a history of repeated self-harm to group therapy plus treatment as usual (TAU) or TAU only. Although there was no apparent effect on depression, group attendees were less likely to repeat DSH, used fewer routine services and had better school attendance than those who received TAU.

Dialectical Behavior Therapy

Dialectical behavior therapy (DBT) is a therapeutic approach that focuses on the management of emotional states and interpersonal relationships. DBT has been researched as a psychotherapeutic intervention with suicidal adults (Linehan, Rizvi, Welch et al., 2000) and is being investigated with adolescents (Rathus & Miller, 2002).

Multisystemic Therapy

Multisystemic therapy (MST) was developed to treat delinquent youth, targeting the systems in which the young people live. MST includes parenting skills, family therapy and educational attainment. In a randomized controlled trial, young people aged 10–17 years were assigned to MST or hospitalization following a psychiatric emergency. MST was significantly more effective
in reducing youth-reported repetition of suicide attempts (Huey, Henggeler, Rowland et al., 2004).

Medication

There has been considerable recent debate about the use of antidepressant medications in the treatment of children and adolescents with depression, with a specific focus on whether selective serotonin reuptake inhibitors (SSRIs) increase the risk of suicidal ideation in some young people (for summary see Ryan, 2005; see also chapters 37 and 67). A recent meta-analysis indicates a modest increased risk of suicidality among those prescribed antidepressant medication (Hammad, Laughren, & Racoosin, 2006). This may be related to the agitation that can occur shortly after starting the drug. In contrast, some researchers have suggested that increased prescribing of SSRIs has resulted in decreased suicide rates (Gibbons, Hur, Bhaumik et al., 2006; Olsson, Shaffer, Marcus et al., 2003). Conversely, based on data from both published and unpublished randomized controlled trials, the British Medicines and Healthcare Products Regulatory Agency has stated that sertraline, citalopram, paroxetine and venlafaxine are contraindicated in those under 18 years with MDD (Medicines and Healthcare Products Regulatory Agency, 2004). These medications are required to carry a “black box” warning label in the USA (US Food and Drug Administration, 2004). Also, fluoxetine for treating depression in adolescents is supported by the European Medicines Agency only where psychological interventions alone have failed (Eaton, 2006). The Society for Adolescent Medicine recommended the prudent use of antidepressant medication for adolescents, under close clinical supervision and as part of an overall therapeutic approach (Lock, Walker, Rickert et al., 2005; see also chapter 37).

Hospitalization

The decision to treat adolescents following DSH in an in-patient setting is usually based on risk of further self-harm and suicide, and severity of psychiatric disorder (Olsson, Gameroff, Marcus et al., 2005). It may also be influenced by other factors including concerns about litigation, characteristics of the individual and their family (Spooren, Jannes, & van Heeringen, 1997), the experience and training of the mental health clinician (Morrissey, Dicker, Abikoff et al., 1995) and the availability of in-patient beds.

However, there is no evidence to suggest that hospitalization prevents young people, particularly those with prior attempts, mood disorder and substance abuse, from making another attempt or dying by suicide (Gould, Greenberg, Velting et al., 2003; Greenhill & Waslick, 1997). Furthermore, prior hospitalization for any injury, not just DSH, is associated with increased risk of suicidal behaviors (Agerbo, Nordentoft, & Mortensen, 2002; Bridge, Goldstein, & Brent, 2006), although this may be related to severity of psychopathology and other risk factors.

Two recent studies have attempted to address these issues. In the first, conducted in the USA, 289 adolescents were randomly allocated to receive social network intervention plus TAU, or TAU alone, following psychiatric hospitalization. There was a reduction in suicidal ideation and parent-reported functional impairment at 6 months follow-up in those assigned to social network intervention, but no effects on repetition of DSH or emotional symptoms (King, Kramer, Preuss et al., 2006). In the second study, 286 adolescents were assigned to rapid response out-patient follow-up or TAU following presentation to an emergency department in Canada. The results showed psychiatric hospitalizations can be prevented using the rapid response model of care (Greenfield, Larson, Hechtman et al., 2002).

Issues of Access to Treatment and Engagement in Treatment

Whereas many adolescents may be offered care following an episode of DSH, only a small proportion are successfully engaged in ongoing treatment. Treatment retention for non-hospitalized adolescents is generally below 50% (Brent, 1997; Swedo, 1989; van Heeringen, Jannes, Buylaert et al., 1995), and can be as low as 20%, with significant and rapid drop-out from treatment (King, Hovey, Brand et al., 1997).

Several studies have investigated mechanisms to improve engagement with treatment, including green-card passes (Cotgrove, Zirinsky, Black et al., 1995), enhanced emergency department protocols (Rotheram-Borus, Piacentini, Cantwell et al., 2000; Spirito, Boergers, Donaldson et al., 2002), enhanced CBT interventions (Rotheram-Borus, Piacentini, Miller et al., 1994) and skills-based interventions (Donaldson, Spirito, & Esposito-Smythers, 2005). However, to date such efforts have largely been unsuccessful and new strategies must be developed to address this important issue (Burns, Dudley, Hazell et al., 2005).

Many young people who engage in DSH do not seek help for their problems. If they do, it is most likely to be from friends and family rather than professionals (De Leo & Heller, 2004; Hawton, Rodham, & Evans, 2006). There are also gender differences, with distressed young men being less likely to seek help of any kind and those who seek help from their GP showing more severe symptoms than their female counterparts when they do (Biddle, Gunnell, Sharp et al., 2004). High school students at highest risk of suicide were found to be more likely to endorse isolative coping strategies such as believing you should be able to sort out your problems on your own and less likely to endorse strategies such as getting advice from friends (Gould, Velting, Kleinman et al., 2004).

Prevention of DSH and Suicide by Children and Adolescents

Suicide prevention strategies include both specific interventions for individuals at risk and population-level interventions aimed at reducing overall risk in the general population. Specific interventions include, for example, treatment and
care of suicidal children or adolescents to help families and communities where a suicide death has occurred to cope with the aftermath (Leenaars & Wenckstern, 1999). Given the complicated nature of the lives of many people who engage in suicidal behavior, no single strategy is likely to provide all the answers (Centers for Disease Control and Prevention, 1992; Evans, 2000).

School-based Interventions
Prevention programs that are aimed at students as helpers, not as victims, are based on evidence that adolescents turn to their peers for support rather than discussing their problems with adults (Beautrais, Joyce, & Mulder, 1998; Hawton, Rodham, & Evans, 2006; Hazell & King, 1996). This approach often raises concerns that not all peer confidants communicate with adults about friends whose problems cause them particular concern (Bennett, Coggan, Lee et al., 2003) and that young men in particular do not respond to troubled peers in helping ways (Hazell & King, 1996; Kalafat, Elias, & Gara, 1993). Skills-based programs in schools, targeting the development of problem-solving, coping and cognitive skills appear to have a positive impact on suicide behavior and coping with distress (Gould, Greenberg, Velting et al., 2003). A school-based intervention in the USA called Signs of Suicide showed fewer suicide attempts in the intervention group compared with controls, and a modest improvement in knowledge and attitudes about depression and suicide. However, no improvement in help-seeking was observed (Aseltine & DeMartino, 2004). A randomized controlled trial of a school-based depression prevention program also showed positive results (Merry, McDowell, Wild et al., 2004).

Reviews of older school-based programs (Garland, Shaffer, & Whittle, 1989) and their effect on suicidal adolescents (Shaffer, Vieland, Garland et al., 1990) raised serious concerns about these programs, in particular the message that suicide is a reaction to stressful life events that could happen to anyone and the minimization of the importance of mental illness, and gave rise to the establishment of the Columbia Teen Screen program. One obvious difficulty with any school-based program is the fact that high-risk individuals, particularly school drop-outs and those with high rates of absenteeism, will not be reached using this approach (Burns & Patton, 2000).

Reducing Access to Methods of Suicide
The strategy of restricting access by the general population to certain methods of suicide is a widely practiced public health initiative and an effective method of preventing suicide. Research suggests that restricting access to particular methods reduces deaths by that method. Most studies show a reduction in overall suicide deaths, while others do not because of substitution of method (for a review see Mann, Apter, Bertolote et al., 2005). Methods of suicide used by young people vary significantly across different countries. Restricting access to firearms has been a significant focus of suicide prevention in North America because of the high number of deaths resulting from firearms (Brent, Perper, Goldstein et al., 1988; Brent, Baugher, Bridge et al., 1999; Gould, Greenberg, Velting et al., 2003). The number of firearms suicides in the UK is small so this does not form a major thrust of suicide prevention (Haw, Sutton, Simkin et al., 2004).

Much suicidal behavior in young people involves intentional overdoses (Bennett, Coggan, Hooper et al., 2002; Hawton, Fagg, Simkin et al., 2000). Preventative approaches include safety packaging, limiting tablet quantity for high-risk drugs such as tricyclic antidepressants, education of practitioners regarding safer practices, disposal of out-of-date and unwanted drugs and limiting advertising (Cantor & Neulinger, 2000; Commonwealth Department of Health and Aged Care, 1999). Acetaminophen (paracetamol) is a drug widely used for self-poisoning among young people in several western countries (Bennett, Coggan, Hooper et al., 2002; Hawton, Fagg, Simkin et al., 2000). Legislation was introduced in the UK in 1998 reducing pack sizes and the number of packs that can be purchased at one time. This was followed by a decrease in the rates of deaths, liver transplants and the average number of tablets ingested in overdose (Hawton, Simkin, Deeks et al., 2004).

Hanging is an increasingly popular method of suicide and attempted suicide in several countries but it is difficult to reduce access to the means of hanging, except in institutional settings such as psychiatric in-patient units and prisons. Carbon monoxide poisoning from car exhaust gases was a common method of suicide. However, the introduction of catalytic converters in cars has had a significant impact in reducing deaths by this method (Amos, Appleby, & Kiernan, 2001).

Crisis Centers and Hot Lines
Crisis centers and hot lines offering direct counseling or links to mental health services are conceptually popular. Overall, research suggests that such services tend to be used by young White females, with less impact on young men (de Anda & Smith, 1993). Beautrais, Joyce, & Mulder, (1998) reported that 14% of serious suicide attempters had used a telephone crisis line in the year prior to their attempt. There is little evidence of beneficial effects on rates of suicide (Burns & Paton, 2000), although this would be difficult to demonstrate.

Guidelines on Media Reporting of Suicides
Media coverage of suicide has been shown to encourage imitative suicides (Gould, 2001; Hawton & Williams, 2005; Pirkis & Blood, 2001). It appears that in the short term, media reporting can lead to an increase in suicidal behavior and in the long term it may model suicide as common and acceptable. Many countries now have voluntary guidelines for media reporting (Pirkis, Blood, Beautrais et al., 2006a). Compliance with guidelines is variable although guidelines leading to reduced reporting of specific types of suicide have been associated with reduced rates of suicide by these methods in
CHAPTER 40

Austria (Etzersdorfer, Sonneck, & Nagel-Kuess, 1992) and Canada (Littmann, 1983).

Conclusions, Future Clinical and Research Directions

Suicidal behavior exists on a continuum. Nearly 1 in 6 adolescents have considered self-harm or suicide in the previous year and 1 in 10 have harmed themselves in the previous year (Evans, Hawton, Rodham et al., 2005b). Death by suicide is relatively infrequent in adolescents. However, in most countries, more males than females die by suicide, although this may not be the case in India and China. In contrast, more females engage in non-fatal suicidal behavior. These differences are thought to reflect differences in the methods of deliberate self-harm utilized by males and females, although there is evidence that more violent methods, especially hanging, may be increasing in females.

Acts of DSH are associated with a variety of motives or intentions. Wanting relief from unbearable feelings or situations, to die and to communicate distress are commonly endorsed motives in both hospital and community samples. Establishing the intent or motives associated with an episode of DSH by adolescents can be difficult. Using the method of DSH as a proxy for intent can be misleading; self-cutting and other methods of self-mutilation do not always involve suicidal intent, but some studies have found that young people who engage in cutting behaviors are at high risk of poor psychosocial outcomes and death by suicide. Community-based studies of adolescents indicate that cutting is the most frequently used method of DSH, whereas adolescents presenting to hospitals are most likely to have taken an overdose. Few differences exist, including in psychiatric symptomatology, between those who engage in self-harm by various methods.

It is now clear that depression, sexual and physical abuse, substance abuse, hopelessness, family breakdown, poor coping, and suicidal behavior by family and friends and in the media increase the risk of suicidal phenomena among children and adolescents. Impulsivity and aggression are vulnerability factors that require further investigation. The role of emergent media forms such as cell phones and the Internet in suicide prevention and contagion is also an area in which one can expect research in the next few years. Relatively little research work has been conducted on factors that protect against the development of suicide behavior. Relevant factors appear to be social connectedness, problem-solving skills, an internal locus of control, involvement with school and recreational activities, life affirming beliefs and religious affiliation.

Whereas many young people who harm themselves do so on only one occasion, others repeat the behavior. A history of previous suicidal behavior increases the risk of future attempts and suicide. The greatest risk of repetition is in the first year following DSH. The reasons why some young people, even those who experience multiple risk factors, stop self-harming require investigation.

The core task of a risk assessment when young people express suicidal thoughts or behaviors is to establish an interactive and dynamic relationship and to be part of a response to the young person’s distress that offers some hope for a better future. Improved assessment and management of deliberate self-harm are highlighted in published guidelines.

A number of key studies have evaluated treatment approaches, including CBT (with or without fluoxetine), MST and DBT. There has been considerable debate about the use of antidepressant medications in the treatment of children and adolescents with depression, with a specific focus on whether SSRIs increase the risk of suicidal behaviors in some young people. Antidepressants should only be used in adolescents when combined with psychological treatment. Further efforts are needed to improve engagement in treatment by children, adolescents and their families.

Many young people who engage in DSH do not seek help for their problems. If they do it is most likely to be from friends and family in preference to formal helping agencies or professionals. There are also gender differences, with distressed young males being less likely to seek help of any kind.

Suicide prevention strategies include specific interventions focused on high-risk groups, such as the management of suicide attempts, and population-level interventions such as restricting access to certain methods of suicide, school-based interventions targeted at the prevention of depression and equipping adolescents who are approached by a distressed peer to respond appropriately. Further refinement of these and other strategies to address the gender differences in help-seeking behavior and the isolation of those who are already experiencing mental health difficulties are required.

SUICIDAL BEHAVIOR AND DELIBERATE SELF-HARM

Hopkins, C. (2002). ‘But what about the really ill, poorly people’: An ethnographic study into what it means to nurses on medical admission units to have people who have harmed themselves as their patients. *Journal of Psychiatric and Mental Health Nursing, 9*, 147–154.

CHAPTER 40

The term “eating disorders” refers to anorexia nervosa and bulimia nervosa and their variants. These disorders typically develop in adolescence or early adulthood but in some cases they start earlier. They are not distinct conditions; they share much the same psychopathology and many patients migrate between them. The etiology of the eating disorders is complex and ill-understood and, with the exception of bulimia nervosa, there has been limited research on their treatment. Cases that present in childhood or adolescence have a fairly good prognosis, but those that persist into adulthood are generally self-perpetuating and difficult to treat. The prompt detection and treatment of childhood and adolescent cases are of paramount importance.

Classification of Eating Disorders in Childhood and Adolescence

The ICD and DSM schemes for classifying and diagnosing eating disorders are similar and recognize two main conditions: anorexia nervosa and bulimia nervosa. Where the schemes differ is in their classification of eating disorders other than anorexia nervosa and bulimia nervosa. In DSM-IV these states are placed in a single category termed “eating disorder not otherwise specified” (eating disorder NOS), whereas in ICD-10 a number of different eating disorder variants are recognized. In this chapter, the DSM-IV scheme is followed because it is more empirically based than ICD-10 and it is the one generally used in research.

Eating disorders need to be distinguished from the DSM-IV diagnosis “feeding disorder of infancy or early childhood.” This refers to a persistent failure to eat adequately resulting in significant failure to gain weight or significant weight loss. The disturbance in eating should not be secondary to a general medical disorder or any other psychiatric condition, and its onset should be before the age of 6 years although typically it is much earlier (see chapter 53). More minor problems with feeding are common, especially in infancy, and faddy eating occurs in over 20% of preschool children. Some of the eating problems seen in late childhood or early adolescence are extensions of these earlier difficulties or variants on them.

Various subtypes have been recognized including “food avoidance emotional disorder,” “selective eating,” “restrictive eating,” “food refusal” and “pervasive refusal” (Bryant-Waugh, 2000). In none of these states is there the overevaluation of shape and weight that characterizes anorexia nervosa and bulimia nervosa.

Diagnostic Criteria

In essence, three features need to be present to make a diagnosis of anorexia nervosa:

1. The overevaluation of shape and weight; that is, judging self-worth largely, or even exclusively, in terms of shape and weight. This is often expressed as an intense fear of becoming fat.
2. The active maintenance of an unduly low body weight (e.g., maintaining a body weight less than 85% of that expected, or a body mass index below the 2nd percentile for age).
3. Amenorrhea (in postpubertal females). The value of the amenorrhea criterion is questionable because the majority of female patients who meet the other two diagnostic criteria are amenorrheic, and those who do menstruate closely resemble those who do not.

Three features also need to be present to make a diagnosis of bulimia nervosa:

1. The overevaluation of shape and weight, as in anorexia nervosa.
2. The presence of recurrent binge eating. A “binge” is an episode of eating during which there is a sense of loss of control and an objectively large amount of food is eaten.
3. The presence of extreme weight-control behavior, such as strict dietary restriction, recurrent self-induced vomiting or marked laxative misuse.

It is also specified that the diagnostic criteria for anorexia nervosa should not be met because otherwise some patients would be eligible to receive both eating disorder diagnoses.

There are no specific diagnostic criteria for eating disorder NOS. Instead, it is a residual category for eating disorders of clinical severity that do not meet the diagnostic criteria for anorexia nervosa or bulimia nervosa. Although neglected until recently, these states are common, both in adults and in children and adolescents. The relationship between the diagnoses anorexia nervosa, bulimia nervosa and eating disorder NOS is illustrated schematically in Fig. 41.1.
Clinical Features

Anorexia nervosa and bulimia nervosa, and most cases of eating disorder NOS, share a distinctive “core psychopathology” which is essentially the same in females and males, adults and adolescents. This is the overevaluation of shape and weight. Whereas most people evaluate themselves on the basis of their perceived performance in a variety of domains of life (such as the quality of their relationships with their family and friends, their work, their sporting prowess), patients with anorexia nervosa or bulimia nervosa judge their self-worth largely, or even exclusively, in terms of their shape and weight and their ability to control them. This overevaluation of shape and weight results in a pursuit of weight loss – note it is weight loss that is sought, not a specific weight – and an intense fear of weight gain and fatness. Most of the other features of these disorders are secondary to this psychopathology and its consequences (e.g., undereating and being severely underweight). Thus, in anorexia nervosa there is a sustained and determined pursuit of weight loss and, to the extent that this pursuit is successful, this behavior is not seen as a problem. Indeed, it tends to be viewed as an accomplishment and, as a consequence, patients have a limited desire to change. In bulimia nervosa equivalent attempts to restrict food intake are punctuated by repeated episodes of binge eating with the result that patients may describe themselves as “failed anorexics.” The great majority of these patients are distressed by their loss of control over eating which makes them easier to engage in treatment, although because of the associated shame and secrecy there is typically a delay of many years before they seek help.

This core psychopathology of anorexia nervosa and bulimia nervosa has other expressions too. Many patients mislabel adverse physical and emotional states as “feeling fat” and equate this with actually being fat. In addition, most repeatedly scrutinize aspects of their shape, focusing on parts that they dislike. This may contribute to them overestimating their size. Others actively avoid seeing their bodies, assuming that they look fat and disgusting. Equivalent behavior is seen with respect to weighing (weight checking) with most patients weighing themselves frequently and as a result becoming preoccupied with trivial day-to-day fluctuations, whereas others actively avoid knowing their weight while nevertheless being highly concerned about it.

Anorexia Nervosa

In anorexia nervosa the pursuit of weight loss is successful in that a very low weight is attained. This is primarily the result of a severe and selective restriction of food intake with foods viewed as fattening being excluded. Generally, there is no true “anorexia” as such. The undereating may also be an expression of other motives including asceticism and competitiveness with others. Some young people engage in a driven type of exercising which also contributes to their weight loss. Self-induced vomiting and other forms of weight-control behavior (such as the misuse of laxatives or diuretics) are practiced by a subgroup, and an overlapping group have episodes of loss
of control over eating although the amount eaten is often not objectively large (subjective binge eating). Depressive and anxiety features, irritability, lability of mood, impaired concentration, loss of sexual appetite and obsessional symptoms are frequently present. Typically, these features get worse as weight is lost and improve with weight regain. Interest in the outside world also declines as patients become underweight with the result that most become socially withdrawn and isolated. This too tends to reverse with weight regain.

**Bulimia Nervosa**

The eating habits of young people with bulimia nervosa resemble those seen in anorexia nervosa. The main distinguishing feature is that the attempts to restrict food intake are punctuated by repeated episodes of binge eating. The amount consumed in these binges varies but is typically 1000–2000 kcal per episode, and their frequency ranges from once or twice a week (the diagnostic threshold) to many times a day. In most cases, each binge is followed by compensatory self-induced vomiting or laxative misuse but there is a subgroup who do not “purge.” The weight of most of these patients is in the healthy range (equivalent to a body mass index of 20–25 in an adult) because the effects of the undereating and overeating cancel each other out. As a result, patients with bulimia nervosa do not experience the secondary psychosocial and physical effects of maintaining a very low weight. Depressive and anxiety symptoms are prominent in bulimia nervosa – indeed, more so than in anorexia nervosa – and there is a subgroup who engage in substance misuse or self-injury or both. This subgroup, which is also present among those anorexia nervosa patients who binge eat, is probably overrepresented in specialist treatment centers.

**Eating Disorder NOS**

The psychopathology of eating disorder NOS closely resembles that seen in anorexia nervosa and bulimia nervosa, albeit the various clinical features are present at somewhat different levels or in different combinations (Fairburn & Bohn, 2005). Many adult cases of eating disorder NOS have had frank anorexia nervosa or bulimia nervosa in the past, their present state being simply the latest expression of an evolving eating disorder. Equivalent information on course has yet to be reported in adolescents.

It is helpful to distinguish two subgroups within eating disorder NOS, although there is no sharp boundary between them. The first comprises cases that closely resemble anorexia nervosa or bulimia nervosa but just fail to meet their diagnostic thresholds (e.g., body weight may be marginally above the limit for anorexia nervosa or the frequency of binge eating may be just too low for a diagnosis of bulimia nervosa). These cases may be classed as “subthreshold” forms of anorexia nervosa or bulimia nervosa, respectively, and should generally be managed as such. In the second group are cases in which the clinical features of anorexia nervosa and bulimia nervosa are combined in a different way to that seen in these two disorders. Such states may be described as “mixed” in character. Other terms have been used to describe the clinical presentations seen in eating disorder NOS including “subclinical” for the former subgroup, a term that is inappropriate given that these states are of clinical severity; and “atypical” or “partial” for the second subgroup. Both the latter terms are problematic; the first because these states are common and the second because of the implication that they are less severe than the full syndromes.

**Distribution**

There is limited reliable information on the distribution of eating disorders and the data that do exist come from studies of western samples. Virtually nothing is known about the distribution of eating disorders in non-western countries. Within western samples, most is known about the distribution of eating disorders among young adults. There have been few studies of children and adolescents, and the findings to date must therefore be regarded as tentative and imprecise (Commission on Adolescent Eating Disorders, 2005).

What is clear is that anorexia nervosa is rare. Most estimates of the point prevalence of anorexia nervosa come from studies of adolescent girls or young adult women, the group thought to be at greatest risk. Even within this group, the prevalence figures obtained are low at 0–0.9% (Hoek, 2006). Outside this age group, and in boys and men, anorexia nervosa is likely to be even less common. Figures for the incidence of anorexia nervosa are particularly suspect as most are based on cases detected medically. They suggest that anorexia nervosa has become more common over recent decades, and especially so in adolescent females, but the apparent increase could well be because of greater help-seeking, better detection and changes in diagnostic practice rather than any true increase in the incidence of the disorder (van Son, van Hocken, Bartelds, van Furth, & Hoek, 2006). In clinical samples, anorexia nervosa is the least common of the three eating disorder diagnoses, comprising 10–15% of adult cases. In adolescent samples the proportion is higher (Nicholls, Chater, & Lask, 2000). The ratio of females : males is about 10:1 in adults but it appears to be somewhat lower in adolescents (Doyle & Bryant-Waugh, 2000).

Unlike anorexia nervosa, epidemiological data indicate that bulimia nervosa is more a disorder of early adulthood than adolescence, with most patients being in their twenties (Fairburn, Welch, Doll, Davies, & O’Connor, 1997; Hoek & van Hocken, 2006). It is more common than anorexia nervosa, in part because the age group at risk is broader (18- to 40-year-old women) and in part because the point prevalence rate is higher (1.0–2.0%). There are no reliable data on the prevalence of bulimia nervosa in boys or men. Clinical experience suggests that bulimia nervosa became considerably more common in the 1970s and 1980s, and limited epidemiological data support this, although there is evidence that the rise has now ceased (van Son, van Hocken, Bartelds et al., 2006). The explanation for these changes is not clear. What
is known is that most cases of bulimia nervosa are not in treatment and the subgroup that is receiving help is atypical in that the eating disorder is more severe and there is greater psychiatric comorbidity (Fairburn, Welch, Norman et al., 1996). Within clinical samples male cases are unusual. Bulimia nervosa comprises about 30–40% of adult eating disorder cases.

The most glaring gap in knowledge about the epidemiology of eating disorders is the total absence of reliable data on the prevalence and incidence of eating disorder NOS in community samples (Hoek, 2006). Studies of adolescents and young adults often report detecting large numbers of people with “partial” or “atypical” syndromes but the status of these cases is unclear in the absence of an agreed definition of eating disorder NOS. What is now well-established is that eating disorder NOS is the most common eating disorder diagnosis among adults, comprising 50–60% of cases (Fairburn & Bohn, 2005) and the same is true of adolescents (Nicholls, Chater, & Lask, 2000). As with anorexia nervosa and bulimia nervosa, it is females who are primarily affected.

**Development and Subsequent Course**

Eating disorders typically develop in adolescence and therefore in the context of “normative” concerns about shape, weight and eating. Physical self-consciousness is common as adolescents come to terms with the changes in their shape that occur at puberty; early pubertal development in girls being associated with especially high rates of body dissatisfaction. Many children, particularly girls, believe that thinness is important to attractiveness, and academic and social success. Even small children believe that fat is undesirable, and girls have been found to prefer thin rather than fat girls as friends. It is therefore not surprising that dieting is common among adolescent girls. This said, there are distinct differences between the behavior and concerns of teenage girls and the psychopathology of people with eating disorders. For example, teenage dieting tends to be intermittent, flexible and not particularly strict, whereas the dietary restraint and restriction of people with eating disorders are persistent, rigid and extreme. While many teenage girls are dissatisfied with their appearance, few show the core psychopathology of eating disorders (i.e., the judging of their self-worth largely, or even exclusively, in terms of their shape and weight). Also, behaviors such as binge eating (as technically defined), self-induced vomiting, laxative misuse and driven exercising are unusual outside those with a frank eating disorder.

The relationship between normative dieting and the development of an eating disorder is ill-understood (for further consideration of this topic see chapter 13). Whereas many adolescent girls diet, few develop an eating disorder of clinical severity. Controlled community-based risk-factor studies have shown that those who develop anorexia nervosa or bulimia nervosa have not only been exposed to circumstances that are likely to increase their risk of dieting (e.g., presence of dieting and weight concern in the family, and a history of childhood obesity in the case of bulimia nervosa), but they have also raised rates of exposure to risk factors for other psychiatric disorders (e.g., family history of depression, adverse childhood experiences including sexual abuse). In addition, premorbid negative self-evaluation and perfectionism are common (Fairburn, Welch, Dou et al., 1997; Fairburn, Cooper, Doll et al., 1999; Fairburn, Cowen, & Harrison, 1999). Thus, it is thought that dieting and shape concern, together with other general psychiatric vulnerability factors, put people at risk of developing an eating disorder. As yet, there have been no satisfactory prospective studies of the development of eating disorders so the findings of the risk-factor research have not been corroborated (Jacobi, 2005). Longitudinal studies such as the Dunedin multidisciplinary health and development study (Arsenault, Moffitt, Caspi et al., 2000; Silva & Stanton, 1997) have the potential to do this and indeed 1.4% of the females in this large cohort had developed an eating disorder by the age of 21 years. However, such studies have been unable to differentiate between risk factors for dieting (e.g., body dissatisfaction), which is an extremely common behavior of no psychopathological significance, and those for clinical eating disorders, which are uncommon. Fairburn, Cooper, Doll et al. (2005) followed almost 3000 16- to 23-year-old dieters over 2 years to determine the characteristics of those who would go on to develop an eating disorder. As expected, only a small proportion of the dieters developed an eating disorder. Not surprisingly, the dieters who developed an eating disorder had more disturbed eating habits and attitudes at baseline than those who did not. Also unsurprising was the fact that several of the features that best identified future cases were features seen in people with eating disorders albeit to a much greater extent (e.g., binge eating, purging and being underweight). Other ominous features were less predictable: eating in secret; preoccupation with food, eating, shape, or weight; fear of losing control over eating; and wanting to have a completely empty stomach.

There are data that suggest that eating disorders are more common than would be expected among models and ballet dancers. It is debatable whether this is as a result of the occupational pressure to be thin, because clinical experience suggests that people who are already concerned about their appearance may be particularly attracted to such careers.

**Anorexia Nervosa**

Anorexia nervosa generally starts as teenage dieting which becomes progressively more extreme and out of control. Often the disorder is short-lived and self-limiting, or it only requires a brief intervention. This is most typical of young cases with a short history. In other cases, it becomes entrenched and may require intensive treatment. Recent outcome studies in which adolescents have been followed-up after 10 years or more report a good outcome in 49–76% of cases, an intermediate outcome in 11–41%, and a poor outcome in 8–14% (Råstam, Gillberg, & Wentz, 2003; Strober, Freeman, & Morrell, 1997). In adults, less than half of cases have a good outcome (Steinhausen, 2002). This heterogeneity in outcome is often neglected in accounts of the disorder.

Even after successful treatment, some residual features are common, particularly a degree of over concern about shape,
weight and eating. In cases that persist a frequent occurrence is the development of binge eating and frank bulimia nervosa. Most prominent among the favorable prognostic factors are an early age of onset and a short history, whereas unfavorable factors include a long history, severe weight loss and vomiting. This said, the prognostic significance of age of onset is inconsistent (Steinhausen, 2002), possibly because the early-onset cases comprise two groups with different outcomes; the prepubertal cases having a poor prognosis whereas the others have a relatively good outcome (Russell, 1992). Anorexia nervosa is the one eating disorder to be associated with a raised mortality rate, anorexia nervosa patients being 12 times more likely to die than women of a similar age in the general population (Keel, Dorer, Eddy et al., 2003). The mortality rate among adolescents is low. Most deaths are either a direct result of medical complications or from suicide.

The outcome in terms of the presence of other psychiatric disorders generally fails to distinguish between those present at the time of diagnosis, which may influence outcome, from those that develop later on. A systematic review of 119 outcome studies found high rates of anxiety disorders and affective disorders at follow-up (Steinhausen, 2002). Difficulties with social and personality functioning are often reported, as are negative physical outcomes such as failure to reach expected height, stunted breast development and reduced bone density. Whereas a range of Axis I psychiatric disorders and personality disorders have been reported at long-term follow-up, these appear to be largely absent in those whose eating disorder has fully remitted.

In the longer term, eating disorders may have an impact on pregnancy and motherhood. In those recovering from anorexia nervosa, fertility problems, spontaneous abortion, prematurity and small-for-dates babies are regularly reported, as are elevated rates of infant mortality (Key, Mason, & Bolton, 2000; Zipfel, Lowe, & Herzog, 2003). In bulimia nervosa, symptoms often improve during pregnancy and in the period after birth, because of the mother’s attempts to exert behavioral control over her eating for the good of the child. Nevertheless, women with bulimia nervosa are at risk of having small babies and higher rates of Cesarean section.

Concerns have been expressed about the parenting abilities of mothers with eating disorders, particularly with respect to difficulties managing infants’ meal times and play. A number have been shown to be intrusive and controlling, and they may have difficulty tolerating messy foods and activities resulting in a strained emotional atmosphere around meal times (Stein, Woolley, & Murray, 2001).

**Bulimia Nervosa**

Both community and clinic-based studies indicate that bulimia nervosa has a somewhat later age of onset than anorexia nervosa although it usually starts in much the same way: indeed, in about one-quarter of cases the diagnostic criteria for anorexia nervosa are met for a time. Eventually, however, episodes of binge eating begin to interrupt the dietary restriction and as a result body weight rises to normal or near normal levels. The disorder is remarkably self-perpetuating once established. Adult patients generally present with a 5–10-year history of unremitting symptoms, and even 5–10 years after presentation between one-third and half still have an eating disorder of clinical severity although in many cases it has evolved into a form of eating disorder NOS (Keel, Mitchell, Miller, Davis, & Crow, 1999). A large-scale prospective study of cases in the community indicated that they have a similarly poor prognosis (Fairburn, Cooper, Doll, Norman, & O’Connor, 2000). Mortality rate does not appear to be raised in bulimia nervosa (Keel Dorer, Eddy et al., 2003). No consistent predictors of outcome have been identified, although childhood obesity, low self-esteem and personality disturbance are often associated with a worse prognosis. The course of bulimia nervosa in adolescence has not been studied.

**Eating Disorder NOS**

The course of eating disorder NOS has barely been studied. As with bulimia nervosa, a 5–10-year history of unremitting symptoms is the norm among adult cases with many patients having a history of anorexia nervosa or bulimia nervosa.

When a longitudinal perspective is taken, the distinctiveness of the three eating disorder diagnoses begins to break down. Most patients with an eating disorder migrate between these diagnoses, and from their perspective they have had one evolving eating problem. This temporal movement, together with the fact that anorexia nervosa, bulimia nervosa and eating disorder NOS share much the same distinctive psychopathology, suggests that common mechanisms are involved in the persistence of these disorders (Fairburn, Cooper, & Shafran, 2003). However, the fact that eating disorders do not evolve into other conditions supports the distinctiveness of the diagnostic category as a whole.

**Etiology**

Research on the etiology of the eating disorders has focused almost exclusively on anorexia nervosa and bulimia nervosa. It is clear that there is a genetic predisposition and a range of environmental risk factors, and there is some information regarding the identity and relative importance of these contributions. However, virtually nothing is known about the individual causal processes involved or how they interact and vary across the development and maintenance of these disorders.

**Genetic Factors**

Eating disorders and certain associated traits run in families with there being cross-transmission between anorexia nervosa, bulimia nervosa and eating disorder NOS (Strober, Freeman, Lampert, Diamond, & Kaye, 2000). This suggests that there is a shared familial liability. There is a raised prevalence of depression in these families, the pattern of familial transmission being unclear (Lilenfeld, Kaye, Greeno et al., 1998). The prevalence of substance abuse is also increased, especially among the relatives of bulimic probands, but in this case there seems
to be no cross-transmission (Lilenfeld, Kaye, Greeno et al., 1998). In addition, there is evidence of familial coaggregation of anorexia nervosa and obsessional and perfectionist traits (Lilenfeld, Kaye, Greeno et al., 1998).

In the absence of adoption studies, twin designs have been used to establish the extent of the genetic contribution to the familiality of eating disorders (Slof-Op ‘t Landt, van Furth, Meulenbelt et al., 2005). Clinic samples show concordance for anorexia nervosa of around 55% in monozygotic twins and 5% in dizygotic twins, with the corresponding figures for bulimia nervosa being 35% and 30%, respectively (Bulik, Sullivan, Wade, & Kendler, 2000; Fairburn, Coven, & Harrison, 1999). These findings suggest a significant heritability of anorexia nervosa but not bulimia nervosa. Because clinic-based samples are potentially biased, population-based studies have also been conducted. These have used broader phenotypes because of the relative rarity of these disorders, and varied findings have emerged. As a result there is still uncertainty as to the extent of the genetic contribution to anorexia nervosa and bulimia nervosa, with there being differing point estimates and wide confidence intervals. The same applies to the contributions of individual-specific and shared (common) environmental factors. There is some evidence that the magnitude of the genetic contribution may increase during adolescence (Klump, McCabe, & Iacono, 2003).

Given the clear and possibly substantial genetic contribution to both anorexia nervosa and bulimia nervosa, molecular genetic studies have been conducted to identify the underlying loci and genes. Genetic association studies have focused in particular on polymorphisms in 5-HT (serotonin) related genes because this neurotransmitter system is important in the regulation of eating and mood, but a range of other polymorphisms have also been investigated. Despite this, no associations with eating disorders have been clearly replicated or confirmed in a family study or by meta-analysis. There has been one multicenter genome-wide linkage study. It found linkage peaks for anorexia nervosa and bulimia nervosa on chromosomes 1, 4, 10 and 14. A further analysis, which covaried for related behavioral traits, identified a different locus on chromosomes 1, 4, 10 and 14. All these findings await replication.

### Other Risk Factors

Many other risk factors have been implicated in clinic and community-based case-control studies (Commission on Adolescent Eating Disorders, 2005; Jacoby, Hayward, de Zwaan, Kraemer, & Agras, 2004). Satisfactory prospective studies are lacking, in part because of the rarity of these disorders. The main putative risk factors are listed in Table 41.1. These differ in the nature, strength and specificity of their association with individual eating disorders. Some are adverse premorbid experiences of the type associated with many psychiatric disorders (e.g., childhood sexual abuse), there being no specific association with eating disorders. Others are common to anorexia nervosa and bulimia nervosa (e.g., parental concerns about shape and weight; a family history of a frank eating disorder; see chapter 27), whereas others appear to predispose especially to bulimia nervosa (e.g., childhood and parental obesity, early menarche, parental alcoholism). Certain of these factors are likely to operate by sensitizing the person to her or his shape thereby encouraging dieting, an effect that is most likely to be seen in women in western societies in view of the social pressure on them to be slim. Yet other risk factors are character traits, the two most prominent being low self-esteem and perfectionism, the latter being a particularly common antecedent of anorexia nervosa. There have been no studies of protective factors.

There is limited information on the distribution and form of eating disorders in non-western societies (Becker & Fay, 2006). There is no doubt that eating disorders occur in most societies, but their relative prevalence is not known. Within western societies there is evidence that some ethnic minority groups may be equally at risk of developing an eating disorder as their White peers. Aspects of the psychopathology of eating disorders may differ in non-western cases. For example, it has been noted that Chinese patients with “anorexia nervosa” often do not show the pathognomonic overvaluation of shape and weight; rather, their purposeful weight loss appears to result from other motives. Similarly, there is evidence that British Asian patients have less marked shape concerns than their

British White counterparts. It has been proposed that bulimia nervosa may be more culturally determined than anorexia nervosa and that heritability estimates for bulimia nervosa may therefore show greater cross-cultural variability than those for anorexia nervosa (Keel & Klump, 2003).

Neurobiological Findings

There has been extensive research on the neurobiology of eating disorders. This has mainly focused on the neuropeptide and monoamine (especially 5-HT) systems thought to be central to the physiology of eating and weight regulation (Kaye, Frank, Bailer et al., 2005). Of the various central and peripheral abnormalities reported, many are likely to be secondary to the disturbance of eating and associated weight loss. However, some aspects of 5-HT function remain abnormal after recovery, leading to speculation that there is a trait monoamine abnormality that may predispose to the development of eating disorders or to associated characteristics such as perfectionism. Furthermore, normal dieting in healthy women alters central 5-HT function, providing a potential mechanism by which eating disorders might be precipitated in women vulnerable for other reasons.

Brain imaging studies have identified altered activity in the frontal, cingulate, temporal and parietal cortical regions in both anorexia nervosa and bulimia nervosa, and there is some evidence that these alterations persist after recovery (Kaye, Wagner, Frank, & Bailer, 2006). Whether they are a consequence of the eating disorder (i.e., a “scar”) or have somehow contributed to it is not known. It is important to stress that the findings to date have not been consistent. The eating disorder field has somewhat lagged behind others in terms of brain imaging research.

Postulated Psychological Processes

Specific psychological theories have been proposed to account for the development and maintenance of eating disorders. Most influential in terms of treatment have been cognitive–behavioral theories. In brief, these propose that the restriction of food intake that characterizes the onset of many eating disorders has two main origins, both of which may operate in an individual case. The first is a need to feel “in control” of life which gets displaced on to controlling eating. This need for control may be greatest in those who are constitutionally anxious, perfectionist or lacking in self-esteem. The second is an overvaluation of shape and weight in those who have been sensitized to their appearance, either by prior experiences (e.g., childhood obesity, parental concerns about eating) or by the changes in shape that occur during puberty. In both instances, the resulting dietary restriction and weight loss are highly reinforcing. Subsequently, other processes begin to operate and serve to maintain the eating disorder. These differ according to the form of the eating disorder. In patients who are severely underweight certain of the so-called “starvation symptoms” have this effect, particularly the preoccupation with food and eating, heightened fullness because of delayed gastric emptying, and social withdrawal. In patients who are binge eating and vomiting, other maintaining mechanisms operate. For example, rigid dietary restraint increases the likelihood of binge eating which in turn encourages further dietary restraint. Self-induced vomiting, while used to compensate for binge eating, results in the binges becoming larger and more frequent. External processes are important too. In those who are primarily restricting their eating, interpersonal conflict (e.g., family arguments) and other forms of stress (e.g., school examinations) tend to lead to an intensification of the dietary restriction thereby bolstering the person’s sense of self-control. In those prone to binge eat, adverse events and negative moods may trigger episodes of binge eating, the binges tending to modulate the negative mood and distract the person from the problem at hand. These processes are described in more detail in cognitive–behavioral accounts of eating disorders (Fairburn, 2006).

Binge Eating Disorder

In comparison to anorexia nervosa and bulimia nervosa, little is known about binge eating disorder. Although it shares with bulimia nervosa the phenomenon of binge eating, its overlap with the other eating disorders is limited: most patients are middle-aged, the gender ratio is less uneven, and the binge eating occurs against the background of a general tendency to overeat rather than dietary restraint (which probably accounts for its strong association with obesity). Furthermore, findings from natural history studies and drug trials suggest that there is a high spontaneous remission rate, unlike the other eating disorders seen in adults. Binge eating disorder does occur in adolescence, generally in combination with obesity, and it is likely to be a risk factor for weight gain. Table 41.2 summarizes current knowledge about the disorder.

Medical Complications and their Management

Most of the physical abnormalities seen in anorexia nervosa are thought to be caused by these patients’ disturbed eating habits and the resulting low weight. Hence, the great majority are reversed by treatment focused on establishing healthy eating habits and a normal weight. The principal physical features are listed in Table 41.3. The physical abnormalities found in bulimia nervosa are usually minor unless purging (vomiting or laxative or diuretic misuse) is frequent, in which case there is risk of fluid and electrolyte disturbance. Those patients who vomit frequently are also at risk of dental damage. The physical abnormalities found in eating disorder NOS depend on the nature of the eating disturbance and the patient’s weight. There are no established medical complications of binge eating disorder per se (other than those secondary to comorbid obesity).

Most of the medical complications occur with equal frequency in adults and adolescents. Some points need to be stressed,
however, when considering adolescents (Commission on Adolescent Eating Disorders, 2005). First, young adolescents have incomplete stores of body fat and other substrates and as a result experience major medical complications after relatively small amounts of weight loss. Second, when anorexia nervosa develops prior to the completion of growth it can result in growth retardation and short stature. This is especially likely in boys because boys grow, on average, for 2 years longer than girls. Catch-up growth can occur with nutritional rehabilitation but nevertheless these adolescents may never reach their height potential. Third, pubertal delay frequently occurs among those who develop the disorder prior to the completion of puberty. Weight gain and the establishment of healthy eating habits usually result in the resumption of spontaneous menstruation but in some cases the amenorrhea may be prolonged. Fourth, the osteopenia and osteoporosis of anorexia nervosa are especially relevant to this age group because adolescence is a critical time for bone mass acquisition. Those who develop anorexia nervosa during adolescence are unlikely to reach their optimal peak bone mass with the consequence that they may be at heightened fracture risk for many years even if they recover from the eating disorder. The underlying pathophysiology is ill-understood and there is uncertainty over the best form of treatment. Restoration of healthy eating habits and weight, and an adequate diet, and with them the resumption of spontaneous menstruation, are of central importance. It is also usual to prescribe calcium supplements, generally given as a multimineral preparation. Hormone replacement therapy is not recommended because there is no evidence that it is effective and there is a risk that it might cause premature closure of the epiphyses.

The panoply of physical abnormalities seen in the eating disorders can cloud thinking about diagnosis and management. The diagnosis of an eating disorder is made on positive grounds by using the history and mental state examination to detect the characteristic behavioral and attitudinal features, not by simply ruling out possible physical causes. No laboratory tests are required to make the diagnosis and, unless there are positive reasons to suspect the presence of physical disease, no tests are required to exclude other medical disorders. In general, the management of any physical abnormalities should focus on the correction of the eating disorder. However, life-threatening complications must be addressed and the patient’s nutritional state needs to be optimized.

CHAPTER 41

Physical symptoms
Heightened sensitivity to cold
Gastrointestinal symptoms (e.g., constipation, fullness after eating, bloatedness)
Dizziness and syncope
Amenorrhea (in females not taking an oral contraceptive); low sexual appetite; infertility
Poor sleep with early morning wakening

Physical signs
Emaciation; stunted growth and failure of breast development (if prepubertal onset)
Dry skin; fine downy hair (lanugo) on the back, forearms and side of the face; in patients with hypercarotenemia, orange discoloration of the skin of the palms and soles
Swelling of parotid and submandibular glands (especially in bulimic patients)
Erosion of inner surface of front teeth (perimylolysis) in those who vomit frequently
Cold hands and feet; hypothermia
Bradyarrhythmia; orthostatic hypotension; cardiac arrhythmias (especially in underweight patients and those with electrolyte abnormalities)
Dependent edema (complicating the evaluation of body weight)
Weak proximal muscles (elicited as difficulty rising from a squatting position)

Abnormalities on physical investigation

Endocrine
Low LH, FSH and estradiol
Low T3, T4 in low normal range, normal TSH (“low T3 syndrome”)
Mild elevation of plasma cortisol
Elevated growth hormone
Severe hypoglycemia (rare)
Low leptin (but possibly higher than would be expected for body weight)

Cardiovascular
ECG abnormalities (especially in those with electrolyte disturbance): conduction defects, especially prolongation of the Q-T interval, of major concern

Gastrointestinal
Delayed gastric emptying
Decreased colonic motility (secondary to chronic laxative misuse)
Acute gastric dilatation (rare, secondary to binge eating or excessive refeeding)

Hematological
Moderate normocytic normochromic anemia
Mild leucopenia with relative lymphocytosis
Thrombocytopenia

Other metabolic abnormalities
Hypercholesterolemia
Increased serum carotene
Hypophosphatemia (exaggerated during refeeding)
Dehydration
Electrolyte disturbance (varied in form; present in those who vomit frequently or misuse large quantities of laxatives or diuretics): vomiting – metabolic alkalosis and hypokalemia; laxative misuse – metabolic acidosis, hyponatremia, hypokalemia

Other abnormalities
Osteopenia and osteoporosis (with heightened fracture risk)
Enlarged cerebral ventricles and external cerebrospinal fluid spaces (pseudoatrophy)

ECG, electrocardiogram; FSH, follicle-stimulating hormone; LH, luteinizing hormone; TSH, thyroid-stimulating hormone.

Table 41.3 Principal physical features of anorexia nervosa. After Fairburn and Harrison (2003).

Management of Eating Disorders

Research Evidence
There has been very little research on the treatment of anorexia nervosa but most of the work that has been carried out has concerned adolescents. There has been much more research on the treatment of bulimia nervosa but so far it has focused exclusively on adults (Commission on Adolescent Eating Disorders, 2005; National Institute for Clinical Excellence, 2004).
One general point is worth stressing at the outset. Treatment outcome among adolescents with anorexia nervosa is generally good, in marked contrast with that amongst adults (Deter, Schellberg, Köpp, Friederich, & Herzog, 2005). This is probably an inherent property of the disorder in these two age groups rather than a reflection of the potency of the treatments used. Adolescents with anorexia nervosa tend to have had the disorder for a very short time – often little more than a year – whereas adults generally have a history of 5 or more years of unremitting symptoms. Thus, many of the maintaining mechanisms that obstruct change in the more enduring cases may not yet be operating in younger patients with the result that they are more responsive to treatment. The same is likely to be true of adolescent cases of bulimia nervosa and eating disorder NOS. Accordingly, priority should be given to the detection and treatment of eating disorders in adolescence in order to prevent them becoming established and progressively more treatment-resistant.

Anorexia Nervosa

There is a range of treatment options for anorexia nervosa. There are various treatment settings, the main ones being outpatient, day patient (partial hospitalization) and in-patient treatment; and within these settings a variety of interventions may be provided, pharmacological or psychological or both. To complicate matters, patients may move from one setting to another, and within any one setting often more than one treatment is employed.

There is no empirical evidence to support the use of any one treatment setting over any other in terms of treatment outcome. There has been just one attempt to randomize patients to different treatment settings and, unfortunately, the comparison was compromised by the unsurprising finding that many patients randomized to in-patient treatment did not want it.

In-patient treatment is used differently in different places; for example, it is common in some countries but unusual in others, and length of stay also varies markedly. Such differences are not evidence-based as in-patient treatment has received scant research attention. Even the most basic questions about in-patient treatment have not been adequately formulated, let alone addressed. For example, not only are the indications for hospitalization not established, but the specific goals are not agreed nor is it known how best to achieve them. Also, it is not clear whether the indications, goals and treatments should differ for adolescents and adults. At best, there is modest evidence from cohort studies to support a focus on eating and an emphasis on weight regain. Comparisons of flexible behavioral programs with more rigid ones have either yielded no significant differences in the rate of weight regain or have favored the more flexible regimes. There is no evidence that drug treatment significantly enhances weight regain.

Even less is known about day patient treatment. Again, the indications are not agreed and the goals not established. It is not clear whether day patient treatment is best viewed as a less expensive alternative to in-patient treatment, as an intensive form of out-patient treatment, or as a distinct modality with particular strengths and weaknesses.

Whatever the place of in-patient and day patient treatment, out-patient treatment is the mainstay of the treatment of anorexia nervosa. Out-patient treatment is the sole treatment for many patients, and even if patients receive in-patient or day patient treatment, it is usually followed by out-patient treatment.

Turning to the form of treatment provided, there is no evidence to support the use of drugs in the treatment of anorexia nervosa. An initial report on young adults suggested that fluoxetine reduced the rate of relapse following in-patient treatment but a subsequent well-conducted two-center study, again on young adults, failed to replicate the finding (Walsh, Kaplan, Attia et al., 2006). Nor is there evidence to support any specific psychological treatment. It is widely thought that there is good evidence to support the use of family therapy to treat adolescents with the disorder. This is not the case.

There have been two comparisons of family therapy with another form of treatment. In the first, Russell, Szmukler, Dare, & Eisler (1987) compared 1 year of an eating disorder-focused form of family therapy with 1 year of supportive psychotherapy in patients who had just been discharged from a specialist in-patient unit (mean age 16.6 years, mean duration of eating disorder 1.2 years). The family therapy studied has since come to be known as the “Maudsley method” (Lock, le Grange, Agras, & Dare, 2001). The results favored the family therapy, both at the end of treatment and 5 years later (Eisler, Dare, Russell et al., 1997; Russell, Szmukler, Dare et al., 1987). The first study involved a comparison of a treatment similar to the Maudsley method with a psychodynamically oriented treatment in which the adolescent patients were seen individually with occasional supportive sessions for their parents (Robin, Siegel, Moye et al., 1999). The outcome of both groups was good, both at the end of treatment and 1 year later. There was one statistically significant difference between them; in terms of increase in body mass index the patients in the family therapy condition did better. However, it is not possible to attribute this finding to the family therapy as many of the patients were hospitalized during their treatment and this was especially common among those who received family therapy.

In summary, only two studies have compared family therapy with another form of treatment and the findings of the second are uninterpretable. Thus, the case for favoring family therapy over other forms of treatment rests on a single study (Russell, Szmukler, Dare et al., 1987) which involved just 21 patients – 10 of whom received family therapy – all of whom had recently been discharged from a specialist in-patient unit. This is a very modest body of data and one of questionable relevance to routine out-patient treatment. It must also be noted that the superiority of the family therapy over the supportive psychotherapy condition might not have been because of the involvement of the patient’s family because there was another important difference between the two treatments: the family therapy placed great emphasis on getting patients to eat well and maintain a healthy weight, whereas there was nothing like
the same focus on eating and weight in the supportive psychotherapy condition. In addition to these two studies, there have been comparisons of different ways of administering the Maudsley method. Their findings are also inconclusive, in part because the studies have been small in size and therefore underpowered. Interestingly, there is no evidence that seeing the family together is superior to seeing them separately from the young person (Eischer, Dare, Hodes et al., 2000). There has also been a larger-scale comparison of a 6-month 10-session version of the treatment with a 12-month 20-session version (Lock, Agras, Bryson, & Kraemer, 2005). They were equally effective.

Clearly, what are needed are adequately powered comparisons of the Maudsley method of family therapy with other forms of treatment, both individual and family-based. It is plausible that family therapy might best suit younger adolescents while a more individually focused form of treatment (such as cognitive-behavior therapy), but one nevertheless involving the family, might be a better option for older patients.

**Bulimia Nervosa**

There have been no studies of the treatment of adolescents with bulimia nervosa. However, there have been over 50 randomized controlled trials evaluating treatments for adults and the main findings are reasonably consistent (National Institute for Clinical Excellence, 2004). Although almost all the trials have been efficacy rather than effectiveness studies, there are good reasons to think that their findings are relevant to most psychiatric settings. Three main findings have emerged. First, the great majority of patients can be managed on an out-patient basis. Second, the most effective treatment is a specific type of cognitive-behavior therapy that focuses on modifying the behavior and ways of thinking that are thought to maintain these patients’ eating disorder (Fairburn, 2006; Fairburn, Marcus, & Wilson, 1993). The treatment typically involves about 20 individual treatment sessions over 5 months. The third finding is that antidepressant drugs have an “antibulimic” effect. They often result in a rapid decline in the frequency of binge eating and purging, and an improvement in mood, but meta-analysis indicates that the effect is not as great as that obtained with cognitive-behavior therapy (National Institute for Clinical Excellence, 2004) and, more importantly, clinical experience and the limited research evidence suggest that it is often not sustained (Walsh, Hadigan, Devlin, Gladis, & Roose, 1991). None of these data have come from studies of adolescents.

Three less robust findings have also emerged. First, combining cognitive-behavior therapy with antidepressant drugs results in few consistent benefits over cognitive-behavior therapy alone. Second, data from two trials suggest that “interpersonal psychotherapy” (IPT), a well-known focal psychotherapy (Weissman, Markowitz, & Klerman, 2000), may be as effective as cognitive-behavior therapy but it takes considerably longer to work. Third, simple, largely behavioral treat-ments (including forms of self-help) that include elements of cognitive-behavior therapy may help a subset of patients although they are unlikely to be sufficient for the majority.

In the absence of research focused on adolescents, the assumption is that cognitive-behavior therapy, suitably modified (Wilson & Sysko, 2006), is likely to be the most effective form of treatment. A possible alternative is interpersonal psychotherapy, an adolescent version of which exists (Mufson, Dorta, Moreau, & Weissman, 2004). For younger adolescents eating disorder-focused family therapy is the other obvious treatment option.

**Eating Disorder NOS**

There have been no studies of the treatment of eating disorder NOS, either in adults or adolescents. This is a remarkable omission given that this is the most common eating disorder diagnosis.

**Clinical Recommendations**

**Assessment**

While the general principles of assessment in child and adolescent psychiatry apply to patients with eating disorders, it is worth emphasizing the importance of certain aspects of the assessment.

Frequently, young people with eating disorders are at a developmental stage when they are negotiating independence from their parents. A significant proportion will be having difficulty with this developmental stage, either attempting to exert their independence and rule parents out of having a role in their lives or else behaving in an immature dependent fashion. It is generally helpful to take an approach that is respectful and age-appropriate but recognizes the role of parents in providing a developmental history, their perspective on the problem and their potential role in treatment. At the same time, whatever the age of the patient, it is important to acknowledge overtly their own perspective. Within any assessment, time should be set aside to enable a sympathetic understanding of the young person’s point of view and a full assessment of their mental state including cognition and risk. This can only be conducted with the young person alone. Thus, there needs to be an individual assessment in addition to a joint interview with the parents. Some advocate a separate parental interview but the gains in terms of information gathering may be offset by the alienation of the young person and potential breaches of confidentiality. Attention to the young person’s physical state is also important if there is a risk that it might be affected.

**Management of Anorexia Nervosa**

Effective management comprises interventions for both the psychological and physical aspects of the disorder. The relative importance of each will depend on the degree of physical illness, but it is important to keep in mind that the physical features are merely consequences of the underlying illness and that restoration of physical health alone cannot be expected
to cure the disorder. When anorexia nervosa has been present for any length of time, adverse social and educational consequences generally follow and so a rehabilitative component will also need to be added to the treatment plan. The psychological features include specific abnormal cognitions related to weight and shape and, commonly, non-specific negative cognitions of ineffectiveness, low mood, guilt and worthlessness. Many young people also have regressed to an immature developmental stage in which they have relinquished age-appropriate responsibility and autonomy. Therefore there is a danger in addressing the physical aspects of the condition that steps by parents and clinicians to take behavioral control will exacerbate the psychological disturbance.

Generally, treatment should be planned to span at least 6 months and only a minority will have fully recovered in 1 year. In other than the mildest cases, treatment should be offered by services experienced in the management of eating disorders. Two important early considerations are when to admit to hospital and the relative importance of family versus individual therapies.

A distinction should be drawn between medical admission to address physical complications and psychiatric admission to treat the underlying disorder. The former is clearly indicated in situations of medical instability, when short-term pediatric management usually benefits from a degree of psychiatric liaison. Although lengthy psychiatric admission is offered in many countries other than the USA, combining psychological therapies with full weight restoration, evidence for the effectiveness of this very expensive approach is lacking.

Education is an essential element of treatment. The young person and his or her parents need to be educated about eating disorders and their management. Often, efforts to give the young person an understanding of the disorder, particularly if the young person is seen alone, make it possible to effectively engage them as a patient. It is often useful if the clinician attempts to empathize with the young person’s experience and how it has led to the eating disorder.

When outlining the treatment plan, it is important to highlight the role of the patient and generally the family in bringing about change. At one end of the spectrum, the parents’ role may be merely to support the young person and encourage their out-patient attendance. At the other extreme (as in the Maudsley method; Lock, le Grange, Agras et al., 2001), their involvement in meal production and supervision may be crucial. Obtaining the young person’s motivation and cooperation can be extremely difficult and it may be necessary to address this continually during treatment. An approach that aims to work with, rather than against the young person, empathizes with their predicament and fears, and instills hope that change will lead to benefits while acknowledging the costs, is generally most productive. In all but the mildest cases, a multidisciplinary approach is recommended. The treating team will usually comprise a psychiatrist, an individual psychotherapist (of whatever discipline), a family therapist, a physician and a nutritionist/dietitian. Specialist in-patient and day patient services may include a physiotherapist, occupational or creative therapists, and teachers.

The management plan will vary for younger children and also for boys. Talking therapies must be age-appropriate and will often use art and other non-verbal approaches with younger patients. Parents of younger children will have a greater role in supporting treatment, particularly in meal planning and supervised eating. In older adolescents, recovery generally implies restoration to a premorbid state of physical health (i.e., return of weight and hormonal functioning against a background of completed growth). In pubescent girls, treatment-imposed weight gain may precipitate the menarche, with all that that implies experientially. A recovering prepubertal child will face the uncertainty of a physical and social identity that has not been experienced before. In a number of respects this will mean “growing up,” and addressing the attendant anxieties that may have played a part in the original development of the condition. A related issue concerns the need to ensure that the “recovered” child or adolescent does not “stand still” – that is to say a 13-year-old restored to a healthy weight might be considered recovered but their health will decline if they are unable to keep pace with the expected trajectories of healthy physical and social development.

The presentation and management of boys are essentially similar to those of girls. However, boys will be expected to continue growth into their late teenage years and ongoing supervision should ensure that their growth potential is maintained. Some boys are uncertain about their sexual identity and such anxieties may be exacerbated by attending a service that predominantly caters for girls. Services should include staff who are familiar with, and comfortable discussing, the common developmental concerns of pubertal boys.

Physical Management

Because of the potentially irreversible effect of anorexia nervosa on adolescent growth and development, the threshold for medical intervention should be lower in children and adolescents than adults. Furthermore, medical complications can occur early in younger subjects before evidence of significant weight loss. Prepubertal children are at particular risk of physical complications of starvation because of their relative lack of body fat and a tendency to dehydrate quickly. Routine blood count, electrolyte levels and liver and thyroid function should be measured. Assessment of serum calcium, phosphate, vitamin B₁₂ and folate is indicated in severe starvation and during refeeding.

Height and weight should be plotted on centile charts and if possible related to premorbid values. Heart rate and blood pressure should be measured and an electrocardiogram performed if cardiac function is compromised or antidepressant treatment proposed. Pubertal status may be assessed by Tanner staging, which provides mean ages and ranges for the development of secondary sexual characteristics. Concerns arise if this staging is more than two standard deviations behind the mean. Ultrasonography can confirm (and enable monitoring
of ovarian function, although an overemphasis on physical progress should be avoided.

When treating the malnourished young person, care should be taken to avoid the refeeding syndrome, a potentially life-threatening disturbance of fluid and electrolyte balance which can follow sudden increases in nutritional intake in those who have been in a state of starvation. This can be achieved by regular monitoring of heart rate, orthostatic vital signs and serum electrolytes including phosphorus, glucose, magnesium and potassium, although total body electrolytes may be depleted even in the presence of normal serum levels. Note that the refeeding syndrome occurs more commonly with parental than enteral feeding. There is a lack of consensus regarding oral feeding requirements. A weight gain of around 1 kg per week is generally recommended for in-patients and 0.5 kg per week for out-patients. After an initial safe weight has been achieved, the young person’s food intake should be adjusted to ensure that growth is in keeping with normal weight and height trajectories.

Weight restoration should utilize the least invasive procedures possible and should be provided within a caring age-appropriate setting. Nasogastric feeding should only be resorted to in the face of persistent refusal to eat normally. Strict behavioral regimes in which young people have to earn privileges through eating and weight gain are not desirable or acceptable as they militate against the therapeutic alliance and there is no evidence that these approaches work, other than by achieving short-term weight gain. In the long term, undue coercion either may be perceived by the young person as a recapitulation of abuse or neglect that they may have suffered previously or it may reinforce low self-esteem and feelings of ineffectiveness, both of which are common antecedents of anorexia nervosa.

**Psychological Treatment**

All young people should have individual psychological therapies to address their specific and non-specific psychopathology. Such features as clinical perfectionism, mood disorder and peer relationship difficulties can usefully be addressed. The behavioral aspects of treatment should also be tackled, hence a cognitive–behavioral approach rather than a supportive or insight-orientated one is to be preferred. The practical aspects of treatment are often ineffective unless the parents are also involved in establishing behavioral control. Parental responsibility for the behavioral aspects of treatment (e.g., dietary planning, involvement in sports), should be age-appropriate and therefore greater with younger patients. Family interventions may also be useful in tackling family communication and relationship problems but it should be noted that the outcomes of family interventions for families with high expressed emotion have to date been poor.

**Pharmacological Treatment**

There is no evidence to support the use of medication in the treatment of eating disorders. Medication may be indicated to treat comorbid disorders, especially depression and obsessive-compulsive disorder. Depressive symptoms are a feature of starvation and so are common in anorexia nervosa. This said, there is a subgroup of adult patients who have a true comorbid clinical depression as indicated by a broad range of depressive features (e.g., hopelessness, thoughts of death and dying, pathological guilt, decreased energy and drive). With such patients, antidepressant medication is indicated. In adolescents in whom “biological” symptoms are less common, the role of antidepressants is less clear and major concerns exist about unwanted effects. Fluoxetine is currently the only antidepressant recommended for first-line use in adolescents in most countries and is sometimes used on empirical grounds. Minor tranquillizers are sometimes used symptomatically to reduce high levels of anxiety, particularly around eating.

**Management of Bulimia Nervosa**

As in the treatment of anorexia nervosa, treatment should include motivational aspects, attention to physical complications, and cognitive and behavioral elements. Young people may benefit from their parents’ involvement, both to assist in meal planning and other practical issues, and also to enable parents to better understand the condition and the treatment plan. As young people rarely present with bulimia nervosa before 16 years of age, the involvement of parents will usually be at the young person’s discretion.

**Psychological Treatment**

Although there have been no adequate studies of psychological treatments for adolescents with bulimia nervosa, it seems appropriate to offer them the empirically supported treatments developed for adults, specifically cognitive–behavior therapy, with appropriate modifications for adolescents (Wilson & Sysko, 2006). The main modifications are the use of age-appropriate written material, the involvement of the family (chiefly the parents), and the addressing of the developmental challenges faced by this age group (e.g., peer relationships, education, use of alcohol, rebellion and conformity). Parents may benefit from psychoeducation delivered either face-to-face, through reading material or by attending a parental support group. Group parental meetings are particularly helpful when the young person declines to involve the parents in their treatment.

**Pharmacological Treatment**

Arguably, this is not indicated because the research on adults indicates that the beneficial effects are less than those obtained with cognitive–behavior therapy and they tend not to be maintained. They could be used as an initial step in management. Recent findings suggest that if patients do not show an early response (within 2 weeks), they are unlikely to benefit (Walsh, Kaplan, Attia et al., 2006).

**Physical Management**

The main physical complications of bulimia nervosa are disturbances of fluid and electrolyte balance resulting from vomiting and laxative misuse. Hypokalemia should be treated with...
oral potassium supplements. Advice on dental hygiene should be offered to avoid the effects of acid erosion. Psychiatric admission to hospital is not recommended, but on rare occasions medical admission may be required to correct physical complications (e.g., when bulimia nervosa coexists with diabetes mellitus).

**Management of Eating Disorder NOS**

The UK NICE guidelines addressed the absence of any research on the treatment of eating disorder NOS by recommending that clinicians follow bulimia nervosa treatment guidelines with cases resembling bulimia nervosa and anorexia nervosa guidelines with cases resembling anorexia nervosa (National Institute for Clinical Excellence, 2004). The trouble with this recommendation is that most cases within eating disorder NOS are of the “mixed” variety rather than subthreshold forms of anorexia nervosa or bulimia nervosa. Of relevance to this gap in knowledge is the development of a new “transdiagnostic” form of cognitive-behavior therapy designed to be suitable for the full range of clinical eating disorders seen in clinical practice including eating disorder NOS (Fairburn, 2006; Fairburn, Cooper, & Shafran, 2003). Emerging evidence suggests that it is as effective as a treatment for eating disorder NOS as it is for bulimia nervosa. This treatment is beginning to be used with adolescents incorporating modifications of the type outlined above.

**Ethical and Legal Issues**

Eating disorders are unusual amongst presentations in Child and Adolescent Psychiatry in that they are potentially life-threatening and may have very serious physical and psychosocial consequences if effective treatment is not provided. Given that young people with eating disorders are often reluctant to seek or accept treatment, practitioners need effective ethical and legal guidelines in order to make treatment decisions (Foreman, 2006).

Where at all possible attempts should be made to establish a therapeutic alliance with the young person, both in order to achieve consent to treatment on ethical grounds and also because effectiveness of treatment depends in large part on the patient’s cooperation. In the former case, many countries permit parents or those with parental authority to consent to treatment on their child’s behalf even in the face of the child’s opposition. In England and Wales, parents may consent on their children’s behalf up to the age of 18 but different countries operate different age limits. In considering the desirability of obtaining the young person’s consent, a distinction should be drawn between treatment directed at reducing risk from the physical consequences of the eating disorder and treatment of the disorder itself. Physical aspects of treatment (e.g., refeeding) may be provided in extreme situations without the young person’s consent and may on occasion be life-saving. However, the psychological and behavioral aspects of the disorder require psychological interventions. While family interventions can proceed to some extent without the young person’s agreement, individual psycho-therapy requires the active participation of the patient if it is to be effective.

On occasion young people with anorexia nervosa decline treatment and clinicians have to decide whether to proceed with treatment against the patient’s will. Rarely, similar considerations apply to extreme cases of bulimia nervosa (e.g., when it is combined with diabetes mellitus). In general, the decision surrounds the desirability of admission to hospital. Given the relatively poor outcome of in-patient treatment for anorexia nervosa in terms of producing full and lasting recovery and the probable poorer outcome in those opposed to treatment, this step should probably only be taken in cases where the child is in acute medical danger. In the UK, there are three potential approaches to the compulsory treatment of young people under the age of 18:

1. Treatment on the basis of parental consent;
2. Treatment under the Mental Health Act (1983); and
3. Treatment under the Children Act (1989; see chapter 8).

Legislation differs between countries but a number of principles underlying the choice apply. Parental consent is often the appropriate framework to employ, particularly in younger patients and in the short term. In many cases, the young person’s opposition will diminish in the early days of an admission once attempts have been made to engage them and they feel safe within the treatment setting. Nevertheless, in these cases the young person’s lack of initial agreement to treatment should be recorded, along with the legal basis for proceeding. Where the young person’s opposition is not readily overcome, is persistent, leads to absconding or requires active treatment against his or her wishes (e.g., nasogastric feeding), consideration should be given to using mental health legislation to provide the basis for treatment.

**Prevention of Eating Disorders**

From conceptual and methodological points of view there are many difficulties to overcome when considering how to develop and test means of preventing eating disorders (Commission on Adolescent Eating Disorders, 2005; Piran, Levine, & Steiner-Adair, 1999). First, there are no substantiated modifiable risk factors. As a result there are no clear targets for preventive interventions. Second, eating disorders are uncommon, with the consequence that to demonstrate that an intervention was effective would require a study on a huge scale. To get round this problem researchers have focused on modifying dieting and concerns about shape and weight. The trouble with this strategy is that these phenomena, while of interest and possible concern, have only a loose relationship to eating disorders of clinical severity. The studies themselves have had other shortcomings. Sample sizes have been relatively small, assessment measures weak and follow-up periods short. As a result of these and other problems, little is known.

The interventions tested so far have mostly been “universal” interventions rather than “targeted” ones, and they have generally taken place in schools. To an extent some have had
limited success in that they have increased knowledge about eating disorders and healthy weight regulation, but few have altered attitudes or actual behavior even in the short term. An unmet challenge is how to integrate eating disorder-focused preventive interventions – which generally aim to reduce dieting and concerns about shape and weight – with those targeted at the prevention of obesity, a more pressing health problem.

Both ICD-10 (WHO, 1996) and DSM-IV (APA, 2000) diag-

Concept of Post-Traumatic Stress Disorder

The diagnosis of PTSD was first conceptualized in response

to observations of Vietnam war veterans presenting with what

came to be recognized as a particular pattern of symp-
mptoms in three clusters: intrusive recollections of a traumatic

event; emotional numbing and avoidance of reminders of that

event; and physiological hyperarousal. In retrospect, similar

patterns were noted as reactions in earlier wars and in prospect,

the criteria were adapted, partly operationalized and applied
to adult civilians. Next, the diagnosis was applied to children

who had experienced an “event outside the range of usual

human experience . . . that would be markedly distressing to

almost anyone” (DSM-III-R, 1987).

Thus, it was argued that there were certain types of stressful

experiences that were very severe and/or unusual and that there

was a distinctive form of stress reaction to these. PTSD was
classified as an anxiety disorder, but many argued that it should

be included as a dissociative disorder. It was increasingly
described as “a normal reaction to an abnormal situation,”

and so, logically, it was queried whether it should be regarded

as a psychiatric disorder at all (O’Donohue & Eliot, 1992). Even

if it were regarded as a normal reaction, it causes substantial

impairment in sufficient cases to be regarded as a disorder.

Results from studies of adults have reasonably established

that PTSD, while being predominantly an anxiety disorder,
differs from other anxiety disorders in important ways. Thus,

Foa, Steketee, & Olasov-Rothbaum (1989) showed that the

trauma suffered violated more of the patient’s safety assump-
tions than did events giving rise to other forms of anxiety. There

was a much greater generalization of fear responses in the PTSD

groups, and, unlike other anxious patients, they reported far

more frequent re-experiencing of the traumatic event. Indeed,
it is this internal, subjective experience that seems most to mark

out PTSD from other disorders (Jones & Barlow, 1992).

Epidemiological investigations in adults suggest that exposure
to traumatic events is common (Kessler, Sonnega, Bromet et

al., 1995), and that only a minority of exposed individuals go

on to develop the disorder (McFarlane, 2005). The argument

is therefore made that PTSD is an “abnormal reaction” that

involves a complex interaction of biological, psychological and

social causes (Yehuda & McFarlane, 1995); exposure to

trauma is insufficient to explain development of the disorder.

Current biopsychosocial and cognitive models (see p. 689) are

paying increasing attention to factors underlying individual
differences in response to traumatic events. Concern has been

expressed that there are other forms of stress reactions to

chronic stressors as experienced in repeated physical or sex-

ual abuse (see chapters 28 and 29). Terr (1991), for example,
draws a distinction between type I and II traumas, roughly

the distinction between acute and chronic. While these are

important debates that will alter the views taken on PTSD,
here we concentrate on acute conditions as manifested in

children and adolescents.

With its roots in studies of adult psychopathology, the concept
has been uneasily extended to apply to stress reactions in

children and adolescents. The major difficulty from the out-

set has been that some of the symptoms are developmentally

inappropriate for younger people. Indeed, the younger the child,

the less appropriate the criteria. Many writers agree that it is

very difficult to elicit evidence of emotional numbing in chil-

dren (Frederick, 1985). Some children do show loss of interest

in activities and hobbies that previously gave them pleasure.

Preschool children show much more regressive behavior as
well as more antisocial, aggressive and destructive behavior. There are many anecdotal accounts of preschool children showing repetitive drawing and play involving themes about the trauma they experienced. Although parents and teachers initially report that young children do not easily talk about the trauma, recent experience has been that many young children easily give very graphic accounts of their experiences and were also able to report how distressing the re-experiencing in thoughts and images was (Misch, Phillips, Evans, & Berelowitz, 1993; Sullivan, Saylor, & Foster, 1991).

All clinicians and researchers need to have a good understanding of children’s development to be able to assist them express their inner distress.

**Manifestations of Stress Reactions in Children and Adolescents**

Immediately following a very frightening experience, children are likely to be very distressed, tearful, frightened and in shock. They need protection and safety. They need to be reunited with their families wherever possible. Clinical experience, surveys and clinical descriptive studies quoted below show that the main manifestations of stress reactions are as follows.

Starting almost immediately, most children are troubled by repetitive, intrusive thoughts about the accident. Such thoughts can occur at any time, but particularly when the children are otherwise quiet, as when they are trying to drop off to sleep. At other times, the thoughts and vivid recollections are triggered off by reminders in their environment. Vivid, dissociative flashbacks are uncommon. In a flashback, the child reports that he or she is re-experiencing the event, as if it were happening all over again. It is almost a dissociated experience. Sleep disturbances are very common, in particular in the first few weeks. Fears of the dark and bad dreams, nightmares, and waking through the night are widespread (and often manifest outside the developmental age range in which they normally occur).

Separation difficulties are frequent, even among teenagers. For the first few days, children may not want to let their parents out of their sight, even reverting to sleeping in the parental bed. Many children become much more irritable and angry than previously, both with parents and peers.

Although child survivors experience a pressure to talk about their experiences, paradoxically they also find it very difficult to talk with their parents and peers. Often they do not want to upset the adults, and so parents may not be aware of the full extent of their children’s suffering. Peers may hold back from asking what happened in case they upset the child further; the survivor often feels this as a rejection.

Children report a number of cognitive changes. Many experience difficulties in concentration, especially in school work. Others report memory problems, both in mastering new material and in remembering old skills such as reading music. They become very alert to danger in their environment, being adversely affected by reports of other disasters.

Survivors have learned that life is very fragile. This can lead to a loss of faith in the future or a sense of foreshortened future, or a premature awareness of their own mortality. Their priorities change. Some feel they should live each day to the full and not plan far ahead. Others realize they have been over-concerned with materialistic or petty matters and resolve to rethink their values. Their “assumptive world” has been challenged (Janoff-Bulman, 1985).

Not surprisingly, many develop fears associated with specific aspects of their experiences. They avoid situations they associate with the disaster. Many experience “survivor guilt” – about surviving when others died; about thinking they should have done more to help others; about what they themselves did to survive.

Adolescent survivors report significantly high rates of depression, some becoming clinically depressed, having suicidal thoughts and taking overdoses in the year after a disaster. A significant number become very anxious after accidents, although the appearance of panic attacks is sometimes considerably delayed. Some children may have been bereaved and may develop traumatic grief reactions.

In summary, children and adolescents surviving a traumatic event may show a wide range of symptoms which tend to cluster around signs of re-experiencing the traumatic event, trying to avoid dealing with the emotions that this gives rise to, and a range of signs of increased physiological arousal. In a substantial minority, this cluster of symptoms will amount to a diagnosable PTSD. Just as in adults, a broad range of adverse outcomes is common (Bolton, O’Ryan, Udwin, Boyle, & Yule, 2000; Pine & Cohen, 2002): there may be considerable overlap of symptoms with depression, generalized anxiety or pathological grief reactions, although whether this indicates the presence of mixed disorders or comorbidity of separate disorders remains to be clarified.

However, this has implications for assessment. It is not sufficient to enquire solely about symptoms of PTSD. Symptoms of anxiety, depression and grief need also to be formally investigated. Nor are self-completed questionnaires measuring these aspects sufficient to make a diagnosis. They have an important role, but sensitive clinical interviews with the child and separately with the parents remain the cornerstone of good assessment.

**Developmental Aspects**

Considerable debate remains as to whether the very young child’s limited cognitive development is protective against developing a chronic post-traumatic stress reaction. Certainly, the diagnostic criteria in both of the major classification schemes are not appropriate for preschool children.

In a series of studies, Scheeringa, Zeanah, Drell et al. (1995); Scheeringa, Peebles, Cook et al. (2001); Scheeringa, Zeanah, Myers et al. (2003); Scheeringa, Wright, Hunt et al. (2006) examined the phenomenology reported in published cases of trauma in infants and young children and evolved an alternative
CHAPTER 42

set of criteria for diagnosing PTSD in very young children. Re-experiencing was seen as being manifested in post-traumatic play; re-enactment of the trauma; recurrent recollection of the traumatic event; nightmares; flashbacks or distress at exposure to reminders of the event. Only one positive item was needed. Numbing was present if one of the following was manifested: constriction of play; socially more withdrawn; restricted range of affect; or loss of previously acquired developmental skill. Increased arousal was noted if one of the following was present: night terrors; difficulty getting off to sleep; night waking; decreased concentration; hypervigilance; or exaggerated startle response. A new subset of new fears and aggression was suggested and is said to be present if one of the following is recorded: new aggression; new separation anxiety; fear of toileting alone; fear of the dark or any other unrelated new fear.

Prospective 2-year follow-up studies have demonstrated good concurrent and predictive validity for this alternative method of diagnosing PTSD in young children. Almqvist & Brandell-Forsberg (1997) provided evidence on how a standard set of play materials can be used to obtain objective data on traumatic stress reactions from preschool children. Thus, one can anticipate further refining of criteria and methods of assessment of PTSD in preschool children in the next few years.

Incidence and Prevalence

Estimates of the incidence of PTSD in trauma-exposed children vary enormously, partly as a result of differing methodologies, and partly as a result of different types of traumatic event. Studies of the mental health of child refugees from war-torn countries find the incidence to be close to 67%. Sexual abuse results in high rates of PTSD (Salmon & Bryant, 2002), as does witnessing violence (Margolin & Gordis, 2000). In various studies of the effects of traffic accidents (that did not result in an overnight stay in hospital), rates of 25–30% are reported (Stallard, Salter, & Velleman, 2004). A study of 200 adolescent survivors of the sinking of the cruise ship Jupiter (Yule, Bolton, Udwin et al., 2000) reported an incidence of PTSD of 51%. Most cases manifested within the first few weeks with delayed onset being rare. Following a nightclub fire in Gothenburg, 25% of the 275 adolescent survivors met DSM-IV criteria for PTSD 18 months after the fire (Broberg, Dyregrov, & Lilled, 2005). Overall, it has been estimated that 36% of children will meet criteria for PTSD following a range of traumas (Fletcher, 1996). This appears fairly constant across developmental levels. In other words, significantly increased demands will be made at all levels of primary and secondary child and adolescent mental health services following traumatic events.

Most epidemiological studies have been of older adolescents and adults. Giaconia, Reinherz, Silverman et al. (1995) reported a lifetime prevalence of 6% in a community sample of older adolescents. Kessler, Sonnega, Bromet et al. (1995) reported a lifetime prevalence of 10% using data collected from older adolescents and adults in the (USA) National Comorbidity Survey. A national sample of eighth grade Danish students estimated a 9% lifetime prevalence (Elklit, 2002). By contrast, the British National Survey of Mental health of over 10,000 children and adolescents (Meltzer, Gatward, Goodman, 2003) reported that only 0.4% of 11- to 15-year-olds were diagnosed with PTSD, with girls showing twice the rate of boys. Below age 10, it was scarcely registered. This lower rate is a point prevalence estimate and is bound to be lower than a lifetime prevalence estimate. Moreover, the screening instrument was not specifically developed to screen for PTSD. The implication is that while the numbers of children and adolescents experiencing PTSD at any one point in time may be as low as 1%, this is still a significant level of morbidity in any community.

Prospective Longitudinal Studies

Data from numerous adult studies show that there is substantial natural recovery from PTSD in the initial months after the trauma. Many individuals recover from PTSD without treatment, and the steepest decline in rates of PTSD is usually seen in the first year. Of course, this still leaves a substantial minority – roughly one-third – who are likely to develop a chronic disorder which may persist for years if left untreated (NICE, 2005). A similar picture is emerging from recent prospective follow-up studies of children. For example, Meiser-Stedman, Yule, Smith et al. (2005) found that among young survivors of assaults and traffic accidents, nearly one in five met criteria for Acute Stress Disorder 2–4 weeks after the event. When reinterviewed at 6 months post-trauma, the rate of PTSD was 12%. The question remains: what factors distinguish those children who will recover spontaneously from those who will go on to develop a chronic reaction requiring treatment (see p. 690)?

There have been very few long-term follow-up studies of children who developed PTSD. The 5–7 year follow-up study of adolescents who survived the sinking of the cruise ship Jupiter found that 15% still met criteria for PTSD that long after the event (Yule, Bolton, Udwin et al., 2000). More recently, a 33 year follow-up of the children who survived the Aberfan landslide disaster found that 29% of those traced and interviewed still met criteria for PTSD (Morgan, Scourfield, Williams et al., 2003). Thus, the long-term effects of life-threatening traumatic events in childhood can be severe and long-lasting.

Risk, Protective and Maintaining Factors

Not all children exposed to trauma will develop PTSD, and of those who do, many will recover without treatment. From this it follows that factors other than exposure to trauma must
influence the onset and maintenance of the disorder. Recent research efforts have attempted to characterize these factors in order to better understand chronic stress reactions, and inform treatment approaches.

**Exposure–Response Relationship**

One of the key concepts in PTSD is that anyone can develop the disorder, irrespective of prior vulnerabilities, provided the stressor is sufficiently great. There is therefore considerable interest in whether there is any evidence for an exposure–response relationship between stressor and pathology. A number of studies bear on this point in relation to children.

In an early study of a sniper attack on a Californian school, Pynoos and colleagues (Pynoos & Eth, 1986; Pynoos & Nader, 1988; Pynoos, Frederick, Nader et al., 1987) reported that approximately 1 month after the event, nearly 40% of the children had moderate to severe PTSD on their Post Traumatic Stress Reaction Index. There was a very strong relationship between exposure and later effects in that those children who were trapped in the playground scored much higher than those who had left the vicinity of the school before the attack or were not in school that day.

Evidence for an exposure–response relationship has also emerged in studies of young people exposed to disasters and war. For example, among children affected by the Armenian earthquake of 1988, there was a clear exposure–response relationship, with the most exposed children at the epicenter reporting highest scores (Goenjian, Pynoos, Steinberg et al., 1995). In a large sample of Rwandese children, Gupta, Dyregrov, Gjestad, & Mukanoheli (1996) found a significant relationship between the number of traumatic events children had been exposed to during the genocide and later stress reactions. In a systematic study of nearly 3000 9- to 14-year-old children following the Bosnian war in Mostar, a very strong relationship between exposure to war trauma and self-reported psychopathology was found (Smith, Perrin, Yule, & Stedman, 2006).

Whereas studies of adults have shown that some types of traumatic event are consistently associated with higher rates of PTSD, data are lacking in this regard with respect to children. Findings from the child studies above strongly suggest that given the same type of exposure, there is a relationship between level of exposure to the stressor and subsequent adjustment. Nevertheless, in most studies, the “objective” level of trauma exposure accounts for a surprisingly small proportion of variance in later adjustment.

**Family Influences**

Various aspects of children’s family environment have been found to be associated with children’s reports of post-traumatic symptoms. These include maternal post-traumatic stress symptoms in cases where mother and child have been exposed to the same trauma (Smith, Perrin, Yule, & Rabe-Hesketh, 2001). Maternal depression (Smith, Perrin, Yule et al., 2002; Wolmer, Laor, Gershon, Mayes, & Cohen, 2000) and general family functioning or emotional atmosphere (Green, Korol, Grace et al., 1991; McFarlane, 1987) have also been implicated. In a recent prospective study of child and adolescent attendees at Accident and Emergency Departments, Meiser-Stedman, Yule, Dalgleish, Smith, & Glucksman (2006) found that parental depression was related to child post-traumatic symptoms at both 2–4 weeks post-accident and again at 6 months after the trauma. Parental worry mediated the relationship between parental depression and child symptoms of stress, but general family functioning appeared less important.

The mechanisms underlying these familial associations remain unclear. In part, they may derive from a complex interaction between parents and children, who can become locked into cycles of not talking about the event for fear of upsetting each other. That is, parents and children may negatively reinforce each other for avoiding processing their traumatic memories, and this is likely to maintain the symptoms of both.

**Cognitive Aspects and Cognitive Models**

Early work recognized that objective measures of exposure were insufficient to explain the variability in children’s post-traumatic stress reactions; subjective appraisal also has a key role. For example, among children exposed to war (Nader, Pynoos, Fairbanks, Al-Ajeel, & al-Asfoor, 1993; Smith, Perrin, Yule et al., 2002) or genocide (Gupta, Dyregrov, Gjestad et al., 1996), perceived direct life threat is strongly related to later PTSD. Similarly, among adolescents involved in a shipping accident, those who made guilt or shame-inducing attributions showed higher levels of PTSD symptoms (Joseph, Brewin, Yule, & Williams, 1993).

More recent work has investigated the applicability to children of adult cognitive models of the disorder (Brewin, 2001; Ehlers & Clark, 2000; Meiser-Stedman, 2002; Salmon & Bryant, 2002). For example, under Ehlers and Clark’s (2000) model, PTSD is maintained by: the disjointed nature of the memory; misappraisals of the trauma and its sequelae; and maladaptive (i.e., avoidant) coping strategies. Retrospective analyses (Stallard, 2003) and well-designed prospective studies (Ehlers, Mayou, & Bryant, 2003; Meiser-Stedman, Yule, Smith et al., 2005) provide evidence that such models do indeed apply to children, at least from the age of about 8 years old. That is, characteristic cognitive distortions and misappraisals appear to have a central role in maintaining PTSD in older children and adolescents, and this has clear implications for treatment (see p. 692).

However, dissociation, which was initially thought to be a key cognitive aspect of the trauma response, appears to be unrelated to the maintenance of PTSD symptoms. Acute stress disorder (ASD) is explicitly conceived as a dissociative response to trauma, requiring three of a possible five dissociation symptoms (APA, 2000). Two recent studies with children show that although acute stress disorder in the first 4 weeks post-trauma is a good predictor of later PTSD, dissociation symptoms do not have a significant role (Kassam-Adams & Winston, 2004; Meiser-Stedman, Yule, Smith et al., 2005). These findings require replication, but are in line with recent adult work which showed that the dissociation criteria do not

---

**POST-TRAUMATIC STRESS DISORDER**

...
enhance the ability of ASD to predict later PTSD (Brewin, Andrews, & Rose, 2003).

Finally, there is a small but growing literature on cognitive biases in memory and attention in children with PTSD (for an overview see Dalgleish, Meiser-Stedman, & Smith, 2005). This approach seeks to examine how basic cognitive processes are affected by trauma exposure, and how such changes may in turn function to maintain post-traumatic stress reactions. An intriguing set of findings has emerged from a handful of experimental studies using the emotional Stroop task, the dotprobe paradigm, and recall tasks. Some studies report evidence for an “avoidant” bias with respect to trauma-related material (Pine, Mogg, Bradley et al., 2005), whereas other studies find a bias in favor of trauma or threat-related material (Moradi, Taghavi, Neshat-Doost, Yule, & Dalgleish, 2000), consistent with the adult literature. In terms of memory, there is evidence for a memory bias for negative material in children with PTSD compared with non-traumatized controls (Moradi, Taghavi, Neshat-Doost et al., 2000). Given the small number of studies, and the mixed set of findings, further research is called for.

**Protective Factors**

There have been few studies that have set out to identify protective factors properly and so inferences have had to be drawn from the general literature on psychopathology and some cross-sectional studies. The main factors commented on have been age, gender, ability and attainment, family factors and coping strategies. In brief, developmental level acts in two opposing ways: younger children may not fully appreciate the extent of the danger facing them, but also immature cognitions may produce more distorted memories. There is generally good agreement from a number of studies that developing PTSD following a traumatic experience is more common in females than in males. Prior poor adjustment and difficult family relationships, including domestic violence, are all associated with a higher risk of developing PTSD and so the opposite, positive attributes are seen as protective. Perceived and actual social support, especially from the family, are noted as being protective, as is possessing a range of effective coping strategies. Where there has been material loss – of home or other possessions – following a natural disaster, then higher income in the family is a protective factor (for reviews see Udwin, Boyle, Yule, Bolton, & O’Ryan, 2000; Yule, Perrin, & Smith, 1999).

**Summary**

In addition to objective exposure severity, subjective appraisals, maladaptive coping strategies and family influences, a number of other factors are implicated in risk for onset and maintenance of PTSD in children. Findings on the role of individual child characteristics such as age, sex and ethnicity have been inconsistent (Vernberg, La Greca, Silverman, & Prinstein, 1996), although there is an emerging consensus that, as with other emotional disorders, girls are more at risk than boys. Udwin, Boyle, Yule et al. (2000) reported that a history of previous exposure to violence and a psychiatric history prior to the trauma increased risk of developing PTSD. In line with adult work (Brewin, Andrews, & Valentine, 2000), the availability of social support in the aftermath of a trauma appears to be import-ant in the subsequent duration and severity of the disorder (Udwin, Boyle, Yule et al., 2000; Vernberg, La Greca, Silverman et al., 1996). Further work is needed to clarify these sets of risk factors.

The implications for intervention remain to be worked out in detail. The successful trials of Narrative Exposure Therapy and of Trauma Focused cognitive–behavioral therapy (CBT) indicate that active CBT therapies must pay close attention both to the trauma narrative and to correcting cognitive distortions in memory. Simple exposure is not enough. The findings from the protective function of social support again indicate that therapists must pay attention to sources of support for the child both within the family and at school.

**Physiological Reactions**

Children’s exposure to trauma can result in biological as well as psychological changes. Recent investigations of a variety of physiological changes in traumatized children have been driven by contemporary neuroscience accounts of fear and stress. These accounts draw on animal models, and have been tested most thoroughly in trauma-exposed adults. In broad summary, traumatic stress activates the locus ceruleus and the sympathetic nervous system (SNS), leading to increased catecholamine turnover, and resulting in increased heart rate, blood pressure, metabolic rate, alertness and circulating catecholamines (adrenaline, noradrenaline and dopamine) – a classic “flight or flight” reaction. During stress, the locus ceruleus also stimulates the hypothalamic–pituitary–adrenal (HPA) axis. The resulting release of corticotropin-releasing factor (CRF) from the hypothalamus stimulates the pituitary to secrete adrenocorticotropin, which in turn promotes cortisol release from the adrenal gland, further stimulating the SNS, and causing intense arousal. Cortisol then suppresses the HPA axis, acting via negative feedback inhibition on the hypothalamus, pituitary and hippocampus, leading to homeostasis. In animals, these neurophysiological processes lead to behaviors consistent with anxiety, hyperarousal and hypervigilance – core symptoms of PTSD. In adults and children, investigation of these two major stress systems – the catecholamine system and the HPA axis – and associated brain structures has therefore been the focus of recent research (for reviews see Cohen, Perel, DeBells, Friedman, & Putnam, 2002; De Bellis, 2001; Pine, 2003). There is evidence that the catecholamine system is disrupted in traumatized children with and without full-blown PTSD. De Bellis, Chrousos, Dorn et al. (1994); De Bellis, Baum, Birmaher et al. (1999a); De Bellis, Keshavan, Clark et al. (1999b) reported significantly increased dopamine in the urine of sexually abused girls, and of maltreated boys and girls with PTSD, which was correlated with the severity of PTSD symptoms. It is hypothesized that excessive dopamine results in under-functioning of the prefrontal cortex, which normally acts...
to extinguish conditioned fear responses. These same studies (De Bellis, Chrousos, Dorn et al., 1994; De Bellis, Baum, Birmaher et al., 1999a; De Bellis, Keshavan, Clark et al., 1999b) also found that children with abuse-related PTSD showed increased 24-h urinary adrenaline and noradrenaline and/or their metabolites. Consistent with a malfunctioning adrenergic response, Perry (1994) found that abused children with PTSD had greater increases in heart rate when exposed to a physiological challenge, compared with non-PTSD control children. In line with this work, Scheeringa, Zeanah, Myers et al. (2004) have more recently shown that even very young (preschool) children with PTSD resulting from exposure to violence or highly invasive medical procedures show increased heart rate in response to trauma reminders, compared to non-traumatized controls. Importantly, it appears that early changes in peripheral physiology may predict later symptoms of PTSD in children. Kassam-Adams, Garcia-España, Fein et al. (2005) reported that among children involved in a road traffic accident, acute heart rate (measured in hospital within hours of the accident) was significantly associated with severity of PTSD symptoms some 6 months later.

In contrast to this relatively straightforward sensitization of the catecholamine system, investigations of HPA axis functioning in traumatized children show that this system works in a rather complex manner. Different patterns of dysregulation may arise, related to time since trauma exposure, and to whether the child has subsequently been exposed to further stress or trauma. In acutely traumatized children, there is evidence for hypersecretion of cortisol (Carrion, Weems, Ray et al., 2002). In contrast, investigations of young samples with chronic PTSD reveal lower resting baseline levels of cortisol (Goenjian, Yehuda, Pynoos et al., 1996) and a blunted corticotropin response (De Bellis, Chrousos, Dorn et al., 1994). The suggestion is that compensatory downregulation of the HPA axis occurs in children with chronic PTSD, leading to an increasingly maladaptive response over time. Furthermore, children with a history of severe maltreatment plus concurrent exposure to new stressors showed an increased corticotropic response and high levels CRF in one study (Kaufman, Birmaher, Perel et al., 1997). De Bellis (2001) suggests that individuals with a history of chronic PTSD may demonstrate a hyperresponding of the HPA axis when encountering new stressors. Evidence for disruption to the HPA axis has led to the administration of low-dose cortisol to treat symptoms of PTSD in adults (Aerni, Traber, Hock et al., 2004), but similar treatments have not been tested in children.

In addition to the study of neurotransmitter systems and neuroendocrine axes, a small number of studies have examined related brain morphology. Of particular interest is the hippocampus, which has a central role in memory processing. High levels of cortisol are toxic to the hippocampus, and studies of adults with chronic PTSD have found the predicted decreased hippocampal volume (Bremner, Randall, Scott et al., 1995; Bremner, Randall, Vermetten et al., 1997).

However, studies with young children have not found this expected damage to the hippocampus (De Bellis, Keshavan, Clark et al., 1999b). It is possible that the adult findings were confounded by alcohol misuse among those with chronic PTSD (because alcohol is also toxic to the hippocampus). Alternatively, the absence of decreased volume in young samples may be because hippocampal damage depends on chronicity of PTSD, occurs at a later developmental stage, or is masked by the normal increase in volume seen during adolescence. Although the expected specific changes to the hippocampus have not been found, it appears that children with PTSD show global adverse brain development: De Bellis, Keshavan, Clark et al. (1999b) found children with PTSD to have smaller intracranial volume and a smaller corpus callosum than controls.

Finally, a number of other psychobiological systems are activated during acute stress. In adults, evidence exists for disruption to the endogenous opiate system, the serotonin system, and to the amygdala and prefrontal cortex, but studies of children are lacking.

In summary, there is growing evidence that children with symptoms of PTSD may show alterations to a number of interrelated neurophysiological systems. Further work will help to develop a better understanding of the complex interplay between physiological and psychological responses to traumatic events. Nevertheless, the need for early identification and treatment of PTSD is already highlighted by studies that have shown that an abnormal neurophysiological response in trauma-exposed children may persist for many years (Goenjian, Yehuda, Pynoos et al., 1996; Ornitz & Pynoos, 1989).

Evidence-based Intervention

There are very few randomized controlled trials of any therapy with children, let alone therapies specifically for PTSD. One has therefore to be cautious in drawing conclusions solely by downward extension of results from work with adults. There have been a number of recent reviews that summarize the published evidence, and they agree to a substantial extent on which studies are included in their reviews (Feeny, Foa, Treadwell et al., 2004; NICE, 2005; Stallard, 2006).

Early Interventions

Whereas prevention is seen as better than cure, in respect of PTSD this has to be seen as preventing the occurrence of traumatic events or children’s exposure to them. Early intervention would be attractive if it could be shown that it prevented later development of PTSD or other disorders, but, as with adult studies, there have been few properly controlled trials of any early intervention. The only one known is that of Stallard Velleman, Salter et al. (2006), in which a trauma-focused discussion on an individual basis was compared with a generally supportive talk. At follow-up, both groups of road traffic accident (RTA) survivors had made good progress and both reported how helpful it had been to talk about the accident (presumably when establishing what happened and inadvertently validating reactions by asking about them systematically).
CHAPTER 42

A later development of this study was to examine a group of survivors of RTAs only at the equivalent time the follow-up interviews were undertaken (i.e., without the baseline interview). This group was also doing well. The study had been designed when single, brief interventions were considered as possible ways of providing early intervention. It is now widely agreed that such one-off, brief, individually administered interventions do not help reduce later PTSD, but this follow-on study demonstrated that children were not upset by talking about their traumatic accident, and this alone should help adults when uncertain about whether to talk to affected children or not.

Cognitive–Behavioral Therapies

PTSD and Single Event Traumas

Few studies have examined the efficacy of psychological treatments for children who have developed PTSD following single event traumas. Goenjian, Karayan, Pynoos et al. (1997) reported that a 7-session schools-based CBT intervention for young people with PTSD some 1.5 years after an earthquake resulted in symptom reduction, whereas an untreated control group showed no such improvement. March, Amaya-Jackson, Murray et al., (1998) used a single-case design to evaluate an 18-session group CBT intervention for 17 young people who had developed PTSD following a variety of trauma (RTAs, accidental injury, gunshot injury and fires). After treatment, there were significant reductions in PTSD symptoms and associated psychopathology (anxiety, depression and anger). This methodologically strong study (using reliable and valid self-report instruments, and a semi-structured interview to evaluate the effect of a manualized treatment protocol) laid the groundwork for subsequent randomized controlled trials (RCTs).

To date, three RCTs of psychological interventions with children who developed PTSD symptoms as a result of single event traumas have been reported (Chemtob, Nakashima, & Hamada, 2002; Smith, Yule, Perrin et al., 2007; Stein, Jaycox, Kataoka et al., 2003).

After Hurricane Iniki hit Hawaii, all elementary school children were screened for serious stress reactions and the high-risk group of 248 children were randomly assigned to one of three treatments (Chemtob, Nakashima, & Hamada, 2002). This comprised four sessions delivered either individually or in groups. The specially developed, manualized treatment had many elements in common with other CBT approaches. Both individual and group treatment had equally good results compared with controls and achieved an effect size of 0.50 on the Kauai Recovery Index (Hamada, Kameoka, & Yanagida, 1996). On the better known Child PTSD Reaction Index (Pynoos, Frederick, Nader et al., 1987) completed on a sample of children by clinicians, the effect size was 0.76. More children dropped out of individual than group treatment.

Stein, Jaycox, Kataoka et al. (2003) report an RCT in which 61 children who had been exposed to violence were given 10 sessions of group CBT and compared with 65 children who were allocated to a delayed intervention condition. At 3 months post treatment, the treated group had significantly lower scores on the Child PTSD Symptom Scale (Foa, Johnson, Feeney et al., 2000). Significant differences were also found on measures of depression and psychosocial dysfunction. Teacher-rated behavioral difficulties did not reflect improvement. The delayed treatment group then made significant PTSD improvement following treatment.

In both of these studies, children were recruited from school-based screening rather than from clinic-referred children. Not all participants had diagnoses of PTSD. The first RCT to report the effects of an individual Trauma Focused Cognitive Behavioural Therapy (TF-CBT) intervention for children following a single event trauma avoided many of the design problems noted above and used a flexible manualized approach to treating 12 children who developed clinician-validated PTSD following assault or RTA (Smith, Yule, Perrin et al., 2007). Treatment was based on Ehlers and Clark’s (2000) model of PTSD, and included a variety of components aimed at reducing known maintaining factors (see p. 689). Post treatment, 11 of the 12 young people who received CBT no longer met criteria for PTSD compared to 5 of the 12 on the waitlist. Treated children also showed significant reductions in symptoms of depression and anxiety. The effect size was 2.20 on the self-report measure and 1.59 on the CAPS-CA (the clinician rated severity on standardized interview). The differences remained at 6 month follow-up. As predicted, therapeutic gains in the CBT group were mediated via changes in maladaptive cognitions.

PTSD and Child Sexual Abuse

In recent years, many of the reactions children develop to sexual abuse have been formulated as part of a spectrum of post-traumatic stress reactions. This has resulted in a number of therapeutic trials of CBT to treat these reactions, including full PTSD.

Ramchandani and Jones (2003) report a systematic review of RCTs treating a range of psychological symptoms in sexually abused children. They identified 12 RCTs: three investigating group CBT; six investigating individual CBT; one of adding group therapy to a family therapy intervention; and two comparing individual (non-CBT) therapy with group therapy. However, the dependent (outcome) measures were very varied, and only four studies looked at recognized specific measures of PTSD.

Celano, Hazzard, Webb et al. (1996) compared 15 girls in an abuse-specific program with 17 given a parallel set of 8 non-directive supportive sessions. There were no differences on child scores including on the Child Impact of Traumatic Events Scale Revised (CITES-R). Deblinger, Stauffer, Steer (2001) enrolled 67 children aged 2–8 years. Although only 44 completed all 11 sessions of treatment, 21 completed group CBT and 23 completed a support group. There was significantly better outcome for CBT, but that group had had higher scores to start with. King, Tonge, Mullen et al. (2000) studied 36 sexually abused children aged 5–17 years who met criteria for PTSD. There were 12 children in each of three conditions:
CBT with child and family; CBT with child alone; and wait-list control. Both treatment conditions consisted of 20 sessions. Using Anxiety Disorders Interview Schedule for Children and Adolescents (ADIS-C) to assess PTSD, there was a significant improvement on PTSD, as well as on self-reported anxiety scales. Both ways of delivering CBT were equally effective. Cohen, Deblinger, Mannarino et al.’s (2004) more recent multisite RCT provides further convincing evidence in favor of CBT.

The immediate and long-term psychological effects of childhood sexual abuse are many, varied and serious (see chapter 29). The studies reviewed by Ramchandani and Jones strongly indicate that CBT is currently the treatment of choice, although there is clearly a great need for better RCTs. As Feeny, Foa, Treadwell et al. (2004) noted, child survivors of sexual abuse may present a different symptom picture to that of children exposed to single incident traumas and so generalization of findings to those may be problematic (see also American Academy of Child and Adolescent Psychiatry, 1998).

**Eye Movement Desensitization and Reprocessing**

Eye Movement Desensitization and Reprocessing (EMDR) was discovered by chance by Shapiro (2001) and has been applied with good results in adults (NICE, 2005). Again, there are a number of case reports claiming effectiveness of EMDR in treating PTSD in children, but a dearth of published RCTs or even other group studies. EMDR is an empirical treatment with little theoretical underpinning. The detailed protocols for treatment include a careful history and ensuring that the patient can have a break if the intrusions during treatment prove too frightening. Essentially, the child is asked to focus on a bad memory while simultaneously following the moving fingers of the therapist. This “dual attention” task is thought to help the child confront the frightening memory and so “process” the emotional reaction to that memory. There is some controversy about the active components of treatment in EMDR. For example, dismantling studies (Pitman, Orr, Altman et al., 1996) have not provided evidence for a cardinal role for saccadic eye movements. The overlap between treatment components of CBT and EMDR (e.g., therapeutic exposure) have led some to suggest that the mechanisms of change may be broadly similar in both approaches.

Chemtob, Nakashima, & Hamada (2002) identified 32 children who still met criteria for PTSD after other attempts at treatment. They achieved significant drops in children’s PTSD symptoms following three sessions of EMDR, with significant but lower drops on depression and anxiety. DeRoos, Greenwald, de Jongh et al. (2004) reported an RCT involving 52 children following the 2000 Enschede (Netherlands) fireworks disaster. Both EMDR and CBT produced significant lowering of stress symptoms, with EMDR doing slightly better in fewer sessions.

Whereas the NICE report (2005) found good evidence from RCTs with adults that allowed a firm recommendation that it be available to patients in the UK NHS, the evidence base with children is far less robust. Even despite the lack of a theoretical basis for EMDR, it appears that it can work very quickly and so should be considered as a possible treatment with children.

**Narrative Exposure Therapy**

Arising in part from South American methods of helping victims of torture and in part from a thoroughgoing analysis of the neurobiology of autobiographical memory and ways of completing fragmented memories, Schauer, Neuner, & Elbert (2004) have developed Narrative Exposure Therapy (NET) and used it in RCTs with adult refugees in the Sudan (Neuner, Schauer, Klascik, Karynakara, & Elbert, 2004) and war-affected children in Sri Lanka (Schauer, Neuner, Elbert et al., 2004). Pennebaker (1995) has long demonstrated that writing about emotional events in structured ways can have very positive effects, and so one can anticipate that structured writing therapies and NET will develop more in the near future.

**Medication**

Despite the paucity of proper trials on children by pharmaceutical companies in developing psychotropic drugs, many children are indeed prescribed such medication following traumas (often by general practitioners rather than child specialists). Given the recent disclosures that trials of selective serotonin reuptake inhibitors (SSRIs) increased suicidal ideation in depressed adolescents, one’s confidence in the use of medication with children is not great. Indeed, the NICE Guideline Development Group (2005) found no study that met its stringent criteria. Medication is not recommended as a treatment for PTSD in children.

**Contingency Planning**

When trauma affects a large number of children at once, as in an accident at school, then a public health approach to dealing with the emergency is required (Pynoos, Goenjian, & Steinberg, 1995). Schools need to plan ahead, not only to deal with large-scale disasters, but also to respond to the needs of children after threatening incidents that affect only a few of them. There are now a number of texts written especially for schools to help them develop contingency plans to deal with the effects of a disaster (Johnson, 1993; Klingman, 1993; Yule & Gold, 1993). Most developed countries have well-established plans to deal with major civil emergencies. Increasingly, these include a psychosocial or mental health component and it is advisable for child and adolescent mental health services to be involved in the planning (Canterbury & Yule, 1999). UN agencies are increasingly prepared to meet the mental health needs of children after war and major disasters (Machel, 2001) and again mental health services need to collaborate with other agencies to meet such needs.

In considering the need to plan for “Mental Health in Complex Emergencies,” Mollica, Lopes Cardoza et al. (2004) argued that all countries should develop plans to meet mental health sequelae of disasters. Because most disasters occur in developing countries, it is vital that appropriate assessment
and intervention tools are developed that are culturally appropriate. It is also essential that such interventions are properly evaluated. Research is essential, not a luxury; that message needs to be accepted by non-governmental officers responding to disasters. Given that disasters happen with great frequency, then by planning ahead, proper consideration can be given to the ethical aspects of intervening soon after a crisis. Unless early interventions are evaluated responsibly, significant resources are wasted and survivors suffer unnecessarily.

Conclusions and Recommendations

Since its formulation in 1980, the diagnosis of PTSD has become widely used in child mental health practice. Using standard criteria and measures, significant minorities of children and adolescents have been diagnosed with PTSD following a variety of major stressors, from transport accidents, natural disasters such as hurricanes or earthquakes, and war. These reactions have now been shown to be long-lasting and disabling in many cases. Most research to date has concerned children of school age, and further work is needed in more closely delineating the stress reactions of very young children.

While it is comforting to children who develop PTSD to be told that their frightening symptoms are "normal," not all children do react this way, and so greater emphasis is needed on attempts to discover why some children are more vulnerable than others. The recent research focus on identifying risk and maintaining factors in carefully designed prospective studies has been fruitful, and has led to effective interventions which aim to reverse those maintaining factors. Further work in identifying modifiable maintaining factors is still required, especially with regard to parent-child interactions in trauma-affected families.

There is considerable overlap in disorders that present after a major traumatic event (Bolton, O’Ryan, Udwin et al., 2000). However, there seems to be more than heuristic value in regarding PTSD to be separate from both other anxiety disorders and from depression. For example, available evidence suggests that PTSD and depression in children are associated with different risks post trauma (Smith, Perrin, Yule et al., 2001), and show a different course and treatment response (Goenjian, Yehuda, Pynoos 2001), and show a different course and treatment response with different risks post trauma (Smith, Perrin, Yule et al., 2001). Further attention to multiple outcomes following trauma would enhance our understanding of the broad range of reactions that children may show, and may lead to more effective treatments for them.

The treatment outcome literature is small but growing. It remains the case that the most solid evidence relates to children traumatized by sexual abuse: here, the evidence is strong for TF-CBT as an effective treatment (NICE, 2005). In contrast, there is a paucity of well-controlled treatment studies for children with PTSD following relatively common single incident stressors such as RTAs and assaults. Published studies support TF-CBT as the treatment of choice for these young people too, but further RCTs are clearly needed. A range of treatments is now available, including EMDR and NET in addition to CBT, and it is expected that RCTs involving more than one active treatment will shed further light on what works for whom.

Studying PTSD has proved a remarkably rich, fertile ground for studying child psychopathology. It is a diagnostic category that helps focus mental health professionals on the needs of children – always providing that they ask the children themselves about their inner experiences and reactions.

CHAPTER 42

Definition: the Concept and Current Issues

Obcessive-compulsive disorder was once considered rare in childhood, but recent advances in diagnosis and treatment have led to recognition that the disorder is a common cause of distress for children and adolescents. It is characterized by the presence of obsessions (unwanted, repetitive or intrusive thoughts) and compulsions (unnecessary repetitive behaviors or mental activities). Because the obsessive-compulsive thoughts and rituals are usually recognized by the child as nonsensical, they are often kept hidden for as long as possible—from both parents and practitioners. This secrecy may have contributed to the fact that until the 1980s OCD was unfamiliar to most child psychiatrists, even though classic descriptions of the disorder featured cases with childhood presentation (Janet, 1903). The recognition that OCD was more common in adults than previously believed, and retrospective reports that one-half to two-thirds of adult subjects had their onset in childhood or adolescence, focused the attention of the child psychiatric community on this chronic and often disabling disorder (Karno & Golding, 1991; Karno, Golding, Sorenson et al., 1988).

Until the mid-nineteenth century, obsessive-compulsive phenomena were considered to be a variant of insanity. However, as the disorder was better defined, it came into focus as one of the neuroses. The descriptions of repetitive unwanted thoughts or rituals, often characterized by magical thinking and usually kept private by the sufferer, were relatively constant observations in those early reports. Debate about core deficits and the relative importance of volitional, intellectual and emotional impairments (all of which are in some way abnormal in OCD) have flourished for over 100 years (Berrios, 1989).

Freud (1906; 1958) speculated about the similarity between obsessive-compulsive phenomena, children’s games and religious rites. Although psychoanalytic theory is empirically unproved and has not been shown to be effective in the treatment of OCD, the broad questions raised by Freud about continuity and discontinuity within individual development and OCD, as well as with regard to secular and religious rituals, remain fascinating issues. In addition, the association between certain neurological disorders, such as Tourette’s disorder (see chapter 44), and OCD, supported by current imaging research, has led to possible localization of brain circuits mediating obsessive-compulsive behaviors as well as mechanisms for behavioral encoding. Over the past decade, interest in these general questions, as well as the possibility of unique pediatric subgroups of OCD, has generated a wealth of clinical and translational research (Apter, Fallon, Jr., King et al., 1996; Fitzgerald, MacMaster, Paulson et al., 1999; Graybiel & Rauch, 2000; Rapoport & Inoff-Germain, 2007). Key issues which appear throughout this chapter are the degree to which at least some cases with childhood onset represent a distinct subtype (e.g., patients with Tourette’s/tics and/or patients with a possible infectious trigger or Pediatric Autoimmune Neuropsychiatric Disorders Associated with Streptococcal infections – PANDAS) and the extent to which there is continuity with normal development. Another important topic is how to optimize treatment for this often chronic condition.

Epidemiology

The Epidemiological Catchment Area (ECA) study of over 18,500 individuals in five different sites in the USA included OCD as a separate category and provided the first large-scale information on the prevalence of this disorder in adults (Karno & Golding, 1991; Karno, Golding, Sorenson et al., 1988) (see page 699). Using the Diagnostic Interview Schedule, a structured interview designed for lay interviewers, lifetime prevalence rates without DSM-III exclusions ranged from 1.9 to 3.3% across sites. Even with DSM-III exclusions, the rates were 1.2–2.4%. These rates were 25–60 times greater than had been estimated on the basis of clinical populations. The mean age of onset across the sites ranged from 20 to 25 years with 50% developing symptoms in childhood or adolescence (Karno & Golding, 1991), providing further support for the retrospective accounts of the frequent pediatric onset of this disorder (Black, 1974). More recent cross-cultural studies with adults have been supportive of similar rates of between 1.9 and 2.5 percent prevalence across widely differing cultures (Horwath & Weissman, 2000). Higher rates are found using DSM-IV than with ICD-10, with only 64% agreement between the two systems (Andrews, Slade, & Peters, 1999). As about a half of adult patients report onset after adolescence or childhood, the similar rates for adult and child populations suggest that...

some pediatric patients must remit. This apparent discrepancy from the chronic nature of most pediatric OCD studied clinically has not been resolved (see discussion below), but may reflect in part that adult cases are typically identified using only one informant, whereas childhood cases are frequently diagnosed on the basis of two informants (the child and parent).

A number of early epidemiological studies of OCD focused on children and adolescents [see review by Zohar (1999)]. One recent additional study examined the results of a large four-site community survey in the USA (the National Institute of Mental Health [NIMH] Methods for the Epidemiology of Child and Adolescent Mental Disorders [MECA] Study) (Rapoport, Inoff-Germain, Weissman et al., 2000). The lifetime prevalence across eight studies (from these two articles combined) indicates relative consistency with a lifetime prevalence from 0.7 to 2.9%. (Also see Table 43.1). Males have an earlier onset than females, contributing to a striking preponderance of males in most pediatric samples (Geller, Biederman, Jones et al., 1998). The variance in prevalence rates is likely to reflect differences in study design, particularly whether clinicians or non-clinicians conducted interviews. Additionally, prevalence estimates may also be sensitive to the diagnostic tools employed. Structured interviews in particular may yield false positives when given to children, who are apt to misinterpret the questions (Breslau, 1987).

There is increasing reliance on standardized interviews and rating scales for both the study and clinical management of OCD. Structured interviews are covered in detail in chapter 19. The most commonly used tools, the Diagnostic Interview for Children and Adolescents (Herjanic & Campbell, 1977; Herjanic & Reich, 1982) and the Schedule for Affective Disorder and Schizophrenia for School-Age Children (Kaufman, Birmaher, Brent et al., 1997), have sections on OCD. In addition, there are several rating scales in general use, including the child version of the Leyton Obsessional Inventory (Berg, Rapoport, Whitaker et al., 1989) and the Yale-Brown Obsessive Compulsive Scale (Y-BOCS) (Goodman, Price, Rasmussen, Mazure, Delgado et al., 1989; Goodman, Price, Rasmussen, Mazure, Fleischmann et al., 1989).

Diagnostic Issues

Continuity with Normal Development

The boundaries of diagnosis are complex in any disorder, and this is clearly the case with OCD. Individual “habits” that
are typical of OCD are extremely common across populations. For example, in one Israeli study, only 18% of the sample endorsed no obsessive-compulsive symptoms at all. Moreover, many ritualistic and “magical” behaviors are part of normal development (Leonard, 1989). As is the case with many disorders, family genetic studies seem to indicate that familiarity of obsessive-compulsive symptoms may extend across the entire range of severity, and similarly twin studies support the model of OCD as the extreme of a continuously distributed trait with biological continuity between normal and abnormal behaviors (Jonnal, Gardner, Prescott, & Kendler, 2000). However, there is evidence from a pediatric sample that symptom levels below the level needed for a categorical diagnosis of OCD do not predict the disorder at follow-up, although interestingly there was some prediction of depression (Berg, Rapoport, Whitaker et al., 1989).

**The Importance of Informant History**

Secrecy appears to be a hallmark of childhood onset OCD. The children recognize that their symptoms are nonsensical and are embarrassed by them, so they go to great lengths to hide them. Hand-washing might be disguised as more frequent voiding and rituals are carried out in private, so that children are often symptomatic for months before their parents are aware of a problem. Teachers and peers typically are aware only for cases with greater severity. As with Tourette’s disorder, children may expend effort controlling their behaviors in public and “let go” when at home. This partial voluntary control of symptoms often baffles and angers parents. Because of the variable degree and timing of the control of symptoms, the nature of the informant has a particularly important influence on recognition and diagnosis of OCD. As shown for the MECA data (Rapoport, Inoff-Germain, Weissman et al., 2000), only 0.3% were identified by parents while 2.5% were identified through self-report from the child, with only one overlapping case.

**Issues with DSM-IV Diagnosis**

OCD is defined in both ICD-10 and DSM-IV as repetitive intrusive thoughts and/or rituals that are unwanted and which interfere significantly with function or cause marked distress. The severity criteria avoid confusion of OCD with many childhood habits that are part of normal development. Both the content and relative insight into the unreasonableness of the thoughts/behaviors differentiate OCD from other disorders.

Whereas clinical experience suggests that the adult criteria can be applied to childhood cases, there are several important caveats. Both DSM-IV and ICD-10 state that compulsions are designed to neutralize or prevent some dreaded event. This may not always be the case, at least for childhood OCD. While some children may not be willing or able to verbalize their obsessive thoughts, long-term contact has demonstrated that about 40% of children with OCD do not have obsessive thoughts; they steadfastly report the presence of only compulsive rituals accompanied by a vague sense of discomfort if the rituals are not carried out (Swedo, Rapoport, Leonard, Lenane, & Cheslow, 1989). At least a third of pediatric patients report that certain stimuli trigger their rituals and that avoidance of the trigger “protects” them from the obsessive-compulsive symptoms (Karno, Golding, Sorenson, & Burnam, 1988). The degree of insight needed for the diagnosis is also in dispute as some patients, at least some of the time, “believe” their obsessive thoughts. It is probable that for both children and adolescents and particularly in severe cases, diagnostic criteria should allow some partial “belief” in the necessity for these thoughts/behaviors.

Changes in diagnostic systems have an obvious impact on estimates of the prevalence of a disorder. In the case of OCD, the most recent version of DSM includes impairment and distress as criteria, as opposed to the earlier version, which included these features only as modifiers. Thus, because of exclusion of either false positives or milder cases, rates of OCD tend to be lower with DSM-IV, with a 12-month prevalence rate of 0.6% being reported in a recent study (Crino, Slade, & Andrews, 2005). Estimates of lifetime prevalence appear to be less affected by the change in diagnostic criteria (Angst, Gamma, Endrass et al., 2004; Swedo, Leonard, & Rapoport, 2004). There are several important differences between the ICD-10 and DSM-IV criteria, such as whether exclusions are made based on comorbid psychotic disorders, such as schizophrenia. DSM-IV (and DSM III-R) allow patients to receive a diagnosis of OCD even in the presence of schizophrenia (APA, 2000) in light of convincing evidence of coexistence with schizophrenia (Byerly, Goodman, Acholonu, Bugno, & Rush, 2005; Poyurovsky & Koran, 2005).

**Continuity with Obsessive-Compulsive Spectrum Disorders**

Another diagnostic issue involves potential “obsessive-compulsive spectrum disorders.” These proposed “spectrum” disorders represent a range of candidates, such as body dysmorphic disorder, hypochondriasis and trichotillomania (involving tension-related, recurrent pulling out of one’s hair). The phenomenological similarities are often striking. For example, similarly to OCD, body dysmorphic disorder and hypochondriasis are characterized by anxiety-arousing concerns and anxiety-reducing rituals, and several impulse control disorders have very prominent compulsive aspects, particularly the repetitive and typically anxiety-relieving motor behavior of trichotillomania. A neurobiological overlap with OCD is suggested by the increased rate of subclinical OCD features in relatives of those with spectrum disorder (Bienvenu, Samuels, Riddle et al., 2000). There are also many studies that have suggested some efficacy for serotonin reuptake inhibiting drugs in the treatment of these disorders, although there are also several notable negative treatment trials (Christenson, Mackenzie, Mitchell, & Callies, 1991; Hollander, 1996; Hollander, King, Delaney, Smith, & Silverman, 2003; Hollander & Wong, 1995; Karno, Golding, Sorenson, & Burnam, 1988). We will consider later the overlap between the neural substrates of OCD and the spectrum disorders.

Children with disorders that are less obviously related to OCD, such as pervasive developmental disorder, frequently
exhibit a compulsive need for sameness but lack other features such as ego-dystonicity (the individual’s sense that the contents of his symptoms are alien and unlike his normal self). Several other disorders exhibit a high comorbidity with OCD but share few of the cardinal symptoms of OCD itself. Thus, disorders such as pyromania, pathological gambling disorder and anorexia nervosa overlap with OCD principally in that their symptoms involve over-focused ideation. There continues to be debate about classification of OCD as an anxiety disorder. Whereas both involve intense internal preoccupation, depression rather than anxiety is the major comorbidity with OCD, and there is evidence from family studies that OCD does not segregate with other anxiety disorders and may have a different pattern of genetic transmission (for a review of this issue, see Bartz & Hollander, 2006).

Unique Childhood Onset Subtypes

This leads to a related question as to whether OCD with very early onset represents an important subtype of the disorder or possibly a different disorder altogether. There is growing evidence that at the very least, early age of onset represents a more familial form of the disorder, particularly for pediatric cases with ordering compulsions (Pauls, Alsobrook, Goodman, Rasmussen, & Leckman, 1995). In one study, no patient with adult onset of OCD had a first-degree relative with OCD (Nestadt, Samuels, Riddle et al., 2000). Additionally, very early onset OCD appears to be more frequently associated with tics and/or Tourette’s disorder (Chabane, Delorme, Millet et al., 2004; Grados, Riddle, Samuels et al., 2001). Moreover, family studies have found that tic disorders are more likely to occur in patients who have relatives with OCD than in patients who lack a familial loading for OCD (Pauls, Alsobrook, Goodman, Rasmussen, & Leckman, 1995).

The postulation of a post-infectious subgroup of pediatric OCD came about as a result of early reports of the association of OCD with Sydenham’s chorea (Freeman et al., 1965; Osler, 1894). This supported converging evidence of basal ganglia involvement in the etiology and/or maintenance of OCD (Wise & Rapoport, 1989). One example of a possible post-infectious subgroup has been identified by research at the NIMH which identified a group of pediatric patients in whom symptom onset or exacerbations are triggered by streptococcal infections; the subgroup is identified by the acronym PANDAS (Pediatric Autoimmune Neuropsychiatric Disorders Associated with Streptococcal infections) (Swedo, Leonard, & Rapoport, 2004). This group of patients appears to have a relatively sudden onset of symptoms, typically has an abnormal neurological examination during exacerbations (particularly tic or choreiform movements – see chapter 44) and tends to have a better outcome. The disorder is thought to arise through a process of molecular mimicry, with the group A β-hemolytic streptococcus (Streptococcus pyogenes) (GABHS) evoking antibodies that are capable of cross-reacting with specific areas of the human brain (e.g., the basal ganglia) to produce neuropsychiatric and behavioral symptoms. However, there remains considerable controversy around the diagnosis, particularly in view of some studies failing to detect elevated levels of autoantibodies in those otherwise meeting criteria for PANDAS (Singer, Hong, Yoon, & Williams, 2005).

Clinical Presentation

Childhood onset OCD has been documented as early as age 2 but more typically begins later in childhood or early adolescence (APA, 1994). In general, the symptoms of OCD in children mirror those in adult patients. Thus, obsessions on the themes of contamination, danger to self or others (such as fears that parents will be harmed), symmetry or moral issues are common; and typical compulsions include washing, checking and repeating – particularly until the child experiences a feeling of “getting it just right” (Despert, 1955; Masi, Millepiedi, Mucci et al., 2005; Thomsen, 1991). Most children have a combination of obsessions and rituals, and pure obsessions are rare compared with the more frequent pure ritualizers. Children with an early age at onset (below age 6) usually begin their rituals or obsessions in an easily recognizable fashion, such as excessive hand-washing or ritualized checking and repeating. In some cases, however, the clinical presentation is altered by the child’s developmental immaturity. For example, one 6-year-old boy, who was compelled to draw zeros repetitively, had started at age 3 to circle manhole covers on city streets. His tantrums when the circling was interrupted, his subjective distress during the behavior and his lack of other psychosocial abnormalities or disorders (such as autism or pervasive developmental disorder) led to the diagnosis of OCD. Another child, who presented at age 7 with clinically significant checking compulsions, had been evaluated previously at 3 years of age when he developed a “compulsion” to walk only on the edges of the floor tiles. Cleaning rituals in children too young to reach the water faucet can present as excessive hand-wiping or licking.

A large community-based study of young adolescents found females more frequently reported compulsions and males more commonly reported obsessions (Valleni-Basile, Garrison, Jackson et al., 1994). The most common compulsions were arranging (56%), counting (41%), washing (17%) and checking (12%). The presenting symptoms of 70 children and adolescents consecutively evaluated at the NIMH are summarized in Table 43.2 (Swedo, Rapoport, Leonard, Lenane, & Cheslow, 1989), which gives greater detail on the content of obsessions. While there is considerable overlap in the symptom profile between the community and clinic samples’ symptom profile, washing compulsions were the most common symptom in the NIMH sample, occurring at some time during the course of the illness in over half of the patients. Hand washing and showering were the most common, and the use of chemicals such as alcohol or detergents provoked eczematoid dermatitis in several cases.

A cluster analysis of symptoms in 213 children with OCD produced five clusters: mental rituals/touching/ordering; cleaning/contamination; superstitions; obsessions/checking/confessing,
and somatic concerns (Ivarsson & Valderhaug, 2006). A similar factor structure of OCD symptoms in children and adolescents was found in an independent analysis (McKay, Piacentini, Greisberg et al., 2006). This shows some overlap with factor analytic studies of symptoms in adult OCD, which have consistently indicated four main symptom clusters in OCD: symmetry/ordering, contamination/cleaning, hoarding and obsessions/checking (Mataix-Cols, Rosario-Campos, & Leckman, 2005). The symptom profiles differ, however, in the absence of a hoarding subgroup in children as well as the prominence of a “superstition” symptom cluster in children with magical thinking and acts as central features. The usefulness of these factors in treatment prediction and genetic studies is being explored (see below).

Approximately one third of pediatric patients report that certain stimuli trigger their rituals and that avoidance of the trigger “protects” them from the obsessive-compulsive symptoms (Swedo, Rapoport, Leonard, Lenane, & Cheslow, 1989). For example, a 16-year-old girl with elaborate front door touching and stepping rituals would “sneak” into her house by a side door, avoiding the sight of the front door and successfully averting the compulsion. Several children avoided looking at certain parts of a room (e.g., “corners of the ceiling”) which set off various gaze rituals. These phenomena have been viewed from an ethological perspective, with the compulsions conceptualized as “fixed action patterns” released by key environmental stimuli (Modell, Mountz, Curtis, & Greden, 1989; Wise & Rapoport, 1989). These triggers are of particular interest for treatment as they often determine the key approach during behavioral desensitization, namely, exposure with response prevention (see below).

### Course and Natural History

Epidemiological studies indicate that over 50% of adults with OCD report that their symptoms started during childhood or adolescence, with males generally having earlier onset than females (Rasmussen & Tsuang, 1984). A single epidemiological study of OCD in a group of 18-year-olds suggested that past depression and substance abuse were predictive of onset of OCD (Douglass, Moffitt, Dar, McGee, & Silva, 1995). There may also be a prodromal phase: parents of nearly half of the NIMH sample revealed that their children had displayed “micro episodes of OCD” years before developing full-blown symptoms. During these episodes, excessive rigidity and repetitive rituals (e.g., wearing the same clothes for a month, refusal to take a different path through the house) were a source of concern, albeit briefly.

A prospective epidemiological survey of 976 children, initially assessed between the ages of 1 and 10 years and then 8, 10, and 15 years later, delineated predictors of OCD symptoms...
OBSESSIVE-COMPULSIVE DISORDER

Associated Disorders

Both epidemiological (Karno & Golding, 1991) and clinical (LaSalle, Cromer, Nelson et al., 2004) studies indicate broad and complex comorbidity for OCD similar to that seen for other major Axis I disorders. The patterns of comorbidity among childhood onset cases are generally comparable with those of adult samples, but with tic disorders and specific developmental disorders appearing more frequently in the pediatric population. In the NIMH sample, only 25% of the pediatric subjects had OCD as a single diagnosis (Swedo, Rapoport, Leonard, Lenane, & Cheslow, 1989). Tic disorders (30%), major depression (26%) and specific developmental disabilities (17%) were the most common comorbidities, and there were also high rates of simple phobias (17%), over-anxious disorder (16%), adjustment disorder (11%), attention deficit disorder (10%), conduct disorder (7%), separation anxiety disorder (7%), and enuresis/encopresis (4%). While our own experience with comorbid bipolar disorder is limited, other groups find increased bipolar comorbidity in severely affected pediatric OCD cases (Masi, Perugi, Toni et al., 2004). This broad comorbidity remains to be explained (for this and other disorders) and is not accounted for by any of the etiological models discussed below. An interesting exception to the broad comorbidity is the lack of association between obsessive-compulsive or anankastic personality disorder and OCD in adults, although the rates (or even the definition, in childhood) of this personality disorder are not known in children and adolescents (Albert, Maina, Forner, & Bogetto, 2004; Masi, Perugi, Toni et al., 2004).

Case Illustrations

Case 1

A 14-year-old boy, whose symptoms had begun gradually, recalls at a very early age having to wash his hands repetitively. He was unable to associate an obsessive thought with this ritual, but he felt compelled to perform it. By age 6, he had developed an obsessive fear of tornadoes. He would repeatedly check the sky for clouds, listen to all weather reports and query his mother about approaching storms. The tornado obsession faded over time and was replaced by a generalized fear of harm coming to himself or his family. He responded with extensive rituals to protect himself and his family. Particularly at times of separating, such as bedtime or leaving for school, the patient would be compelled to repeat actions perfectly or to check repetitively. When asked how many times he would have to repeat an action, he replied, “It depends. The number isn’t always the same, I just have to do it right.” When asked how many times he would have to repeat an action, he replied, “It depends. The number isn’t always the same, I just have to do it right.” When asked how many times he would have to repeat an action, he replied, “It depends. The number isn’t always the same, I just have to do it right.” When asked how many times he would have to repeat an action, he replied, “It depends. The number isn’t always the same, I just have to do it right.” When asked how many times he would have to repeat an action, he replied, “It depends. The number isn’t always the same, I just have to do it right.” When asked how many times he would have to repeat an action, he replied, “It depends. The number isn’t always the same, I just have to do it right.” When asked how many times he would have to repeat an action, he replied, “It depends. The number isn’t always the same, I just have to do it right.” When asked how many times he would have to repeat an action, he replied, “It depends. The number isn’t always the same, I just have to do it right.” When asked how many times he would have to repeat an action, he replied, “It depends. The number isn’t always the same, I just have to do it right.” When asked how many times he would have to repeat an action, he replied, “It depends. The number isn’t always the same, I just have to do it right.” When asked how many times he would have to repeat an action, he replied, “It depends. The number isn’t always the same, I just have to do it right.” When asked how many times he would have to repeat an action, he replied, “It depends. The number isn’t always the same, I just have to do it right.” When asked how many times he would have to repeat an action, he replied, “It depends. The number isn’t always the same, I just have to do it right.” When asked how many times he would have to repeat an action, he replied, “It depends. The number isn’t always the same, I just have to do it right.” When asked how many times he would have to repeat an action, he replied, “It depends. The number isn’t always the same, I just have to do it right.” When asked how many times he would have to repeat an action, he replied, “It depends. The number isn’t always the same, I just have to do it right.” When asked how many times he would have to repeat an action, he...
was slovenly and dirty. He never tied his shoelaces because they had touched the ground and were “contaminated”; if he tied them, his hands would be “dirty” and he would have to wash until they were “clean” again. Remarkably, although his family was aware that “something had been wrong for a long time,” most of the content of his obsessions was kept secret. This case illustrates the contamination concerns common to adolescents as well as the variety and evolution of obsessive-compulsive symptoms during development.

Case 2
A 16-year-old girl had symptoms that began abruptly, shortly after the onset of menses. She called herself “a prisoner of my own mind.” Her obsessions centered around a fear of harm to her parents. She was plagued by recurrent thoughts of her mother dying in a car accident, her father being killed by an intruder, or both her parents dying of burns received in a house fire. Always a light sleeper, she began to get up during the night to check. She spent hours checking that the doors were locked, that the coffee pot was unplugged, and that the family dog was safely ensconced in the garage. Despite her obsessions about fire, however, she did not check the smoke detector, an excellent example of the irrationality of this superficially rational disorder. This patient involved her family in her rituals. Her mother made a checklist that the daughter carried to school, and both parents had to check the twenty-four items on the list, signing that they had done so. At night she would wake her father to help her check. The family involvement was so profound that behavioral treatment could only take place after a period of family counseling in which the parents were helped to separate from their daughter’s illness.

The Differential Diagnosis: Distinguishing OCD from Other Disorders
The broad comorbidity of OCD and an array of associated features make the diagnosis in theory seem difficult; in practice, however, it is usually more straightforward. The diagnosis of OCD must be made only if the “obsessive worries” are true obsessions, rather than symptoms of another disorder such as depressive ruminations or phobic avoidance. For example, when OCD is comorbid with bulimia or anorexia, the content of the obsessions or compulsions must be typical for OCD, e.g., washing, arranging, counting and repeating, and not be solely over-focused ideas about food or diet. Depressive ruminations and psychotic preoccupations are also distinguished by the negative content (e.g., everyone dislikes me, I fail at everything). Phobic disorders are distinguished not only by the content of the preoccupation (more often heights, spiders, the dark, etc.), but also by the absence of discomfort when the patient is not confronted with the phobic object. It may be more difficult to separate the obsessional concerns of OCD from the fears and worries of generalized anxiety disorder (Brown, Moras, Zinbarg, & Barlow, 1993). Comorbidity of OCD and anxiety disorders is common, so assigning specific symptoms to a specific disorder may be less important than identifying the presence of OCD in a child presenting with generalized anxiety or separation anxiety disorder.

Asperger syndrome can be differentiated from OCD by its lack of ego-dystonicity and, in addition, by the content of the preoccupations. For example, in Asperger’s disorder, concerns about danger or contamination occur only rarely, while these are common among children with OCD. Autistic patients also may exhibit obsessive-compulsive symptoms, but these occur within the context of cognitive and psychosocial abnormalities and should not be confused with symptoms of OCD.

The differential diagnosis from Tourette’s disorder is problematic, and the relationship between the two disorders remains obscure. Distinguishing between a compulsion and a tic may be difficult, given the presence of premonitory urges before tics and the complexity of some motor tics (Miguel, do Rosário-Campos, Prado et al., 2000). Some 20–80% of patients with clear Tourette’s disorder have been reported to have obsessive-compulsive symptoms or OCD, while 24–67% of children with primary OCD have been observed to have comorbid tics (Leonard, Lenane, Swedo et al., 1992; Zohar, Ratzoni, Pauls et al., 1992). Tics are seen often in younger patients, those with acute illness and in males. Preliminary impressions are that compulsions associated with Tourette’s disorder may be more likely to involve symmetry, rubbing, touching, or staring and blinking rituals than washing and cleaning (Baer, 1994; Leckman, Grice, Barr et al., 1994). Additionally, aggressive and/or sexual thoughts or rituals have been reported as more frequent in patients with tics and OCD than in those with OCD alone (Despert, 1955; Masi, Millepiedi, Mucci et al., 2005; Thomsen, 1991). However, although some features distinguish the two disorders, the overlapping clinical profiles and family studies provide partial support for the speculation that some cases of OCD and Tourette’s may be alternative forms of the same disorder. Any Tourette/OCD formulation, however, is likely to be oversimplified, as both tic disorders and OCD may be symptoms of basal ganglia-frontal circuitry dysfunction for which genetic, toxic, traumatic and infectious agents can be etiological. In particular, the working model of PANDAS involves the origin of both the tics and OCD through an autoimmune response to group A beta-hemolytic streptococcus.

Theories of Etiology
Over the past thirty years, it has become increasingly clear that OCD is not caused solely by psychological factors as had been posited by Kanner when he cited “an ‘overdose’ of parental perfectionism” as the source of obsessional neuroses (Kanner, 1962). Instead, accumulated evidence suggests that OCD is caused by a combination of biological and psychological factors, with both genetic and environmental influence.

Biological Factors
OCD is remarkable in the consistency of support for a conceptual model which links a disorder characterized by endless, repetitive thoughts and actions with uncontrolled activity of
parallel, discrete loops within the brain. These loops connect the basal ganglia, prefrontal cortex – particularly the orbitofrontal and anterior cingulate regions – and thalamus, the so-called cortico-striato-thalamocortical (CSTC) loops (Alexander, DeLong, & Strick, 1986; Kopell, Greenberg, & Rezai, 2004; Modell, Mountz, Curtis, & Greden, 1989; Rapoport & Wise, 1988; Saxena, Bota, & Brody, 2001).

Several CSTCs have been assumed to be of particular importance in OCD, based on clinical, imaging and lesion studies. The first “direct” pathway is in essence a positive feedback loop that results in the initiation and continuation of thought and action. It is counterbalanced by an “indirect” pathway that acts as a check on the activation of the direct pathway (Fig. 43.1). The direct pathway starts with a glutamatergic signal to the striatum, which in turn sends an inhibitory GABA-ergic signal to the globus pallidus. This results in a disinhibition of the thalamus which is fed forward to the prefrontal cortex, particularly orbitofrontal regions. The indirect pathway differs in that the striatum projects an inhibitory signal to the globus pallidus, which increases inhibition on the thalamus and thus decreases prefrontal cortical activation. While there are multiple neurotransmitters involved in this circuit, including substance P and GABA, there are also serotonergic projections to this component from the dorsal raphe to the ventral striatum. These projections are speculated to be inhibitory. OCD symptoms could arise when an aberrant positive feedback loop develops in the first circuit, which is inadequately modulated by the output from the second circuit. Finally, some have recently argued for the need to incorporate limbic structures to account for the strong anxiety component of OCD.

**Neuroanatomical Anomalies**

The implication of abnormal activity in CSTCs is supported by consistent findings of structural and functional anomalies within these circuits in children with OCD. For example, a host of neurological disorders that affect the basal ganglia, including Huntington’s chorea, post-encephalitic Parkinsonism and acquired lesions of the caudate and putamen, have been linked with the development of OCD in adulthood (Chacko, Corbin, & Harper, 2000). The autoimmune sequelae of streptococcal infection, which may target the caudate, have long been recognized in the pathogenesis of Sydenham’s chorea, and may be of particular importance in the etiology of obsessions in a subgroup of children (PANDAS) (Swedo, Leonard, & Rapoport, 2004). All the components of the basal ganglia (caudate, putamen and globus pallidus) have been reported as abnormal in children with OCD – see Table 43.3. Volumetric studies of the caudate are typical for the field in the inconsistency of findings, with reports of increase, decrease and no change in caudate volume in children with OCD (Giedd, Rapoport, Garvey, Perlmutter, & Swedo, 2000; Luxenberg, Swedo, Flament et al., 1988; Rosenberg, Averbach, O’Hearn et al., 1997; Szaszko, MacMillan, McMeniman et al., 2004). The marked variability in findings may reflect not only technical aspects relating to heterogeneity of definitions of regions of interest, but also comorbidities such as tic disorder and...

the possible contribution of post-infectious inflammatory processes contributing to volume enlargement, as is proposed in PANDAS (Swedo & Grant, 2005). Importantly, some structural changes normalize as symptoms resolve, suggesting that they may be epiphenomenal and do reflect underlying neurobiological vulnerability. Prompted partly by the inconsistent volumetric findings in the basal ganglia, Bartha and colleagues (1998) examined ultrastructural features of the caudate nucleus using magnetic resonance spectroscopy (MRS) in adults with OCD. They reported no gross structural changes in the volume of the caudate but found a reduced amount of N-acetyl-aspartate (NAA) in the left caudate. The exact physiological function of NAA is unclear, but appears to relate to the regulation of metabolic processes within neurons and may thus reflect subtle neuronal dysfunction within the caudate, not usually detectable by gross anatomic techniques.

Turning to the frontal lobes, acquired lesions of the ventromedial and polar frontal cortex have also been linked with the de novo onset of OCD and some of its cardinal symptoms, such as hoarding (Anderson, Damasio, & Damasio,
In children with OCD, specific reduction in the volume of the orbitofrontal cortex has been reported, a finding congruent with our preliminary reports of a highly localized thinning of the cortex in right orbitofrontal and polar frontal regions in early onset OCD (Shaw & Rapoport, unpublished data; Szeszko, Robinson, Alvir et al., 1999). Expansion of gray matter in the left anterior cingulate cortex in an unmedicated pediatric OCD population, which was not found in other prefrontal regions, was found to be positively correlated with obsessive symptoms scores and has been consistently reported by several groups (Rosenberg & Keshavan, 1998; Szeszko, MacMillan, McMeniman et al., 2004). Positive correlations between expansion of the anterior cingulate and the putamen were also reported, compatible with the postulation of abnormal cingulate-striatal circuitry. Reports of anomalies in the dorsolateral prefrontal cortex are less common, although magnetic resonance spectroscopy has demonstrated anomalies in the level of the putative neuronal marker NAA in the dorsolateral prefrontal cortex of unmedicated children with OCD (Russell, Cortese, Lorch et al., 2003).

Thalamic hyperactivation, which is fed forward to the frontal cortex, is the final component of the pathophysiological circuit in OCD, and might be predicted to have trophic effects. Indeed, thalamic enlargement which resolves following successful treatment with paroxetine has been reported in pediatric OCD (Gilbert, Moore, Keshavan et al., 2000). This is complemented by reports of abnormal thalamic NAA and choline levels in pediatric OCD (Fitzgerald, Moore, Paulson, Stewart, & Rosenberg, 2000). One interpretation is that the NAA levels reflect neuronal perturbations and the abnormal choline levels reflect anomalous myelination in childhood; both factors could contribute to volume change in the thalamus.

Turning to white matter, Rosenberg and colleagues have demonstrated a positive correlation between increased surface area of the corpus callosum and symptoms scores in children with OCD. They also found abnormal signal intensity (which might reflect anomalous myelination) in the portion of the corpus callosum that connects the ventral prefrontal cortex with the striatum (MacMaster, Keshavan, Dick, & Rosenberg, 1999; Rosenberg, Averbach, O’Hearn et al., 1997; Rosenberg, Keshavan, O’Hearn et al., 1997). More recent developments in white matter imaging such as the use of diffusion tensors to assess the integrity and coherence of white matter tracts have been reported in adults only and similarly show anomalies in the region of the anterior cingulate (Russell, Cortese, Lorch et al., 2003). The white matter changes may represent a possible neuroanatomical substrate for aberrant connectivity between these regions.

Functional neuroimaging studies also support the fronto-striatal model. Both functional MRI (fMRI, measuring change in blood flow) and positron emission tomography (PET, measuring glucose utilization as an index of brain activity) studies have demonstrated symptom-provoked hyperactivation (fMRI) and resting hypermetabolism (PET) in the orbitofrontal cortex, cingulate gyrus and the caudate in patients with OCD (Szeszko, Ardekani, Ashtari et al., 2005). The specificity of these regional anomalies is demonstrated by the partial normalization following effective treatment (Saxena, Brody, Maidment et al., 1999). Functional imaging studies using the OCD symptom-provocation paradigm report additional hyperactivation of many of the same regions, with some recent work suggesting that different components of the fronto-striato-thalamic circuit may mediate the anxiety associated with different symptom clusters (Mataix-Cols, Cullen, Lange et al., 2003; Mataix-Cols, Wooderson, Lawrence et al., 2004; Perani, Colombo, Bressi et al., 1995).

Neurochemistry

Monoaminergic neurotransmitters which extensively project from the brain stem to regions within the fronto-striato-thalamic circuitry may contribute to the pathogenesis of OCD. OCD symptoms are frequently exacerbated by serotonin agonists (such as meta-chlorophenylpiperazine), and the serotonin reuptake inhibitors are the most effective therapeutic agents (Gross-Isseroff, Cohen, Sasson, Voet, & Zohar, 2004). Abnormalities of serotonergic transmission in OCD are suggested by imaging studies of central serotonin receptors using specific ligands, which have demonstrated a reduction in 5-HT synthesis in the ventral prefrontal cortex and caudate in eleven treatment-naïve pediatric subjects, which partially normalized following successful treatment (Simpson, Lombardo, Slishfet et al., 2003). Inconsistent findings on the levels of central serotonin transporter availability may be partly attributable to developmental effects, as an increase in central serotonin transporter availability (indexed by the binding profiles of a ligand thought to bind to the transporter) was reported only for those with child- but not adult-onset OCD (Pogarell, Hamann, Popperl et al., 2003; Simpson, Lombardo, Slishfet et al., 2003; Stengler-Wenzke, Muller, Angermeyer, Sabri, & Hesse, 2004). There are less consistent findings for the dopaminergic system, with mixed results concerning changes in peripheral dopaminergic markers and the provocation of obsessive symptoms by dopamine agonists (Denys, Zohar, & Westenberg, 2004). PET neuroimaging studies, however, have demonstrated higher caudate dopamine transporter densities in tandem with lower concentrations of the dopamine D2 receptor, consistent with receptor down-regulation resulting from higher synaptic concentrations of striatal dopamine in adults with OCD (Denys, van der Wee, Janssen, De Geus, & Westenberg, 2004; van der Wee, Stevens, Hardeman et al., 2004). Glutamate is the major excitatory neurotransmitter in the fronto-striatal circuitry, and magnetic resonance spectroscopy has demonstrated elevation in levels of glutamate and glutamine in the thalamus of treatment-naïve children with OCD, with a reduction in symptoms occurring in tandem with normalization of the glutamatergic marker (Rosenberg, MacMaster, Keshavan et al., 2000). A decrease in glutamate levels in the anterior cingulate has also been found, although this may not be specific to OCD as it was also seen in children with major depression (Rosenberg, Mirza, Russell et al., 2004). There is, thus, some direct support for anomalous serotonergic neurotransmission and more indirect and somewhat
CHAPTER 43

inconsistent evidence of abnormal dopaminergic and glutamatergic signaling.

Neuroendocrinology

Several lines of evidence suggest that endocrine perturbations may play an etiological role in OCD. Obsessive symptoms frequently worsen around the time of menses and during the post-partum period, and there are case reports of improvement with anti-androgen therapy (Brandes, Soares, & Cohen, 2004; Casas, Alvarez, Duro et al., 1986; Rasmussen & Eisen, 1992). The finding of short stature in children with OCD (Hamburger, Swedo, Whitaker, Davies, & Rapoport, 1989) implicates the growth hormone (GH) axis and is supported by evidence of a lower bone age in OCD (Katz, Gothelf, Hermesh et al., 1998). However, assaying the growth hormone axis using a clonidine challenge (which acts at the alpha 2 adrenergic receptor to cause GH release) found an enhanced GH response in children with OCD and comorbid anxiety, suggesting an intact growth axis (Sallee, Richman, Sethuraman et al., 1998). Additionally, the only direct study of growth hormone in OCD found no difference from healthy controls in baseline levels, but did find reduced sensitivity for the OCD group following stimulation of growth hormone with growth hormone releasing hormone (Brambilla, Bellodi, Perna, Arancio, & Bertani, 1998).

Neuropsychological Models

Failure to resist obsessions and compulsions has been conceptualized as a failure of cognitive control in childhood OCD (Chamberlain, Blackwell, Fineberg, Robbins, & Sahakian, 2005). Deficits in suppressing prepotent motor responses in children with OCD have been reported, which in turn have been linked to reduced amplitude of evoked potentials in the orbitofrontal cortex (Malloy, 1987). Similarly, children with OCD have deficits in suppressing oculomotor reflexive responses to external cues, suggesting compromise in prefrontal cortical circuitry (Rosenberg, Dick, O’Hearn, & Sweeney, 1997). Using a probe designed to assess cognitive control (requiring the monitoring of repeated or conflicting information), anomalous activation in the anterior cingulate was found in a group of young adult OCD subjects, with much more extensive anomalous activation of posterior brain regions in those subjects who reported little resistance to their obsessions (Viard, Flamant, Artiges et al., 2005). Similarly, deficits in the inhibition of irrelevant information have been demonstrated using variants of the Stroop task (Nakao, Nakagawa, Yoshiura et al., 2005).

A related model of OCD views the disorder as the result of over-activation of a system designed to monitor performance completion, leading to a constant feeling that an action is “not just right”, which thus creates a need to correct perceived mistakes. A range of tasks assessing aspects of performance monitoring, error detection and response to conflicts have converged to show hyperactivity in the anterior cingulate in patients with OCD (Fitzgerald, Welsh, Gehring et al., 2005; Malloy, Tolin, Worhunsky, O’Keefe, & Kiehl, 2005; Ursu, Stenger, Shear, Jones, & Carter, 2003; van Veen & Carter, 2002).

Other fMRI studies have delineated aberrant processing of affectively charged material in OCD, by both the amygdala (for frightening stimuli) and the insula (for disgust) in OCD (Cannistraro, Wright, Wedig et al., 2004; Shapira, Liu, He et al., 2003; van den Heuvel, Veltman, Groenewegen et al., 2004). These data provide the basis for the incorporation of the rich structural and functional interactions between these components of the limbic system with the fronto-striato-thalamic loops in current models of OCD (for such a model see Figure 43.1).

A wide range of deficits on standard neuropsychological tasks has been reported, particularly in visuospatial ability and non-verbal memory (reviewed in Kuelz, Hohagen, & Voderholzer, 2004). Some of these deficits can be related to dysfunction in frontostriatal circuitry. For example, implicit learning (knowledge acquired through repetition or exposure and expressed without conscious reference to the learning experience) is thought to rely on the striatum, in contrast to explicit learning (learning with conscious coding and retrieval), which relies on fronto-temporal cortical integrity. Subjects with OCD show normal implicit learning, but unlike healthy controls do not recruit the striatum during this learning, but rather show possible compensatory activation of the medial temporal lobes (Rauch, Whalen, Curran et al., 2001). Planning abilities have been inconsistently reported as impaired in OCD (Chamberlain, Blackwell, Fineberg, Robbins, & Sahakian, 2005; Veale, Sahakian, Owen, & Marks, 1996) and, in one functional imaging study, such dysfunction was accompanied by abnormal activation of the dorsal prefrontal cortex and caudate in patients with OCD (van den Heuvel, Veltman, Groenewegen et al., 2005). However, many of these neuropsychological deficits are not specific to OCD, their causal relationship with the symptoms of OCD is unclear, and the deficits are more consistently reported in adults rather than children with OCD (Douglass, Moffitt, Dar, McGee, & Silva, 1995; Thomsen & Jensen, 1991).

Behavioral formulations of compulsions have formed the mainstay of psychological treatments and view compulsive behaviors as a form of avoidance that maintains obsessive fears through reducing anxiety (negative reinforcement) and by blocking opportunities for habituation to feared situations. Cognitive psychologists emphasize elements such as the interaction of intrusivewith dysfunctional underlying assumptions (e.g., having an over-inflated sense of personal responsibility) in maintaining symptoms (for a review, see Salkovskis, Shafran, Rachman, & Freeston, 1999).

How specific is this neural substrate to OCD? Similar anomalous interaction between the striatum and prefrontal cortex is also held to be important in ADHD (see Castellanos & Tannock, 2002; see also chapter 33). Additionally, the neural circuitry underpinning several anxiety disorders, particularly social phobia and post-traumatic stress disorder, includes the limbic regions implicated in more recent refinements of models of OCD (Shin, Wright, Cannistraro et al., 2005; Stein, 2002). Some degree of overlap is perhaps inevitable,
but there are several unique features in the OCD model outlined above, most importantly, the emphasis on an imbalance of the direct and indirect pathways in OCD and the prominence given to glutaminergic neurotransmission.

The overlap between the neural substrates for OCD and the spectrum disorders is harder to disentangle, as only a few studies have attempted a direct comparison of the neural circuitry. For example, specific attentional biases to specific OCD-related stimuli, underpinned by anomalous fronto-striatal activation, were found in an fMRI study of adults with OCD, which was distinct from a more pervasive attentional bias to all affectively arousing material found in patients with panic disorder and hypochondriasis (van den Heuvel, Veltman, Groenewegen, Witter et al., 2005).

Genetics

There is now little doubt that OCD is a highly heritable neuropsychiatric disorder. Twin studies show a much higher concordance rate in monozygotic (~80–90%) over dizygotic twins (~50%), and family studies report an increased prevalence of 7–15% in first-degree relatives of children with OCD (reviewed in Grados, Walkup, & Walford, 2003). In a study of over 4,000 child twin pairs, Hudziak and colleagues used structural equation modeling (see chapter 9) to estimate that genetic (~50%) and unique environmental (~50%) factors both equally influence parental ratings of obsessive and compulsive symptoms in children (Hudziak, Van Beijsterveldt, Althoff et al., 2004). Most studies have focused on the heritability of the DSM-IV diagnosis of the disorder. Others, however, have looked at other aspects of the OCD endophenotype which may be more meaningful for genetic studies, such as symptom dimensions, or have tried to fractionate the disorder into subcategories (e.g., by age of onset or by association with common comorbidities).

Candidate gene studies have examined the monoaminergic and glutamatergic neurotransmitters in OCD, and more recently there has been interest in the trophic factors which regulate brain development. One of the most promising genes lies on the small arm of chromosome 9 (9p24), a region which has been linked with OCD in two independent genomewide scans on different families with multiply-affected individuals (Hanna, Veenstra-VanderWeele, Cox et al., 2002; Willour, Yao Shugart, Samuels et al., 2004). This region contains the gene SLC1A1 which codes for the neural glutamate transporter excitatory amino acid carrier 1. While one initial study failed to show biased transmission in a family-based associated analysis of two single nucleotide polymorphisms (Veenstra-VanderWeele, Kim, Gonen et al., 2001), two more recent comprehensive and independent analyses, including more polymorphisms within the gene, found a positive association between the gene and OCD in males (Arnold, Sicard, Burroughs, Richter, & Kennedy, 2006; Dickel, Veenstra-VanderWeele, Cox et al., 2006). The functional significance of these findings is unclear, but SLC1A1 is a strong candidate for OCD given the evidence for altered glutamate neurotransmission in the disorder.

Most of the remaining genetic findings are more typical for the field, with few being replicated and even fewer polymorphisms having been shown to have clear functional effects that can be linked plausibly to the pathogenesis of the disorder. Association studies of functional variants of a promoter region variant in the serotonin transporter (l and s variants of the SLC6A4 gene on chromosome 17) (Bengel, Greenberg, Cora-Locatelli et al., 1999; Billett, Richter, King et al., 1997) and one receptor gene (5-HT1D) have given inconsistent evidence for linkage with OCD (Di Bella, Cavallini, & Bellodi, 2002; Mundo, Richter, Zai et al., 2002). Polymorphisms of genes encoding the monoaminergic system enzymes, monoamine oxidase A, and catechol-O-methyl-transferase (COMT) have also been linked to OCD, particularly in males (Karayiorgou, Sobin, Blundell et al., 1999). Moves to examine associations between risk genes and specific symptom dimensions have proved promising, with reports of links between the serotonin transporter polymorphisms and clusters of religious and somatic concerns (Camarena, Aguilar, Loyzaga, & Nicolini, 2004; Kim, Lee, & Kim, 2005) and between polymorphisms of COMT and compulsive hoarding (Lochner, Kinnear, Hemmings et al., 2005). Association with the dopaminergic DRD4 receptor gene emerges, particularly when probands who have comorbid tic disorder are studied, demonstrating the promise of phenotypic definitions which may cut across traditional diagnostic boundaries (Cruz, Camarena, King et al., 1997; Millet, Chabane, Delorme et al., 2003). Within the glutamatergic neurotransmitter system, positive associations have been reported for N-methyl D-aspartate (NMDA) receptors (GRIN2B) and for GRIK2 (a kainate receptor) recently also associated with autism (Arnold, Rosenberg, Mundo et al., 2004; Delorme, Krebs, Chabane et al., 2004). As some cases of pediatric OCD may represent an impaired immune response to streptococcal infection, the association between alleles of the myelin oligodendrocyte glycoprotein (MOG) gene, which plays an important role in mediating the complement cascade in the immune response, and OCD is of interest (Zai, Bezchlibnyk, Richter et al., 2004).

Neurodevelopmental models of OCD emphasize anomalies of the neurotrophic factors which regulate cell survival, differentiation and death, particularly in early development. Animal models show that deficiencies of brain-derived neurotrophic factor (BDNF) in early development lead to a loss of serotonergic transmission in adulthood. Interestingly, different sequence variants of this gene in humans are associated with not only the risk for OCD, but also its age of onset (Hall, Dhilla, Charalambous, Gogos, & Karayiorgou, 2003).

Treatment Approaches

Psychological Treatment

The cornerstone of psychological therapies for children is exposure and response prevention (ERP), and its efficacy has been demonstrated in multiple open studies and two randomized controlled trials (Barrett, Healy-Farrell, & March, 2004; POTS, 2004). A hierarchy of increasingly intense anxiety-provoking
situations that trigger obsessional thinking is constructed, and subjects are exposed gradually to these situations and encouraged to refrain from engaging in compulsive behaviors (March & Mulle, 1998). Gradually, the patient progresses through the hierarchy so that situations can be tolerated with minimal anxiety, thus attaining an ever-decreasing urge to engage in compulsions. In clinical practice, and in all controlled studies, ERP is usually combined with other behavioral techniques, such as anxiety management training and extinction (e.g., instructing parents not to give reassurance when a child compulsively seeks it). This makes it difficult to disentangle the relative therapeutic importance of each element. Frequently, cognitive components are added, such as normalizing intrusive thoughts and reappraising notions of personal responsibility. Again, the necessity of these cognitive components is unclear in children as there are no controlled trials comparing these approaches. Tailoring therapy to the symptom profile of the child may be helpful. For example, ERP may be ideal for younger children as it has been shown to be effective in those under 11 and may be particularly helpful for symptoms such as contamination fears and symmetry rituals (Barrett, Healy, & March, 2003). By contrast, cognitive approaches may be more suited to the child with obsessional moral guilt or pathological doubt.

The involvement of the family in treatment is essential. Psycho-education can help the family to avoid both punitive responses and the alternative “enabling” that can occur if the family becomes enmeshed in rituals. A randomized controlled study demonstrated that such family-based cognitive behavioral therapy may be equally efficacious when conducted either with individual families or in a group setting (Barrett, Healy, & March, 2004).

While the efficacy of behavior therapy (BT) with ERP as a core component is accepted, the most efficient and efficacious method of providing this treatment is less clear. At one extreme lies computer-based delivery systems with minimal therapist contact time (Kenwright, Marks, Graham, Franses, & Mataix-Colos, 2005); at the other extreme are highly intensive day or in-patient treatment programs. Only one trial has directly compared once weekly with daily therapy; no significant differences in outcome were found, although this study was not randomized and thus limited conclusions can be drawn (Franklin, Kozak, Cashman et al., 1998). A meta-analysis suggested that while more therapist-intensive approaches were more efficacious, even those involving relatively little therapist contact time (less than 10 hours) were also effective (NICE, 2005).

In practice, the severity of the symptom profile, the complexity of comorbidity, and resources available within the family and local health care services are likely to determine the treatment intensity. Many countries also have self-help groups which provide a valuable source of support and information, as well as act as advocates for those living with the disorder.

Pharmacotherapy

There is a relative abundance of randomized controlled trials demonstrating the efficacy of clomipramine and of selective serotonin re-uptake inhibitors – SSRIs (sertraline, fluoxetine, paroxetine and fluvoxamine) in the acute phase treatment of childhood OCD, reviewed in Table 43.4.

A meta-analysis of 12 studies of SSRIs and clomipramine (an SRI) found all medications to be superior to placebo and found that clomipramine showed superiority over all the SSRIs, which did not differ from one another (Geller, Biederman, Stewart et al., 2003). However, clomipramine is associated with several adverse side effects, including potential arrhythmogenic effects.

Although generally well tolerated, SSRIs are associated with a range of side effects, with nausea, headache and agitation being common to all in this class. Of greatest concern are reports of increased suicidal ideation and behavior, which have led to recommendations that treatment should be closely monitored with regular follow-up, perhaps ideally in conjunction with BT. As a result of these concerns, the pharmacological options have become limited in several countries.

Depression is highly comorbid with OCD, and the treatment of this combination is often challenging. Two studies have found that adding imipramine (Foa, Kozak, Steketee, & McCarthy, 1992) or SSRIs (Abramowitz, Franklin, Street, Kozak, & Foa, 2000) either before or during ERP may be effective for alleviating depressive symptoms but did not potentiate ERP. There are case reports supporting the use of cognitive therapeutic techniques to increase motivation and compliance in the depressed patient to help them engage with difficult exposure assignments (Abramowitz, 2004).

In children, low initial doses with slow upward titration is the rule. Patients should be made aware of the common side effects and the need for a 12-week treatment trial. Partial or complete failure to respond to the first SSRI should prompt treatment with BT and consideration of another SSRI. The use of augmenting agents for youths with treatment-resistant OCD is discussed below.

Combination Treatment

How do pharmacological and psychological treatments compare? The best current evidence comes from the Pediatric OCD Treatment (POTS) multi-center study, which randomized 112 children to either sertraline, cognitive behavioral therapy (CBT), the treatments combined or pill placebo for 12 weeks (POTS, 2004). All active treatments were superior to pill placebo. Combined treatment also proved superior to CBT alone and to sertraline alone, which did not differ from each other. Site differences emerged for CBT and sertraline but not for combined treatment, suggesting that combined treatment is less susceptible to setting-specific variations, and, given this generalizability, combined treatment may be the option of choice. Notably, there was no evidence of treatment-emergent suicidality. Much smaller studies similarly found that a combination of behavior therapy (based on ERP) and fluvoxamine was superior to medication alone, both in short-term response and at a follow-up period of one year (Neziroglu, Yaryura-Tobias, Walz, & McKay, 2000). A direct comparison of behavior therapy with clomipramine in 22 children found a non-significant superiority for psychotherapy (de Haan,
Overall, it is clear that while medication alone is effective and generally safe and well tolerated, CBT may have the edge in terms of a first-line treatment, particularly when combined with an SSRI or clomipramine.

Augmenting Strategies for Partial Responders

Up to 50% of children will show only a partial response to initial SSRI treatment (Geller, Biederman, Jones et al., 1998). For adults showing such sub-optimal response to an SSRI, several trials have shown a significant reduction of obsessive

CHAPTER 43

symptoms in patients with either adjunctive haloperidol or risperidone (Li, May, Tolbert et al., 2005; McDougle, Epperson, Pelton, Waslynk, & Price, 2000). Other treatment strategies in adults include augmentation with clonazepam or oral morphine or combining two SSRIs (for a review see Walsh & McDougle, 2004). There are some case reports demonstrating the potential for the use of each of these strategies in children, although there are no controlled studies to guide the clinician in this complex field (Lombroso, Rosenberg, Birmaher, & Keshavan, 1998; Leonard, Topol, Bukstein et al., 1994; Lombroso, Scanhill, King et al., 1995). Clearly, the side effects of each augmenting agent need to be considered, particularly the risk of tardive dyskinesia with haloperidol, metabolic side effects of risperidone, and risk of tolerance and dependence with clonazepam.

In spite of the major advances in drug treatment, at least 10% of the OCD population remains severely affected. In adults, for extreme cases there is an option for neurosurgical procedures, which are aimed at disrupting the CSTC loops either through creating a permanent lesion through excision or through repetitive deep brain stimulation (Greenberg, Price, Rauch et al., 2003). Such physical therapies are not appropriate for children, and less invasive alternatives such as transcranial magnetic stimulation, while giving insight into the abnormal responsivity of the motor cortex in OCD (Gilbert, Bansal, Sethuraman et al., 2004; Greenberg, Murphy, & Swedo, 1998) have not proved effective in the treatment of adults and remain untested in children (Martin, Barbanoj, Perez, & Sacristan, 2003).

Maintenance treatment

OCD is frequently a chronic disorder and long-term maintenance therapy should be anticipated, with the current recommendation being a minimum treatment period of six months following full remission. The need for such maintenance was illustrated by an 8-month study of 26 children and adolescents with severe OCD who had received clomipramine for a mean of 17 months; a 2-month double-blind desipramine-substitution phase resulted in 89% of the substituted (versus 18% of the non-substituted) subjects relapsing during the substitution phase (Leonard, Swedo, Lenane et al., 1991).

Immunomodulatory treatments

Based on the observation that some childhood-onset OCD patients had onset apparently related to infection with group A beta-hemolytic streptococcus (GABHS), a subgroup of children were proposed who were hypothesized to have an autoimmune based form of the disorder – PANDAS (Swedo, Leonard, & Rapoport, 2004). As a partial test of this model, two treatments were examined. A controlled trial of intravenous immunoglobulin was carried out, together with an open trial of plasmaphoresis (Perlmutter, Leitman, Garvey et al., 1999). Both treatments were effective in lessening of symptom severity for children with infection-triggered OCD and tic disorders. Penicillin or arithromycin prophylaxis of sufficient intensity to decrease streptococcal infections was also found to decrease neuropsychiatric symptom exacerbations among children in the PANDAS subgroup (Snider, Lougee, Slattery, Grant, & Swedo, 2005). This study is limited by the absence of a placebo control, particularly as a previous placebo-controlled trial using penicillin prophylaxis was negative (Garvey, Perlmutter, Allen et al., 1999). These fascinating findings have yet to be replicated but raise the possibility of the prevention of OCD in at least a subset of children with the disorder.

Conclusions

Public awareness of OCD has increased greatly over recent years, allowing this once “secret” disorder to be more readily recognized by both families and mental health professionals. Functional neuroimaging studies increasingly inform and refine models of the pathogenesis of the disorder, and are being matched by neuroanatomical imaging studies which allow a delineation of structural change at an ever-increasing level of resolution. Whereas candidate gene studies have provided some validation of the implication of monoaminergic anomalies in the disorder, the application of new technologies to scan the entire genome is likely to provide novel insights into the genetics of OCD. Of most practical importance, though, are the strengthening of the evidence base for treatment through recent large-scale double-blind trials and the renewed interest in the management of those with treatment-resistant symptoms. The strides in understanding the neurobiology of the disorder are thus matched by definitive demonstrations of treatment efficacy in children, and make it all the more important that children, parents and health care professionals remain aware of the disorder and the availability of effective help.

CHAPTER 43

Tic disorders are transient or chronic conditions associated with difficulties in self-esteem, family life, social acceptance or school or job performance that are directly related to the presence of motor and/or phonic tics. Although tic symptoms have been reported since antiquity, systematic study of individuals with tic disorders dates only from the 19th century with the reports of Itard (1825) and Gilles de la Tourette (1885). Gilles de la Tourette described nine cases characterized by motor “incoordinations” or tics, “inarticulate shouts accompanied by articulated words with echolalia and coprolalia.” In addition to identifying the cardinal features of severe tic disorders, his report noted an association between tic disorders and obsessive-compulsive symptoms as well as the hereditary nature of the syndrome in some families.

In addition to tics, individuals with tic disorders may present with a broad array of behavioral difficulties including disinhibited speech or conduct, impulsivity, distractibility, motoric hyperactivity, and obsessive-compulsive symptoms (Leckman & Cohen, 1998). Scientific opinion has been divided on how broadly to conceive the spectrum of maladaptive behaviors associated with Tourette syndrome (TS) (Comings, 1988; Shapiro, Shapiro, Young, & Freinberg, 1988). This controversy is fueled in part by the frustration that parents and educators encounter when they attempt to divide an individual child’s repertoire of problem behaviors into those that are “Tourette-related” and those that are not. Population-based epidemiological studies and family-genetic studies have begun to clarify these issues, but much work remains to be done.

In this chapter, a presentation of the phenomenology and classification of tic disorders precedes a review of the etiology, neurobiological substrates, assessment and management of these conditions. The general perspective presented is that TS and related disorders are model neurobiological disorders in which to study multiple genetic and environmental (epigenetic) mechanisms that interact over the course of development to produce a distinctive range of complex syndromes of varying severity.

Definitions and Classifications

Phenomenology of Tics

A tic is a sudden repetitive movement, gesture or utterance that typically mimics some aspect or fragment of normal behavior. Individual tics rarely last more than a second. Many tics occur in bouts with brief inter-tic intervals (Peterson & Leckman, 1998). Individual tics can occur singly or together in an orchestrated pattern. They vary in their intensity or forcefulness. Motor tics vary from simple abrupt movements such as eye blinking, head jerks or shoulder shrugs to more complex, apparently purposive behaviors such as facial expressions or gestures of the arms or head. In extreme cases, these movements can be obscene (copropraxia) or self-injurious (e.g., hitting or biting). Phonic or vocal tics can range from simple throat clearing sounds to more complex vocalizations and speech. In severe cases, coprolalia (obscene or socially unacceptable speech) is present.

By the age of 10 years, most individuals with tics are aware of premonitory urges that may be experienced either as a focal perception in a particular body region where the tic is about to occur (like an itch or a tickling sensation) or as a mental awareness (Leckman, Walker, & Cohen, 1993). Most patients also report a fleeting sense of relief after a bout of tics has occurred. These premonitory and consummatory phenomena contribute to an individual’s sense that tics are habitual yet partially intentional responses to unpleasant stimuli. Indeed, most adolescent and adult subjects describe their tics as either “voluntary” or as having both voluntary and involuntary aspects. In contrast, many young children are oblivious to their tics and experience them as wholly involuntary movements or sounds. Most tics can also be suppressed for brief periods of time. The warning given by premonitory urges may contribute to this phenomenon.

Clinicians characterize tics by their anatomical location, number, frequency and duration. The intensity or “forcefulness” of the tic can also be an important characteristic. Finally, tics vary in terms of their “complexity.” Complexity usually refers to how simple or involved a movement or sound is, ranging from brief meaningless abrupt fragments (simple tics) to ones that are longer, more involved and seemingly more goal-directed in character (complex tics). Each of these elements has been incorporated into clinician rating scales, which have proven to be useful in monitoring tic severity (Leckman, Riddle, Hardin et al., 1989).
CHAPTER 44

Diagnostic Categories

Diagnostic categories provide a common basis for discussion and are an essential tool in epidemiological and clinical research. Several widely used diagnostic classifications currently include sections on tic disorders. These include both the DSM-IV classification system published by the American Psychiatric Association (1994), and the ICD-10 criteria by the World Health Organization (1996). Although differences exist, these classification schemes are broadly congruent, with each containing three major categories: TS or its equivalent; chronic motor or vocal tic disorder (CMT or CVT) or its equivalent; and transient tic disorder or its equivalent.

To minimize error in case ascertainment and produce an instrument measuring lifetime likelihood of having had TS, clinical members of the American Tourette Syndrome Association International Genetic Collaboration have developed the Diagnostic Confidence Index (DCI) (Robertson, Banerjee, Kurlan et al., 1999). The DCI produces a score from 0 to 100 that is a measure of the likelihood of having or ever having had TS. However, the DCI along with the ICD-10 and DSM-IV diagnostic groupings suffer from uncertainties on how best to categorize conditions that potentially encompass a broad range of symptoms that wax and wane in severity. Because the current nosological boundaries are set by convention and clinical practice, they may not reflect true etiological differences.

Prevalence

Children are 5–12 times more likely to be identified as having a tic disorder than adults (Burd, Kerbeshian, Wikenheiser, & Fisher, 1986a,b). Although boys are more commonly affected with tic behaviors than girls, the male : female ratio in most community surveys is less than 2:1. For example, in the Isle of Wight study of 10- to 11-year-olds, approximately 6% of boys and 3% of girls were reported by their parents to have “twitches, mannerisms, tics of face or body” (Rutter, Tizard, & Whitmore, 1970).

Once thought to be rare, current estimates of the prevalence of TS vary 100-fold, from 2.9 per 10,000 (Caine, McBride, Chiverton et al., 1988) to 299 per 10,000 (Mason, Banerjee, Eapen, Zeitlin, & Robertson, 1998). In the largest study to date, Apter, Pauls, Bleich et al. (1993) have reported a prevalence rate of 4.5 per 10,000 for full-blown TS among 16- to 17-year-olds in Israel. More recently, Khalifa and von Knorring (2003, 2005) studied a total population of 4479 Swedish children aged 7–15 years. Twenty-five were identified as having TS, yielding a prevalence estimate of 5.6 per 1000 pupils.

Clinical Descriptions and Natural History

With the exception of TS (Bloch, Landeros-Weisenberger, Kelmendi et al., 2006b; Leckman, Zhang, Vitale et al., 1998b), relatively few cross-sectional or longitudinal studies of tic disorders have been performed so that most of the information provided below is based on clinical experience and anecdotal reports.

Transient Tic Disorder

Almost invariably a disorder of childhood, transient tic disorder is usually characterized by one or more simple motor tics that wax and wane in severity over weeks to months. The anatomical distribution of these tics is usually confined to the eyes, face, neck or upper extremities. Transient phonic tics, in the absence of motor tics, can also occur, although more rarely. The age of onset is typically 3–10 years. Boys are at greater risk. The initial presentation may be unnoticed. Family practitioners, pediatricians, allergists and ophthalmologists are typically the first to see the child. Missed diagnoses are common, particularly as the symptoms may have completely disappeared by the time of the consultation. To meet diagnostic criteria for transient tic disorder, there must be fewer than 12 consecutive months of active symptomatology. This is therefore often a retrospective diagnosis as the clinician is unable to know with certainty which children will show progression of their symptoms and which children will display a self-limiting course.

Chronic Motor or Vocal Tic Disorder

This chronic condition can be observed among children and adults. As with other tic disorders, chronic motor tic disorder (CMTD) is characterized by a waxing and waning course and a broad range of symptom severity. Chronic simple and complex motor tics are the most common manifestations. A majority of tics involve the eyes, face, head, neck and upper extremities. Although some children may display other developmental difficulties such as attention deficit/hyperactivity disorder (ADHD), the disorder is not incompatible with an otherwise normal course of childhood. This condition can also appear as a residual state, where a predictable repertoire of tic symptoms may be seen only during periods of heightened stress or fatigue.

Tourette Syndrome (Combined Vocal and Multiple Motor Tic Disorder)

The most severe tic disorder is best known by the eponym Gilles de la Tourette’s syndrome. Typically, the disorder begins in early childhood with transient bouts of simple motor tics such as eye blinking or head jerks. These tics may initially come and go, but eventually they become persistent and begin to have adverse effects on the child and the family. The repertoire of motor tics can be vast, incorporating virtually any voluntary movement by any portion of the body. Although some patients have a “rostral-caudal” progression of motor tics (head, neck, shoulders, arms, torso), this course is not predictable. As the syndrome develops, complex motor tics may appear. Typically, they accompany simple motor tics. Often they have a “camouflaged” or purposive appearance (e.g., brushing hair away from the face with an arm), and can only be distinguished as tics by their repetitive character.
They can involve dystonic movements. In a small fraction of cases (<5%), complex motor tics have the potential to be self-injurious. These self-injurious symptoms may be relatively mild (e.g., slapping or tapping) or quite dangerous (e.g., punching one side of the face, biting a wrist or gouging eyes to the point of blindness).

On average, phonic tics begin 1–2 years after the onset of motor symptoms and are usually simple in character (e.g., throat clearing, grunting and squeaks). More complex vocal symptoms such as echolalia (repeating another’s speech), palilalia (repeating one’s own speech) and coprolalia occur in a minority of cases. Other complex phonic symptoms include dramatic and abrupt changes in rhythm, rate and volume of speech.

Motor and phonic tics tend to occur in bouts. Their frequency ranges from non-stop bursts that are virtually uncountable (>100 tics per minute) to rare events that occur only a few times a week. Single tics may occur in isolation or there may be orchestrated combinations of motor and phonic tics that involve multiple muscle groups. The forcefulness of motor tics and the volume of phonic tics can also vary from behaviors that are not noticeable (a slight shrug or a hushed guttural noise) to strenuous displays (arm thrusts or loud barking) that are frightening and exhausting. During periods of waxing tic symptoms, clinicians may find themselves under extreme pressure to intervene medically. While such interventions may be warranted, it is often the case that the tic symptoms will wane substantially within a few weeks.

By the age of 10 years, most children and adolescents have some awareness of the premonitory urges that frequently precede both motor and vocal tics. These urges add to the subjective discomfort associated with having a tic disorder. They may also contribute to an individual’s ability to suppress their tics for longer periods of time.

The factors that determine the degree of disability and handicap versus resiliency are largely unknown. They are likely to include the presence of additional developmental, mental and behavioral disorders; the level of support and understanding from parents, peers and educators; and the presence of special abilities (as in sports) or personal attributes (intelligence, social abilities and personality traits). The behavioral and emotional problems that frequently complicate TS range from impulsive, “disinhibited” and immature behavior to compulsive touching or sniffing. At present, there are no clear dividing lines between these disruptive behaviors and complex tics on the one hand and comorbid conditions of ADHD and obsessive-compulsive disorder (OCD) on the other. Some investigators believe that the “spectrum” of TS includes attentional deficits, impulsivity, hyperactivity, compulsive behavior, learning disabilities, pervasive developmental disorders and affective and anxiety disorders, as well as tics and OCD (Comings, 1988).

Although children with TS can be loving and affectionate, maintaining age-appropriate social skills is a particularly difficult area for many of them (Bawden, Stokes, Camfield, Camfield, & Salisbury, 1998; Dykens, Leckman, Riddle et al., 1990; Stokes, Bawden, Camfield, Backman, & Dooley, 1991). Whether this is because of the stigmatizing effects of the tics, the patient’s own uneasiness or some more fundamental difficulty linked to the neurobiology of this disorder is unknown.

Tic disorders tend to improve in late adolescence and early adulthood. In many instances, the phonic symptoms become increasingly rare or may disappear altogether, and the motor tics may be reduced in number and frequency. Complete remission of both motor and phonic symptoms has also been reported (Shapiro, Shapiro, Young et al., 1988). In contrast, adulthood is also the period when the most severe and debilitating forms of tic disorder can be seen. The factors that influence the continuity of tic disorders from childhood to adulthood are not well understood but likely involve the interaction of normal maturational processes occurring in the CNS with the neurobiological mechanisms responsible for TS, the exposure to cocaine, other CNS stimulants, androgenic steroids and the amount of intramorbid emotional trauma and distress experienced by affected individuals during childhood and adolescence. In addition, tic disorders may be etiologically separable so that some of these factors, such as activation of the immune system or exposure to heat stress, may influence the pathogenesis and intramorbid course for some tic disorders but not others. Other factors, such as psychological stress, may have a more uniform impact.

Coexisting Conditions

The past decade has seen a renewed emphasis on the range of neurological and psychiatric symptoms seen in patients with TS (Leckman & Cohen, 1998). In both clinical and epidemiological samples, TS alone is the exception rather than the rule (Khalifa & von Knorring, 2005, 2006). Symptoms associated with ADHD and OCD have received the most attention. It is also becoming clear that the more severe the tic disorder, the greater the likelihood of detecting coexisting conditions, even in representative population-based samples (Khalifa & von Knorring, 2005).

Coexisting Attention Deficit Hyperactivity Disorder

Both clinical and epidemiological studies vary according to setting and established referral patterns, but it is not uncommon to see reports of 30–50% of children with TS diagnosed with comorbid ADHD (Khalifa & von Knorring, 2006). TS has the highest rate of ADHD relative to the other lesser variants of tic disorders. Although the etiological relationship between TS and ADHD is in dispute, it is clear that those individuals with both TS and ADHD are at a much greater risk for a variety of untoward outcomes (Carter, O’Donnell, Schultz et al., 2000; Peterson, Pine, Cohen, & Brook, 2001a; Sukhodolsky, Schall, Zhang et al., 2003, Sukhodolsky, do Rosario-Campos, Schall et al., 2005). They are often regarded as less likeable, more aggressive and more withdrawn than their classmates (Stokes, Bawden, Camfield et al., 1991). These social difficulties are amplified in a child with TS who also has ADHD (Bawden, Stokes, Camfield et al., 1998; Dykens, Leckman, Riddle et al., 1990; Sukhodolsky, Schall, Zhang
et al., 2003, Sukhodolsky, do Rosario-Campos, Schiull et al., 2005). Surprisingly, levels of tic severity are less predictive of peer acceptance than is the presence of ADHD (Bawden, Stokes, Camfield et al., 1998).

**Obsessive-Compulsive Symptoms**

More than 40% of individuals with TS experience recurrent obsessive-compulsive (OC) symptoms (Hounie, do Rosario-Campos, Diniz et al., 2006; Khalifa & von Knorring, 2005; Leckman, Walker, Goodman et al., 1994, Leckman, Grice, Boardman et al., 1997). Genetic, neurobiological and treatment response studies suggest that there may be qualitative differences between tic-related forms of OCD and cases of OCD in which there is no personal or family history of tics. Specifically, tic-related OCD has a male preponderance, an earlier age of onset, a poorer level of response to standard antipsychotic medications and a greater likelihood of first-degree family members with a tic disorder (Hounie, do Rosario-Campos, Diniz et al., 2006). Symptomatically, the most common OC symptoms encountered in TS patients are obsessions concerning a need for symmetry or exactness, repeating rituals, counting compulsions and ordering/arranging compulsions (Leckman, Grice, Boardman et al., 1997). Also, OC symptoms, when present in children with TS, appear more likely to persist into adulthood than the tics themselves (Bloch, Landeros-Weisenberger, Kelmendi et al., 2006b).

**Coexisting Depression and Anxiety Disorders**

The co-occurrence of depression and anxiety symptoms with TS is commonplace and may reflect the cumulative psychosocial burden of having tics or shared biological diatheses or both (Robertson & Orth, 2006; Robertson, Williamson, & Eapen, 2006). Antecedent depressive symptoms do predict modest increases in tic severity (Lin, Katsovich, Ghebremichael et al., 2007). However, this study also documented that future depression severity is more closely associated with antecedent worsening of psychosocial stress and OC symptoms than it is with future measures of tic severity.

**Other Developmental and Neurological Disorders**

Children with a range of developmental disorders are at increased risk for tic disorders. Kurlan, Whitmore, Irvine, McDermott, and Como (1994) reported a four-fold increase in the prevalence of tic disorders among children in special educational settings in a single school district in upstate New York. These children were not intellectually impaired but did have significant learning disabilities or other speech or physical impairments. Children with autism and other pervasive developmental disorders are also at higher risk for developing TS (Baron-Cohen, Mortimore, Moriarty, Izaguirre, & Robertson, 1999).

**Neurophysiological Findings**

Although motor and phonic tics constitute the core elements of the diagnostic criteria for TS, perceptual and cognitive difficulties are also common. These neuropsychological symptoms are potentially informative about the pathobiology of the disorder. Moreover, these associated difficulties can be more problematic for school and social adjustment than the primary motor symptoms.

Review of the literature suggests that the most consistently observed deficits occur on tasks requiring the accurate copying of geometric designs (i.e., “visual–motor integration” or “visual–graphic” ability; Schultz, Carter, Gladstone et al., 1998). Even after controlling statistically for visual–perceptual skill, intelligence and fine motor control, children with TS performed worse than controls on the visual–motor tasks, suggesting that the integration of visual inputs and organized motor output is a specific area of weakness. Poorer performance with the dominant hand on the Purdue Pegboard test during childhood is associated with worse adulthood tic severity (Bloch, Sukhodolsky, Leckman et al., 2006c).

In studies of procedural memory (habit learning), children with severe tic symptoms had a higher level of impairment than those with less severe symptoms. In contrast, no deficits were seen in declarative memory functioning (Keri, Szlobodnyik, Benedek, Jenka, & Gadoros, 2002; Marsh, Alexander, Packard et al., 2004, Marsh, Alexander, Packard et al., 2005).

**Etiology and Pathogenesis**

**Genetic Factors**

Twin and family studies provide evidence that genetic factors are involved in the vulnerability to TS and related disorders (Pauls & Leckman, 1986). The concordance rate for TS among monozygotic twin pairs is greater than 50% while the concordance of dizygotic twin pairs is about 10% (Price, Kidd, Cohen, Pauls, & Leckman, 1985). If cotwins with chronic motor tic disorder are included, these concordance figures increase to 77% for monozygotic and 30% for dizygotic twin pairs. These differences in the concordance of monozygotic and dizygotic twin pairs indicate that genetic factors have an important role in the etiology, but the fact that concordance for monozygotic twins is less than 100% also indicates that non-genetic factors are critical in determining the nature and severity of the clinical syndrome.

Other studies indicate that first-degree family members of probands with TS are at substantially higher risk for developing TS, chronic motor tic disorder and OCD than unrelated individuals (Pauls, Raymond, Stevenson, & Leckman, 1991). The rates are substantially higher than might be expected by chance in the general population, and greatly exceed the rates for these disorders among the relatives of individuals with other psychiatric disorders except OCD.

The pattern of vertical transmission among family members has led several groups of investigators to test specific genetic hypotheses. While not definitive, segregation analyses could not rule out autosomal transmission (Pauls & Leckman, 1986). However, subsequent efforts to identify susceptibility genes within large multigenerational families or using affected
siblings, whereas the indirect pathway provides a mechanism of negative feedback which is important for the inhibition of behaviors and in switching between behaviors. Based on postmortem studies, as well as structural and functional neuroimaging studies, it appears that an imbalance between these frontal–striatal circuits might mediate tic symptomatology as well as that of related disorders.

**Neuropathological Data**

Although neuropathological studies of postmortem TS brains are few in number, a recent stereological study indicates that there is a marked alteration in the number and density of GABA-ergic parvalbumin-positive cells in basal ganglia structures (Kalanithi, Zheng, Kataoka et al., 2005). In the caudate there was a greater than 50% reduction in the GABA-ergic fast spiking interneurons and a 30–40% reduction of these same cells in the putamen. This same study found a reduction of the GABA-ergic parvalbumin-positive projection neurons in the external segment globus pallidus (GPe) as well as a dramatic increase (>120%) in the number and proportion of GABA-ergic projection neurons of the internal segment of the globus pallidus. These alterations are consistent with a developmental defect in tangential migration of some GABA-ergic neurons. Further studies are needed to confirm and extend these findings, such as toward a more complete understanding of how the different striatal interneurons are affected, and to determine how alterations in GABA-ergic interneurons and globus pallidus projection neurons could lead to a form of thalamocortical dysrhythmia (Leckman, Vaccarino, Kalanithi, & Rothenberger, 2006; Llinas, Urbano, Leznik, Ramirez, & van Marle, 2005).

**Structural Brain Imaging**

Volumetric magnetic resonance imaging (MRI) studies of basal ganglia in individuals with TS are largely consistent with these postmortem results — with the finding of a slight reduction in caudate volume (Hyde, Stacey, Coppola et al., 1995; Peterson, Thomas, Kane et al., 2003). For example, in a study of 154 subjects with TS and 130 healthy controls, Peterson, Thomas, Kane et al. (2003) found a significant decrease in the volume of the caudate nucleus in both children and adults. Although there was no correlation between symptom severity and caudate volumes in this cross-sectional study, Bloch, Leckman, Zhu, and Peterson (2005) found an inverse correlation between caudate volumes measured in childhood and tic severity rated in early adulthood.

The same group of individuals with TS had larger volumes in dorsal prefrontal regions, larger volumes in parieto-occipital regions, and smaller inferior occipital volumes (Peterson, StaiB, Schall et al., 2001b). Regional cerebral volumes were significantly associated with the severity of tic symptoms in orbitofrontal, midtemporal and parieto-occipital regions. This may reflect the natural history of the disorder, or brain compensations, or may yet be explained by other subtle confounding variables, such as the manner in which brain volumes are determined in different studies. In addition, Lee, Yoo, Cho

**Neural Circuits**

**Neuroanatomy**

Investigators interested in procedural learning, habit formation and internally and externally guided motor control have focused their attention on multisynaptic cortico-striato-thalamocortical (CSTC) circuits or loops that link the cerebral cortex with several subcortical regions (Graybiel & Canales, 2001; Middleton & Strick, 2000). As a result the most widely accepted neuroanatomical model of TS proposes a regional imbalance of the direct vs. the indirect pathway within one of more of these CSTCs (Albin & Mink, 2006). In the direct pathway, an excitatory glutamatergic signal projects to the striatum, sending an inhibitory gamma-aminobutyric acid (GABA)-ergic signal to the internal part of the globus pallidus. This signal results in a decreased inhibition (disinhibition) of the thalamus and thus an increased excitatory effect on the prefrontal cortex. In the indirect pathway, the striatum projects an inhibitory signal to the external part of the globus pallidus and the subthalamic nucleus, sending an excitatory signal to the internal part of the globus pallidus. The net effect is an increased inhibition of the thalamus and decreased excitation of the prefrontal cortex. It is hypothesized that the direct pathway functions as a self-reinforcing positive feedback loop and contributes to the initiation and continuation of behaviors, whereas the indirect pathway provides a mechanism of negative feedback which is important for the inhibition of behaviors and in switching between behaviors. Based on postmortem studies, as well as structural and functional neuroimaging studies, it appears that an imbalance between these frontal–striatal circuits might mediate tic symptomatology as well as that of related disorders.
et al. (2006) used volumetric MRI methods to compare thalamic volume in 18 treatment-naive boys with 16 healthy control subjects, finding larger left thalamic volume in the TS cases. More volumetric studies using comparable methods across all implicated brain regions are needed to clarify the brain morphology of TS.

Functional Brain Imaging
Thus far, there have only been a few published studies of TS using functional magnetic resonance imaging (fMRI), which takes advantage of state-dependent blood oxygenation as a measure of brain activity. In adults with TS, Peterson, Skudlarski, Anderson et al. (1998a) compared brain activity during blocks of time during which tics were voluntarily suppressed or not suppressed. During tic suppression, prefrontal cortical, thalamic and basal ganglia areas were activated. These activations were inversely correlated with tic severity (i.e., lower activation was associated with higher tic severity). This suggests that a greater ability of basal ganglia to suppress cortical activity might be linked with decreased tic severity, and is in agreement with single photon emission computed tomography (SPECT) and positron emission tomography (PET) studies that suggest involvement of the basal ganglia in TS (Braun, Randolph, Stoetter et al., 1995). More recently, Bohilhalter, Goldfine, Matteson et al. (2006) studied the neural correlates of tics and associated urges using an event-related fMRI protocol. On the basis of synchronized video/audio recordings, fMRI activities were analyzed 2 s before and at tic onset. A brain network of paralimbic areas including the anterior cingulate and insular cortex, supplementary motor area and parietal operculum was found to be activated before tic onset. In contrast, at the beginning of tic action, significant fMRI activities were found in sensorimotor areas including superior parietal lobule bilaterally and cerebellum. The results of this study indicate that paralimbic and sensory association areas are critically implicated in tic generation.

Changes in the coupling of the putamen and ventral striatum with a number of other brain regions also differentiate patients with TS from controls. For example in PET studies, Jeffries, Schooeler, Schoenbach et al. (2002) noted a reversal in the pattern of CSTC circuit interactions in motor and lateral orbitofrontal cortices. Similarly, Stern, Silbersweig, Chee et al. (2000) found that increased activity in a set of neocortical, paralimbic and subcortical regions (including supplementary motor, premotor, anterior cingulate, dorsolateral–rostral prefrontal and primary motor cortices, Broca’s area, insula, claustrum, putamen and caudate) were highly correlated with tic behavior. Perhaps not surprisingly, in the one patient with prominent coprolalia the vocal tics were associated with increased activity in perioral and postoral cortex.

Neurophysiology
Non-invasive in vivo neurophysiological research in TS has led to several areas of significant progress. The first concerns the use of a startle paradigm to measure inhibitory deficits by monitoring the reduction in startle reflex magnitude. Swerdlow, Karban, Ploum et al. (2001) have confirmed and extended earlier findings indicating that patients with TS have deficits in sensory gating across a number of sensory modalities. Prepulse inhibition abnormalities have been observed across a variety of neuropsychiatric populations including schizophrenia, OCD, Huntington’s disease, nocturnal enuresis, ADHD, Asperger syndrome and TS, suggesting that some final common pathways mediate abnormal prepulse inhibition in all of these conditions. With respect to TS, these deficits are consistent with the idea that there is diminished ability to appropriately manage or “gate” sensory inputs to motor programs, which are released as tics (Swerdlow & Sutherland, 2006).

A second advance has been the investigation of motor system excitability by means of single and paired pulse transcranial magnetic stimulation. Studies of groups of patients with TS have indicated that the cortical silent period (a period of decreased excitability following stimulation) is shortened. This intracortical excitability is frequently seen in children with ADHD comorbid with a tic disorder (Moll, Wischer, Heinrich et al., 1999; Ziemann, Paulus, & Rothenberger, 1997). This heightened level of cortical excitability may be related to a reduction in the number of GABA-ergic interneurons in the cortex.

Serrien, Orth, Evans, Lees, & Brown (2005) recently identified similar sensorimotor–frontal connections involved in the acute suppression of involuntary tics as evidenced by increased EEG coherence in the alpha frequency band (8–12 Hz) during suppression of voluntary movements in individuals with TS and healthy subjects during a Go–NoGo task. This finding, taken with the functional findings from Peterson, Skudlarski, Anderson et al. (1998a), suggests that the frontal lobes may have a key role in tic suppression, and coherence in the alpha band may be part of this process.

The preliminary findings that ablation (or high-frequency stimulation using deep brain electrodes) in regions of the globus pallidus and/or the midline thalamic nuclei can ameliorate tics in severe persistent cases of TS (Hassler & Dieckmann, 1973; Vandewalle, Van der Linden, Groenwegen, & Caemaert, 1999) powerfully support the view that electrophysiological studies and interventions hold promise just as they do for disorders such as Parkinson’s disease.

Prospective longitudinal studies with higher resolution will be needed to examine fully the developmental processes, sexual dimorphisms and possible effects of medication on critical cell compartments. It will also be important to confirm if any of these volumetric and functional findings in childhood are predictive of later clinical outcomes. The combination of imaging techniques with real-time neurophysiological techniques, such as electroencephalography or magnetoencephalography, may help to determine whether any abnormalities seen on brain imaging contribute to the production of tics or whether they constitute a compensatory response (Leckman, Vaccarino, Kalanithi et al., 2006; Linas, Urbano, Leznik et al., 2005).
Neurochemical and Neuropharmacological Data

Extensive immunohistochemical studies of the basal ganglia have demonstrated the presence of a wide spectrum of classic neurotransmitters, neuromodulators and neuropeptides. The most compelling data have implicated central dopaminergic systems in the pathobiology of TS (Albin & Mink, 2006).

Dopaminergic Systems

Explicit “dopamine” hypotheses for TS posit either an excess of dopamine release or an increased sensitivity of D2 dopaminergic receptors. These hypotheses are consistent with multiple lines of empirical evidence as well as emerging data from animal models of habit formation. Data implicating central dopaminergic mechanisms include the results of double-blind clinical trials in which haloperidol, pimozide, tiapride and other neuroleptics that preferentially block dopaminergic D2 receptors have been found to be effective in the temporary suppression of tics for a majority of patients (Scahill, Erenberg, Berlin et al., 2006). Tic suppression has also been reported following administration of agents such as tetrabenazine that reduce dopamine synthesis (Kenney & Jankovic, 2006). Increased tics have been reported following withdrawal of neuroleptics or following exposure to agents that increase central dopaminergic activity such as l-dopa and CNS stimulants, including cocaine. Using these imaging techniques, a number of investigators have also found increased levels of dopaminergic innervation of the striatum in TS subjects compared with controls (Albin, Koeppe, Bohne et al., 2003; Cheon, Ryu, Namkoong et al., 2004; Malison, McDougle, van Dyck et al., 1995; Singer, Szymanski, Giuliano et al., 2002; Wolf, Jones, Knable et al., 1996). Although not all studies agree, the strongest evidence suggests an increased density of dopaminergic terminals in the ventral striatum (Albin, Koeppe, Bohne et al., 2003). Postmortem brain studies have reported alterations in the number or affinity of presynaptic dopamine carrier sites in the striatum (Singer, Hahn, & Moran, 1991). In summary, while the evidence that dopaminergic pathways are intimately involved in the pathobiology of TS is compelling, the exact nature of the abnormality remains to be elucidated but likely involves the potentiation of limbic inputs to the striatum.

Amino Acid Systems

The excitatory neurotransmitter glutamate is released upon depolarization by the corticostral, corticosubthalamic, subthalamic and thalamocortical projection neurons. These excitatory neurons are key players in the functional anatomy of the basal ganglia and the CSTC loops and likely have a crucial role in the emergence of tics as well as related normal behaviors.

Neurons containing inhibitory amino acid neurotransmitters, particularly GABA, also form major portions of CSTC loops and are also present in key sets of interneurons in the cortex, striatum and thalamus. If the initial reports of a reduced number of GABA-ergic fast-spiking interneurons in the caudate and an increased number of GABA-ergic projection neurons in the globus pallidus are confirmed, this may provide a basis for understanding the anatomical and neurophysiological origins of some cases of severe TS (Kalanithi, Zheng, Kataoka et al., 2005; Leckman, Vaccarino, Kalanithi et al., 2006).

Cholinergic Systems

Cholinergic projections from the basal forebrain are found throughout the cortex and within key structures of the basal ganglia and mesencephalon, including the internal segment of the globus pallidus (GP), the pars reticulata of the substantia nigra, and the locus ceruleus. Evidence of cholinergic involvement in the pathobiology of TS comes from the reported potentiation of D2 dopamine receptor blocking agents through the use of transdermal nicotine or nicotine gum (Sanberg, Silver, Shytle et al., 1997).

Noradrenergic Systems

Noradrenergic projections from the locus ceruleus project innervate the prefrontal and other cortical regions. Noradrenergic pathways are also likely to indirectly influence central dopaminergic pathways via projections to areas near the ventral tegmental area (Grenhoff & Svensson, 1989). Speculation that noradrenergic mechanisms might be relevant to the pathobiology of TS was based initially on the beneficial effects of α2-adrenergic agonists including clonidine and guanfacine. The involvement of the noradrenergic pathways may be one mechanism by which stressors influence tic severity. For example, a series of adults with TS had elevated levels of cerebrospinal fluid (CSF) norepinephrine (Leckman, Goodman, Anderson et al., 1995) and excreted high levels of urinary norepinephrine in response to the stress of the lumbar puncture (Chappell, Riddle, Anderson et al., 1994). These elevated levels of CSF norepinephrine may also contribute to the elevation in levels of CSF corticotopin-releasing factor seen in some patients with TS (Chappell, Leckman, Goodman et al., 1996).

Serotonergic Systems

Ascending serotonergic projections from the dorsal raphe have been invoked as playing a part in the pathophysiology of both TS and OCD. The most compelling evidence relates to OCD and is based largely on the well-established efficacy of potent serotonin reuptake inhibitors such as clomipramine and fluvoxamine in the treatment of OCD. However, some investigators have reported that the serotonin reuptake inhibitors are less effective in treating tic-related OCD than other forms of OCD (McDougle, Goodman, Leckman et al., 1993).

Gender-Specific Endocrine Factors

Males are more frequently affected with TS than females (Shapiro, Shapiro, Young et al., 1988), but male–male transmission within families rules out the presence of an X-linked vulnerability gene. This observation has led us to hypothesize that androgenic steroids act at key developmental periods to influence the natural history of TS and related disorders.
(Peterson, Leckman, Scahill et al., 1992). These developmental periods include the prenatal period when the brain is being formed, adrenarche when adrenal androgens first appear at age 5–7 years, and puberty. Androgenic steroids may be responsible for these effects or they may act indirectly through estrogens formed in key brain regions by the aromatization of testosterone.

The importance of gender differences in expression of associated phenotypes is also clear given the observation that women are more likely than men to develop OC symptoms without concomitant tics (Pauls, Raymond, Stevenson et al., 1991) and that boys with TS are much more likely than girls to display ADHD disruptive behaviors.

Surges in testosterone and other androgenic steroids during critical periods in fetal development are involved in the production of long-term functional augmentation of subsequent hormonal challenges (in adrenarche and during puberty) and in the formation of structural CNS dimorphisms (Sikich & Todd, 1988). Sexually dimorphic brain regions include portions of the amygdala (and related limbic areas) and the hypothalamus (including the medial preoptic area, which mediates the body’s response to thermal stress; Boulant, 1981). These regions contain high levels of androgen and estrogen receptors and influence activity in the basal ganglia both directly and indirectly. Indeed, a proportion of patients with TS appear to be uniquely sensitive to thermal stress such that when their core body temperature increases and they begin to sweat their tics increase (Lombroso, Mack, Scahill, King, & Leckman, 1991). It is also of note that some of the neurochemical and neuropeptidergic systems implicated in TS and related disorders, such as dopamine, serotonin and the opioids, are involved with these regions and appear to be regulated by sex-specific factors.

Further support for a role for androgens comes from anecdotal reports of tic exacerbation following androgen use (Leckman & Scahill, 1990) and from trials of antiandrogens in patients with severe TS and/or OCD (Peterson, Zhang, Anderson, & Leckman, 1999b). In the most rigorous study to date, Peterson, Zhang, Anderson et al. (1999b) found that the therapeutic effects of the antiandrogen flutamide were modest in magnitude and these effects were short-lived, possibly because of physiological compensation for androgen receptor blockade.

The view that sex steroids of gonadal origin organize the neural circuits of the developing brain has recently been challenged by the finding that, independent of the masculinizing effects of gonadal secretions, XY and XX brain cells have different patterns of gene expression that influence their differentiation and function. Remarkably, one of the male-specific genes, Sry, is specifically expressed in the dopamine-containing cells of the substantia nigra (Dewing, Chiang, Sinchak et al., 2006). It appears that Sry directly affects the function of these dopaminergic neurons and the specific motor behaviors they control. Because these results demonstrate a direct male-specific effect on the brain by a gene encoded only in the male genome, without any mediation by gonadal hormones, it is possible that allelic variation or epigenetic effects at this locus may be important in the pathophysiology of TS.

Perinatal Risk Factors

The search for non-genetic factors that mediate the expression of a genetic vulnerability to TS and related disorders has also focused on the role of adverse perinatal events. This interest dates from the report of Pasamanick and Kawi (1956) who found that mothers of children with tics were 1.5 times more likely to have experienced a complication during pregnancy than the mothers of children without tics. Further, among monozygotic twins discordant for TS, the index twins with TS had lower birth weights than their unaffected cotwins (Hyde, Stacey, Coppola et al., 1995; Leckman, Price, Walkup et al., 1987). Low Apgar scores, severity of maternal life stress during pregnancy, maternal smoking, and severe nausea and/or vomiting during the first trimester have also emerged as potential risk factors in the development of tic disorders (Burd, Severud, Klug, & Kerbeshian, 1999; Leckman, Dolansky, Hardin et al., 1990; Mathews, Bimson, Lowe et al., 2006).

Finally, there is limited evidence that smoking and alcohol use, as well as forceps delivery, can predispose individuals with a vulnerability to TS to develop comorbid OCD (Santangelo, Pauls, Goldstein et al., 1994). The only nested case–control study to date, which examined TS cases arising in a Swedish community sample, found that the mothers of children with TS were two times more likely to have had complications during pregnancy (Khalifa & von Knorring, 2005).

Post-Infectious Autoimmune Mechanisms

It is well established that group A β hemolytic streptococci (GABHS) can trigger immune-mediated disease in genetically predisposed individuals (Bisno, 1991). Speculation concerning a post-infectious (or at least a post-rheumatic fever) etiology for tic disorder symptoms dates from the late 1800s (Kushner, 1999). Acute rheumatic fever is a delayed sequela of GABHS, occurring approximately 3 weeks following an inadequately treated upper respiratory tract infection. Rheumatic fever is characterized by inflammatory lesions involving the heart (rheumatic carditis), joints (polymigratory arthritis) and/or central nervous system (Sydenham’s chorea). The immune response in the CNS of patients with Sydenham’s chorea appears to involve molecular mimicry between streptococcal antigens and self-antigens (Kirvan, Swedo, Heuser, & Cunningham, 2003). Sydenham’s chorea and TS, OCD and ADHD share common anatomical targets – the basal ganglia of the brain and the related cortical and thalamic sites (Husby, van de Rijn, Zabriskie, Abdin, & Williams, 1976). Furthermore, people with Sydenham’s chorea frequently display motor and vocal tics, OC and ADHD symptoms, suggesting the possibility that at least in some instances these disorders share a common etiology (Swedo, Rapoport, Cheslow et al., 1989).

It has been proposed that pediatric autoimmune neuropsychiatric disorder associated with streptococcal infection (PANDAS) represents a distinct clinical entity, and includes Sydenham’s chorea and some cases of TS and OCD (see
Garvey

patients with the PANDAS phenotype (Perlmutter, Leitman, et al. 2005). The PANDAS hypothesis is indirectly supported by the presence of high levels of antistreptococcal antibodies in some patients with TS (Cardona & Orefici, 2001; Church, Dale, Lees, Giovannoni, & Robertson, 2003). Thus far, however, prospective longitudinal studies have provided little support for the idea that GABHS infections induce future tic exacerbations (Luo, Leckman, Katsovich, et al., 2004; Perrin, Murphy, Casey et al., 2004).

A number of studies have been designed to detect and characterize the putative cross-reactive epitopes. Patients with TS may have higher levels of circulating antineural antibodies (Church, Dale, Lees et al., 2003; Morshed, Parveen, Leckman et al., 2001; Singer, Giuliano, Hansen et al., 1998), but no specific epitopes have been unequivocally identified (Dale, Candler, Church, & Pocock, 2004; Kirvan, Swedo, Heuser, & Cunningham, 2006; Singer, Hong, Yoon, & Williams, 2005a). Animal models that involve the injection of patient sera high in levels of antineural antibodies into tic-related basal ganglia areas have also led to equivocal results (Singer, Mink, Loiselle et al., 2005b). However, there is evidence that tic and OC symptoms may improve following plasma exchange in selected patients with the PANDAS phenotype (Perlmutter, Leitman, Garvey et al., 1999).

Additional evidence that acute exacerbations of TS and OCD could also be triggered by GABHS comes from four independent reports demonstrating that the majority of patients with childhood-onset TS or OCD have elevated expression of a stable B-cell marker (Hockstra, Bijzet, Limburg et al., 2001; Luo, Leckman, Katsovich et al., 2004; Swedo, Leonard, Mittelman et al., 1997). The D8/17 marker identifies close to 100% of rheumatic fever patients (with or without Sydenham’s chorea) but is present at low levels of expression in healthy control populations.

The bias for studies addressing the role of B-cell immunity in TS pathogenesis has been driven by the common view that GABHS is an extracellular bacterium and that its clearance is mediated primarily by antibodies. However, GABHS can be internalized in human cells with the same frequency as the classic intracellular pathogens Listeria and Salmonella species and activates human T lymphocytes (Degnan, Kehoe, & Goodacre, 1997). This topic is just beginning to be addressed with the finding that there may be a reduced number of regulatory T cells in selected patients with TS (Kawikova, Leckman, Kronig et al., 2007). There is also a single report that suggests that individuals with TS may have elevated levels of proinflammatory cytokines under baseline conditions and a further increase during periods of tic exacerbations (Leckman, Katsovich, Kawikova et al., 2005).

In summary, a substantial body of circumstantial evidence links post-infectious autoimmune phenomena with TS, OCD and ADHD. However, these data are not compelling with regard to specific immunological mechanisms, nor do they establish where in the sequence of causal events these immune changes occur. These potentially important findings require replication in independent samples and warrant more intensive investigation using prospective longitudinal designs.

Psychological Factors

Tic disorders have long been identified as “stress-sensitive” conditions. Typically, symptom exacerbations follow in the wake of stressful life events. As noted by Shapiro, Shapiro, Young et al. (1988), these events need not be adverse in character. Clinical experience suggests that in some instances a vicious cycle is initiated in which attempts to suppress the symptoms by punishment and humiliation lead to a further exacerbation of symptoms and further increase in stress in the child’s interpersonal environment. Unchecked, this vicious cycle can lead to the most severe manifestations of TS. Prospective longitudinal studies have shown that patients with TS experience more stress than matched healthy controls (Findley, Leckman, Katsovich et al., 2003) and that antecedent stress may have a role in subsequent tic exacerbation (Lin, Katsovich, Ghebremichael et al., 2007). Increases in depressive symptoms have also emerged as a significant predictor of future tic severity (Lin, Katsovich, Ghebremichael et al., 2007).

In addition to the intramorbid effects of stress, anxiety and depression, premorbid stress may also act as a sensitizing agent in the pathogenesis of TS among vulnerable individuals (Leckman, Cohen, Price et al., 1984). It is likely that the immediate family environment (e.g., parental discord) and the coping abilities of family members have some role (Leckman, Dohnansky, Hardin et al., 1990), and this may lead to a sensitization of stress responsive biological systems such as the hypothalamic–pituitary–adrenal axis (Chappell, Riddle, Anderson et al., 1994, Chappell, Leckman, Goodman et al., 1996; Leckman, Goodman, Anderson et al., 1995).

Differential Diagnosis

The differential diagnosis of simple motor tics includes a variety of hyperkinetic movements: myoclonus, tremors, chorea, athetosis, dystonias, akathitic movements, paroxysmal dyskinesias, ballistic movements and hyperekplexia (Jankovic & Mejia, 2006). These movements may be associated with genetic conditions such as Huntington’s chorea or Wilson’s disease; structural lesions, as in hemiballismus (associated with lesions to the contralateral subthalamic nucleus); infectious processes as in Sydenham’s chorea; idiopathic functional instability of neuronal circuits, as in myoclonic epilepsy; and pharmacological treatments such as acute akathisia and dystonias associated with the use of neuroleptic agents. Differentiation between these conditions and tic disorders is usually based on the presentation of the disorder and its natural history. Although aspects of tics such as their abruptness, their paroxysmal timing or their suppressible nature may be similar
CHAPTER 44

to symptoms seen in other conditions, it is rare for all of these features to be combined in the absence of a bona fide tic disorder. Occasionally, diagnostic tests are needed to exclude alternative diagnoses.

Complex motor tics can be confused with other complex repetitive behaviors such as stereotypies or compulsive rituals. Differentiation among these behaviors may be difficult, particularly among retarded individuals with limited verbal skills. In other settings where these symptoms are closely intertwined, as in individuals with both TS and OCD, efforts to distinguish between complex motor tics and compulsive behaviors may be futile. In cases of a tic disorder, it is unusual to see complex motor tics in the absence of simple tics. Involuntary vocal utterances are uncommon neurological signs in the absence of a tic disorder. Examples include sniffing and uttering brief sounds in Huntington’s disease and involuntary moaning in Parkinson’s disease, particularly as a result of l-dopa toxicity. Complex phonic tics characterized by articulate speech typically can be distinguished from other conditions including voluntary coprolalia. Because of their rarity in other syndromes, phonic tics can have an important role in differential diagnosis.

Anamnesis, family history, observation and neurological examination are usually sufficient to establish the diagnosis of a tic disorder. There are no confirmatory diagnostic tests. Neuroimaging studies, electroencephalography (EEG) based of a tic disorder. There are no confirmatory diagnostic tests. Neuroimaging studies, electroencephalography (EEG) based

Assessment

Once the diagnosis has been established, care should be taken to focus on the overall course of an individual’s development, not simply on his or her tic symptoms. This may be a particular problem in the case of TS, where the symptoms can be dramatic and there is the temptation to organize all of an individual’s behavioral and emotional difficulties under a single all-encompassing rubric.

The principal goal of an initial assessment is to determine the individual’s overall level of adaptive functioning and to identify areas of impairment and distress (Leckman, King, Scatihill et al., 1998a). Close attention to the strengths and weaknesses of the individual and his or her family is crucial. Relevant dimensions include the presence of comorbid mental, behavioral, developmental or physical disorders; family history of psychiatric and/or neurological disease; relationships with family and peers; school and/or occupational performance; and the history of important life events. Medication history is important, particularly if the disorder is long-standing or if medications have been prescribed for physical disorders. It may be necessary to evaluate the adequacy of the prior trials with pharmacological agents used to treat tic disorders. Inventories such as the Yale Child Study Center: Tourette’s Syndrome Obsessive-Compulsive Disorder Symptom Questionnaire (Leckman & Cohen, 1998, Appendix 1) completed by the family prior to their initial consultation can help gain a long-term perspective of the child’s developmental course and the natural history. In addition, several valid and reliable clinical rating instruments have been developed to quantify recent tic symptoms including the Yale Global Tic Severity Scale (YGTSS; Leckman, Riddle, Hardin et al., 1989), the Shapiro Tourette Syndrome Severity Scale (Shapiro, Shapiro, Young et al., 1988) and the Hopkins Motor and Vocal Tic Scale (Walkup, Rosenberg, Brown, & Singer, 1992).

The YGTSS is a state-of-the-art, clinician-rated, semi-structured scale that begins with a systematic inventory of tic symptoms that the clinician rates as present or absent over the past week. Current motor and phonic tics are then rated separately according to number, frequency, intensity, complexity and interference on a 6-point ordinal scale (0 = absent; 1–5 for severity) yielding three scores.

Direct observational methods include videotaping tic counting procedures or in vivo evaluation of tic symptoms (Chappell, Riddle, Anderson et al., 1994; Goetz, Pappert, Louis, Raman, & Leurgans, 1999). These direct observational methods are objective, but the frequency of tics varies according to setting and activity. In addition, many individuals with TS can suppress their symptoms for brief periods of time. In practice, videotaped tic counting appears to be most useful for acute research procedures that take place over several hours. Clinically, videotaping can be valuable when the diagnosis is in doubt or when tics are not observed in the consultation room.

Treatment

Tic disorders are frequently chronic, if not lifelong, conditions. Continuity of care is desirable and should be considered before embarking on a course of treatment. Usual clinical practice focuses initially on the educational and supportive interventions. Pharmacological treatments are typically held in reserve. Given the waxing and waning course of the disorders, it is likely that whatever is done (or not done) will lead in the short term to some improvement in tic severity. The decision to employ psychoactive medications is usually made after the educational and supportive interventions have been in place for a period of months and it is clear that the tic symptoms are persistently severe and are themselves a source of impairment in terms of self-esteem, relationships with the family or peers, or school performance.

Educational and Supportive Interventions

Educational activities are among the most important interventions available to the clinician. They should be undertaken first, not only with children with TS but also with those with milder presentations. Although the efficacy of these educational and supportive interventions has not been rigorously assessed, they appear to have positive effects by reshaping familial expectations and relationships (Cohen, Ort, Leckman, Riddle, & Hardin, 1988). This is particularly true when the family and others have misconstrued the tic symptoms as being
intentionally provocative. Families also find descriptions of the natural history comforting in that the disorders tend not to be relentlessly progressive and usually improve during adulthood. This information often contradicts the impressions gained from the available lay literature on TS, which typically focuses on the most extreme cases. Armed with this knowledge, patients and family members and others can begin to understand why waiting before beginning medical treatment makes sense. If a child is in the midst of a bad period of tics it is likely that, whether or not a new medication is prescribed, the tics will improve in the near future. This insight will also help children and their families realize why at times in the past their medications have suddenly stopped working. These dialogues can be relieving and can interrupt a vicious cycle of recrimination that leads to further tic exacerbation, and it can help parents shift the focus from blame to problem-solving.

For children, contact with their teachers can be enormously valuable. By educating the educators, clinicians can make significant progress towards securing for the child a positive and supportive environment in the classroom. If possible, teachers need to respond to outbursts of tics with grace and understanding. Repeatedly scolding a child for his or her tics can be counterproductive. The child may develop a negative attitude to authority figures and may be reluctant to attend school, and classmates may feel freer to tease the child. If tics interfere with a student’s ability to receive information in the classroom, it is imperative to find alternative ways to present the material. By helping the student find a way to function even during periods of severe tics, teachers model problem-solving skills that will foster future self-esteem. It is also important for teachers to know that in unstructured settings such as the cafeteria, gym, playground and school bus, peers who tease or taunt tend to take advantage of the lack of adult supervision. The assignment of a paraprofessional aide to accompany the student can be remarkably beneficial – particularly in situations where there is a history of teasing. Other useful strategies that teachers may consider include providing short breaks out of the classroom to let the tics out in private, allowing students with severe tics to take tests in private so that a child does not have the pressure to suppress tics during the test period, and being flexible with regard to scheduling so that the child is not expected to make an oral presentation at a point when the tics are severe (Bronheim, 1991). A compendium of educational accommodations is available at http://www.tourettesyndrome.net/.

Educated peers are equally important. Many clinicians actively encourage children, families and teachers to help educate peers and classmates about TS. It is remarkable what can be tolerated in the classroom and playground when teachers and peers simply know what the problem is and learn to disregard it.

Finally, it is important for clinicians to determine the family's awareness of and potential interest in advocacy organizations such as the Tourette Syndrome Association (www.tsa-usa.org/), Obsessive Compulsive Foundation (http://www.ocfoundation.org/) and the Children and Adults with Attention Deficit Disorder (http://www.chadd.org/). In the USA, these organizations have made a positive contribution to the lives of many patients and their families by providing support and information. They can also be a valuable outlet for families – to advance research and raise the general level of awareness among health care professionals, educators and the public at large.

Behavioral, Cognitive and Other Psychotherapeutic Treatments

The presence of premonitory urges and the characteristic suppressibility of tic symptoms may have broad implications for behavioral interventions and treatment. Prior to seeking professional consultation, many families will have experimented with a variety of ad hoc behavioral approaches on their own. It is useful to elicit information concerning these efforts and their sequelae.

A variety of cognitive and behavioral approaches have been used with TS (King, Scahiil, Findley, & Cohen, 1998). Although success with various techniques such as assertiveness training, biofeedback, massed practice, time-out, hypnosis and differential reinforcement has been reported, most of these studies have involved small numbers of poorly characterized participants with no replication (Piacentini & Chang, 2006). To date, only habit reversal training has been shown to be efficacious in two randomized clinical trials with moderately to severely affected adults with TS (Deckersbach, Rauuch, Buhlmann, & Wilhelm, 2005; Wilhelm, Deckersbach, Coffey et al., 2003). This intervention includes a number of techniques: awareness training, self-monitoring, contingency management, inconvenience review, relaxation and competing responses. For example, awareness training includes:

1. Response description (i.e., the patient is trained to describe tic occurrences in detail and to re-enact tic movements while looking in a mirror);
2. Response detection, where the therapist helps the patient's ability to detect tics;
3. An early warning procedure, in which the patient is taught to become aware of the earliest signs of tic occurrence (such as the premonitory urge); and
4. Situation awareness training, in which situations that make tics more likely are identified.

When the patient is able to detect the tic and related urges, he or she is instructed to invoke a Competing Response at each occurrence of the tic or the urge and to hold it until the urge passes. Azrin and Nunn (1973) proposed that the Competing Response should be opposite to the tic movement, be able to be maintained for several minutes, produce heightened awareness of the tic movements by contraction of involved muscles, be socially inconspicuous and compatible with normal activities. Patients using habit reversal training are taught to design their own Competing Response to ensure that the responses are acceptable to them and to prepare them for potential changes in tic repertoire.

Although not indicated for the treatment of tics, individual and family counseling may alleviate secondary symptoms such as low self-esteem, defiant and disruptive behavior as well as...
family conflict. These interventions may also serve to reduce a significant source of psychological stress.

**Pharmacological Treatments**

The decision whether or not to use medication is based on the level of symptoms and the clinical presentation of the individual case. Given the waxing and waning of tic symptoms, it is best to withhold psychotropic medications until the tics, even at their best, are a significant source of impairment. Many cases of TS can be successfully managed without medication. When patients present with coexisting ADHD, OCD, depression or bipolar illness it is often better to treat these comorbid conditions first, as successful treatment of these disorders often will diminish tic severity.

**Pharmacotherapy of Tics**

A variety of therapeutic agents are now available to treat tics (Scahill, Erenberg, Berlin et al., 2006). Each medication should be selected on the basis of expected efficacy and potential side effects. Clonidine and guanfacine are potent α2-receptor agonists that are thought to reduce central noradrenergic activity. Initial randomized trials of clonidine had mixed results (Goetz, Tanner, Wilson et al., 1987; Leckman, Hardin, Riddle et al., 1991). However, a subsequent trial involving 136 subjects with chronic tics or TS confirmed the efficacy of clonidine in the treatment of tics (Tourette’s Syndrome Study Group, 2002). Clinical trials indicate that subjects can expect on average a 25–35% reduction in their symptoms over an 8–12-week period. Motor tics may show greater improvement than phonic symptoms. The usual starting dose is 0.05 mg on arising. Further 0.05-mg increments at 3–4-h intervals are added weekly until a dosage of 5 μg·kg−1 is reached or the total daily dose exceeds 0.25 mg. Although clonidine is clearly less effective than haloperidol and pimozide for immediate tic suppression, it is considerably safer. The principal side effect associated with its use is sedation, which occurs in 10–20% of subjects and usually abates with continued use. Other side effects include dry mouth, transient hypotension and rare episodes of worsening behavior. Clonidine should be tapered and not withdrawn abruptly, to reduce the likelihood of symptom or blood pressure rebound (Leckman, Ort, Caruso et al., 1986). Guanfacine is another α2-receptor agonist that has been demonstrated in double-blind studies to be effective in the treatment of TS and TS with comorbid ADHD (Scahill, Chappell, Kim et al., 2001). Guanfacine is generally preferred to clonidine because it is less sedating and not associated with rebound hypertension following withdrawal. Guanfacine is generally started at a dose of 0.5 mg at night and then gradually increased by approximately 0.5 mg weekly to three times daily dosing with a maximum dose of 4 mg·day−1 (Scahill, Chappell, Kim et al., 2001).

Dopamine D2 receptor antagonists remain the most predictably effective tic-suppressing agents in the short term. Documentation of the effectiveness of haloperidol in the early 1960s was a landmark in the history of TS as it called into question the prevailing view that tics were psychogenic in nature. The most widely used typical D2 receptor antagonists are haloperidol, pimozide, fluphenazine and tiapride (not currently available in the USA). Favorable data from double-blind clinical trials are available for haloperidol, pimozide and tiapride (Eggers, Rothenberger, & Berghaus, 1988; Sallee, Nesbitt, Jackson, Sine, & Sethuraman, 1997; Shapiro, Shapiro, Fulop et al., 1989; Tourette’s Syndrome Study Group, 1999). The US Food and Drug Administration has approved TS as an indication for haloperidol and pimozide use. Long-term experience has been less favorable, and the “reflexive” use of these agents should be avoided. Typically, treatment is initiated with a low dose (0.25 mg haloperidol or 1 mg pimozide) given before sleep. Further increments (0.5 mg haloperidol or 1 mg pimozide) may be added at 7–14-day intervals if the tic behaviors remain severe. In most instances, 0.5–6.0 mg·day−1 haloperidol or 1.0–10.0 mg·day−1 pimozide administered over a period of 4–8 weeks is sufficient to achieve adequate control of tic symptoms. Common potential side effects include tardive dyskinesia, acute dystonic reactions, sedation, depression, school and social phobias and/or weight gain. In many instances, by starting at low doses and adjusting the dosage upwards slowly, clinicians can avoid these side effects. The goal should be to use as little of these medications as possible to render the tics “tolerable.” Efforts to stop the tics completely risk overmedication.

To avoid the extrapyramidal side effects associated with typical neuroleptics, atypical neuroleptics (e.g., risperidone, olanzapine and ziprasidone) have been used to treat tic symptoms. These agents have potent 5-HT2 blocking effects as well as more modest blocking effects on dopamine D2. Four randomized controlled trials have shown that risperidone was superior to placebo (Bruggeman, van der Linden, Buitelaar et al., 2001; Dion, Annable, Sandor, & Choinard, 2002; Gaffney, Perry, Lund et al., 2002; Scahill, Leckman, Schultz, Katsovich, & Peterson, 2003). Dosage in the range 1.5–3.5 mg·day−1 was effective and neurological side effects were rare. The most common adverse effects were weight gain, lipid metabolism abnormalities, sedation and sleep disturbance; social phobia and erectile dysfunction occurred in a few patients.

Pergolide is a mixed dopamine agonist used in Parkinson’s disease which, in lower doses, is thought to have a greater effect on presynaptic autoreceptors, and lead to decreased dopamine release. Pergolide has been evaluated in two placebo-controlled trials (Gilbert, Sethuraman, Sine, Peters, & Sallee, 2000), which suggest that it has a positive, but moderate effect on tics. Adverse effects include nausea, syncope, sedation and dizziness. This agent may be especially useful if a child presents with comorbid restless legs syndrome.

Only small open-label pilot studies are available for medications such as tetrabenazine and benzodiazepines. Tetrabenazine is a non-antipsychotic dopamine antagonist, approved as an investigational drug; it may be useful but more study is needed (Scahill, Erenberg, Berlin et al., 2006). The benzodiazepines (e.g., clonazepam) are used as anxiolytics and occasionally as an adjunctive treatment for tics, although it has not been well studied (Scahill, Erenberg, Berlin et al., 2006). Common
side effects with benzodiazepine use include sedation, ataxia, short-term memory problems, disinhibition, depression and addiction. Given these drawbacks, clonazepam is not used widely in TS.

The use of botulinum toxin injections to weaken temporarily muscles associated with severe motor or vocal tics also appears effective (Jankovic, 1994; Kwak, Hanna, & Jankovic, 2000), and also appears to significantly reduce the premonitory urges associated with both motor and vocal tics in the regions injected.

Pharmacotherapy of Coexisting ADHD
The stimulants methylphenidate, d-amphetamine, and mixtures of d- and l-amphetamine are first-line agents for the medical management of ADHD (Brown, Amler, Freeman et al., 2005). However, the use of stimulants in ADHD associated with a tic disorder is controversial. While many patients with both ADHD and a pre-existing tic disorder will do well on stimulants, data from clinical case reports and controlled studies indicate that some children with ADHD will exhibit tics de novo when exposed to a stimulant. In other cases, tics may increase to a level that warrants discontinuation of the stimulant. To address this question, a multicenter randomized double-blind clinical trial was conducted with 136 children with ADHD and a chronic tic disorder (Tourrette’s Syndrome Study Group, 2002). Subjects were randomly administered clonidine alone, methylphenidate alone, or the combination in a 2 × 2 factorial design. Significant improvements in ADHD symptoms occurred for subjects assigned to clonidine alone and those assigned to methylphenidate alone. Compared with placebo, the greatest benefit occurred with combination regimens. Clonidine appeared to be most helpful for impulsivity and hyperactivity, while methylphenidate appeared to be most helpful for inattention. The proportion of individuals reporting a worsening of tics was no higher in those treated with methylphenidate (20%) than those being administered clonidine alone (26%) or placebo (22%). Sedation was common with clonidine treatment (28% reported moderate or severe sedation), but otherwise the drugs were tolerated well, with no evidence of cardiac toxicity. This trial did not provide prior recommendations to avoid methylphenidate in these children because of concerns of worsening tics. Commonly used non-stimulants for the treatment of ADHD include the tricyclic antidepressants desipramine and nortriptyline, atypical antidepressants such as bupropion, and α2-agonists clonidine and guanfacine (Brown, Amler, Freeman et al., 2005). The latter has been demonstrated to be effective in subjects with both ADHD and coexisting tics (Scahill, Chappell, Kim et al., 2001).

Pharmacotherapy of Coexisting OCD
Unfortunately, many patients with OCD and a coexisting tic disorder do not respond well to cognitive-behavioral therapies, which are the standard interventions for OCD (McDougle, Goodman, Leckman et al., 1993). Controlled clinical trials have shown that addition of small doses of the neuroleptic haloperidol, or the atypical neuroleptic risperidone increases the response to serotonin reuptake inhibitors (Bloch, Peterson, Scahill et al., 2006a; McDougle, Goodman, Leckman et al., 1994).

Special Populations – PANDAS
Although initial results from immunomodulatory treatments, including plasma exchange, are promising, caution is warranted (Perlmutter, Leitman, Garvey et al., 1999). It is also premature to recommend prophylactic antibiotic treatment (King, 2006).

Neurosurgical Interventions
Neurosurgical interventions for TS have been appropriately reserved for adults with intractable tics that severely affect social functioning. Many neurosurgical sites have been targeted for tics in previous lesioning studies: frontal cortex, limbic cortex, thalamus, infralthalamic area and cerebellum (Rauch, Baer, Cosgrove, & Jenike, 1995). Deep brain stimulation (DBS) is a relatively reversible, stereotactic technique, which has been looked to as the preferred method of neurosurgical treatment for medically intractable tics. The original electrode placement for DBS surgery was in the medial part of the thalamus, based on the results of previous lesioning studies (Hassler & Dieckmann, 1973). All four patients who received bilateral medial thalamic DBS surgery experienced a substantial improvement in tic severity (Ackermans, Temel, Cath et al., 2006; Visser-Vandewalle, Temel, Boon et al., 2003). Subsequent case reports demonstrated comparable efficacy in bilateral pallidal stimulation compared with bilateral medial thalamic stimulation (Mink, Walkup, Frey et al., 2006).

However, currently in DBS for tics, the site of electrode placement and the electrode stimulation parameters have not been examined in carefully controlled clinical studies and differ markedly in the few sites willing to engage in this procedure. Therefore DBS is currently not advisable for all but the most severe and treatment-refractory adults with TS (Mink, Walkup, Frey et al., 2006).

Future Directions
Along with a deepening appreciation of the clinical phenomenology of TS and related disorders, recent progress in genetics, neuroanatomy, systems neuroscience and functional in vivo neuroimaging has set the stage for a major advance in our understanding of TS and related disorders. Success in this area will lead to the targeting of specific brain circuits for more intensive study. Diagnostic and prognostic advances can also be anticipated (e.g., which circuits are involved and to what degree?). How does that degree of involvement affect the patient’s symptomatic course and outcome?

Given this potential, TS can be considered a model disorder to study the dynamic interplay of neurobiological systems during development. It is likely that the research paradigms utilized in these studies and many of the empirical findings resulting from them will be relevant to other disorders of childhood onset and will enhance our understanding of normal development.

CHAPTER 44

Schizophrenia is one of the most devastating psychiatric disorders to affect children and adolescents. Although extremely rare before the age of 10, the incidence of schizophrenia rises steadily through adolescence to reach its peak in early adult life. The clinical severity, impact on development, and poor prognosis of child- and adolescent-onset schizophrenia reinforce the need for early detection, prompt diagnosis, and effective treatment.

The current concept of schizophrenia in children and adolescents evolved from a different perspective held during much of the 20th century. Until the early 1970s, the term childhood schizophrenia was applied to children who would now be diagnosed with autism. Until the 1990s, there was doubt about the validity of diagnosing schizophrenia in children and younger adolescents. However, in DSM-III and ICD-9, the separate category of childhood schizophrenia was removed, and the same diagnostic criteria for schizophrenia were applied across the age range. Good evidence for the validity of the diagnosis of schizophrenia in childhood and adolescence comes from the Maudsley Child and Adolescent Psychosis Follow-up Study (Hollis, 2000). First, a DSM-III-R diagnosis of schizophrenia in childhood and adolescence predicted a significantly poorer adult outcome compared to other non-schizophrenic psychosis. Second, the diagnosis of schizophrenia showed a high level of stability, with 80% having the same diagnosis recorded at adult follow-up (Jarbin, Ott, & Van Knorring, 2003).

**Clinical Features**

Schizophrenia is characterized by psychotic symptoms as follows.

1. **Hallucinations** These are sensory perceptions in the absence of external stimuli. Auditory hallucinations (hearing voices) are by far the most common type of hallucination in schizophrenia. Typically, their content is threatening, derogatory or commanding. Auditory hallucinations are classified according to their form: voices addressing the patient directly (second person); voices discussing or commenting on the patient’s actions in the third person (third person or running commentary); and voices speaking the patient’s thoughts aloud (thought echo).

2. **Delusions** These are false beliefs, incompatible with the patient’s social, religious, and educational background, arising from an incorrect inference about external reality and not amenable to reason. Paranoid delusions (belief that one is persecuted), delusions of reference (belief that events or people’s behavior refer to oneself) or delusions of control (belief that one’s own thoughts, emotions, or movements are controlled by external forces) are particularly common in schizophrenia.

3. **Passivity phenomena** These include the experience of one’s own thoughts becoming automatically available to others (thought broadcast); alien thoughts being inserted into one’s mind (thought insertion); and the experience of one’s thoughts being removed from one’s mind (thought withdrawal).

4. **Disordered thought and speech** This may present as incoherent speech (loosening of associations), neologisms or a paucity of content and ideas (poverty of speech).

5. **Reduced or inappropriate emotional reactivity and lack of volition** People with schizophrenia may demonstrate reduced emotional expression (flattened affect) or incongruous emotional reactions, lack of drive and initiative, and social withdrawal.

6. **Motor abnormalities** These phenomena may include posturing, mannerisms, stereotopies, and catatonic immobility or excitement.

Symptoms in schizophrenia can be seen as representing either an excess or distortion of normal function (positive symptoms) or a reduction or loss of normal function (negative symptoms). Positive symptoms include hallucinations, delusions, passivity phenomena, thought disorder, disorganized behavior and inappropriate affect. Negative symptoms include poverty of thought and speech, blunted affect, impaired volition and social withdrawal. Liddle (1987) showed that symptoms in chronic schizophrenia cluster into three syndromes: psychomotor disorder (negative symptoms); reality distortion (hallucinations and delusions); and disorganization (bizarre behavior, inappropriate affect, and disorganized thought). The relationship between these different groups of symptoms and underlying brain function in schizophrenia is considered in more detail below.

A wide variety of anomalous perceptual experiences may occur at the onset of an episode of schizophrenia, leading to a sense of fear or puzzlement which may constitute a delusional mood and herald a full psychotic episode. These anomalous experiences may include the sense that familiar places and
people and their reactions have changed in some subtle way. These experiences can result from a breakdown between perception and memory (for familiar places and people) and associated affective responses (silence given to these perceptions). For example, a young person at the onset of illness may study their reflection in the mirror for hours because it looks strangely unfamiliar, misattribute threatening intent to an innocuous comment or experience family members or friends as being unfamiliar, leading to a secondary delusional belief that they have been replaced by doubles or aliens. In summary, some clinical phenomena in schizophrenia can be understood in terms of a loss of normal contextualization and co-ordination of cognitive and emotional processing.

Clinical Phases of Schizophrenia

Premorbid Social and Developmental Impairments

Child- and adolescent-onset schizophrenia is associated with poor premorbid functioning and early developmental delays (Alaghband-Rad, McKenna, Gordon et al., 1995; Hollis, 1995, 2003). Similar developmental and social impairments in childhood have been reported in adult-onset schizophrenia, but premorbid impairments appear to be more common and severe in the child- and adolescent-onset forms of the disorder. In the Maudsley study (Hollis, 2003), significant early delays were particularly common in the areas of language (20%), reading (30%) and bladder control (36%). Just over 20% of cases of adolescent schizophrenia had significant early delays in either language or motor development. In contrast, language and motor developmental delays have been reported in only about 10% of individuals who develop schizophrenia in adult life (Jones, Rogers, Murray, & Marmot, 1994). A consistent characteristic in the premorbid phenotype is impaired sociability. For example, in the Maudsley study of child- and adolescent-onset psychoses (Hollis, 2003), about one-third of cases with schizophrenia had significant difficulties in social development affecting the ability to make and keep friends.

Premorbid IQ in child- and adolescent-onset schizophrenia is in the mid to low 80s, some 10–15 points lower than in the adult form of the disorder (Alaghband-Rad, McKenna, Gordon et al., 1995; Asarnow, Thompson, Hamilton, Goldstein, & Guthrie, 1994; Hollis, 2000). In the Maudsley study (Hollis, 2000), one-third of child- and adolescent-onset cases had an IQ below 70, with the whole distribution of IQ shifted down compared to both adolescent affective psychoses and adult schizophrenia.

Cannon, Caspi, Moffitt et al. (2002) reported a specific association between adult schizophreniaform disorder and an antecedent pattern of childhood pan-developmental impairments involving motor development, receptive language and IQ. These findings are consistent with the view that premorbid impairments are manifestations of a genetic and/or developmental liability to schizophrenia. It seems clear that the premorbid phenotype does not just represent non-specific psychiatric disturbance. Looking backward from schizophrenia to early impairment, subtle problems of language, attention and social relationships are typical, whereas, in contrast, conduct problems are rare. However, looking forward from childhood impairments to later schizophrenia, prediction is much weaker. In addition, premorbid social and behavioral difficulties are not unique to schizophrenia and occur in other psychoses.

Are Premorbid Impairments a Risk or Precursor of Psychosis?

Premorbid impairments could lie on a causal pathway for psychosis or, alternatively, they could be markers of an underlying neuropathological process, such as aberrant neural connectivity, which may be the cause of both premorbid social impairment and psychosis. Frith (1994) has speculated on the possible cognitive mechanisms that might link deficits in social cognition or “theory of mind” in a causal pathway to both positive and negative psychotic symptoms. If these characteristics are causally related then modifying the “primary” cognitive or social deficits may reduce the risk of psychosis. Alternatively, cognitive and social deficits, although often present, may not be necessary in the pathogenesis. The fact that individuals may develop schizophrenia without obvious premorbid impairments supports this view. In these circumstances, an intervention aimed at the neurobiological level (e.g., antipsychotic medication) may be necessary. Only a high-risk longitudinal intervention study can adequately address the issue of causality, and this would require an intervention that had benefits for individuals who had the premorbid phenotype but did not develop psychosis.

Premorbid Psychopathology

A diverse range of clinical diagnoses, including attention deficit/hyperactivity disorder (ADHD), conduct disorder, anxiety, depression and autism spectrum disorders, may precede the diagnosis of schizophrenia in children and adolescents (Schaeffer & Ross, 2002) and in adults (Kim-Cohen, Caspi, Moffitt et al., 2003). However, there is a lack of any specific premorbid diagnosis that could practically aid early clinical identification of those at high risk for schizophrenia. A more promising line of research has demonstrated a strong link between self-reported psychotic symptoms in childhood and later schizophrenia (Poulton, Caspi, Moffitt et al., 2000).

In the Dunedin cohort, psychotic symptoms at age 11 increased the risk of schizophreniaform disorder at age 26 but not other psychiatric diagnoses. Relative to the rest of the cohort, those identified at age 11 with “strong” psychotic symptoms also had significant impairments in motor development, receptive language and IQ (Cannon, Caspi, Moffitt et al., 2002). Whereas none of these cases met criteria for a diagnosis of schizophrenia during adolescence, it appears that isolated or attenuated psychotic symptoms, in combination with pan-developmental impairment, constitute a significant high-risk premorbid phenotype.

Prodromal Symptoms and Onset of Psychosis

People who develop schizophrenia typically enter a prodromal
phase characterized by a gradual but marked decline in social and academic functioning that precedes the onset of active psychotic symptoms. An insidious deterioration prior to the onset of psychosis is typical of the presentation of schizophrenia in children and adolescents (Werry, McClellan, Andrews, & Ham, 1994), and is more common in schizophrenia than in affective psychoses (Hollis, 1999). Non-specific behavioral changes including social withdrawal, declining school performance and uncharacteristic and odd behavior began, on average, over a year before the onset of positive psychotic symptoms. In retrospect, non-specific behavioral changes were frequently early negative symptoms, which had their onset well before positive symptoms such as hallucinations and delusions.

Early recognition of disorder is difficult, as premorbid cognitive and social impairments gradually shade into prodromal symptoms before the onset of active psychotic symptoms (Hafner & Nowotny, 1995). Prodromal symptoms can include odd ideas, eccentric interests, changes in affect, unusual experiences and bizarre perceptual experiences. Whereas these are also characteristic features of schizotypal personality disorder, in a schizophrenic proclivity there is usually progression to more severe dysfunction.

### Diagnosis of Schizophrenia in Childhood and Adolescence

#### Diagnostic Criteria for Schizophrenia

The two dominant diagnostic systems (DSM and ICD) have slightly different definitions for schizophrenia, although both require the clear evidence of psychosis (in the absence of predominant affective symptoms) with minimum duration criteria. The reader should refer to the original manuals (DSM-IV and ICD-10) when making diagnoses in clinical or research practice.

ICD-10 criteria are closer to the Schneiderian concept of schizophrenia and place more reliance than DSM-IV on the presence of first-rank symptoms. In contrast, the DSM-IV definition reflects Kraepelin’s concept of a psychotic disorder with a chronic and deteriorating course (Maj, 1998). In addition, DSM-IV stipulates a 6-month duration of disturbance, which makes it more restrictive than the 1-month duration criterion of ICD-10. The DSM-IV category of schizophreniform disorder is used for cases with the same symptoms but an overall duration of disturbance of less than 6 months. As a result, the DSM-III-R/DSM-IV definition of schizophrenia has greater specificity but lower sensitivity than ICD-10 in first-episode psychoses (Mason, Harrison, Croudace, Glazebrook, & Medley, 1997). Not surprisingly, cases of schizophrenia defined using DSM-IV have a worse prognosis than those defined using ICD-10.

DSM-IV also describes various subtypes of schizophrenia defined by the most prominent symptomatology:

1. **Paranoid type** characterized by delusions and hallucinations;
2. **Disorganized type** characterized by disorganization of speech, behavior and negative symptoms (i.e., flat or inappropriate affect);
3. **Catatonic type** characterized by motor abnormalities; and
4. **Residual type**.

#### Clinical Characteristics of Schizophrenia in Childhood and Adolescence

Even if strict adult definitions of schizophrenia (DSM-III-R/DSM-IV or ICD-10) are applied, there are age-dependent variations in phenomenology. Child- and adolescent-onset cases are characterized by a more insidious onset, negative symptoms, hallucinations in different modalities and fewer systematized or persecutory delusions (Green, Pátron-Gayol, Hardesty *et al.*, 1992; Werry, McClellan, Andrews *et al.*, 1994). Early-onset schizophrenia is characterized by greater disorganization (incoherence of thought and disordered sense of self) and more negative symptoms, while in later-onset cases there is a higher frequency of systematized and paranoid delusions (Hafner & Nowotny, 1995).

#### Course and Outcome

**Short-Term Course**

Child- and adolescent-onset schizophrenia characteristically runs a chronic course, with only a minority of cases making a full symptomatic recovery from the first psychotic episode. Hollis (1999) found that only 12% of schizophrenic cases were in full remission at discharge compared to 50% of cases with affective psychoses. The short-term outcome for schizophrenia presenting in early life appears to be worse than that of first-episode adult patients (Robinson, Woerner, Alvir *et al.*, 1999). If full recovery does occur then it is most likely within the first 3 months of the onset of psychosis. In the Maudsley study, those adolescent-onset patients who were still psychotic after 6 months had only a 15% chance of achieving full remission, whereas over half of all cases that made a full recovery had active psychotic symptoms for less than 3 months (Hollis, 1999). The clinical implication is that the early course over the first 6 months is the best predictor of remission and that longer observation over 6 months adds relatively little new information.

**Long-Term Outcome**

A number of long-term follow-up studies of child- and adolescent-onset schizophrenia describe a typically chronic unremitting long-term course with severely impaired functioning in adult life (Eggers & Bunk, 1997; Fleischhaker, Schulz, Tepper *et al.*, 2005; Hollis, 2000; Jarbin, Ott, & Von Knorring, 2003; Lay, Blanz, Hartmann, & Schmidt, 2000; Schmidt, Blanz, Dippe, Koppe, & Lay, 1995; Werry, McClellan, & Chard, 1991). Referral bias towards selecting more severe cases is a potential problem in clinical follow-up studies. However, population-based studies have yielded similar results (Hollis, 2000). Several common themes emerge from these studies. First, the generally poor outcome of early onset schizophrenia conceals considerable heterogeneity. About one-fifth of patients in most studies have a good outcome with only mild impairment, whereas at the other extreme about one-third of patients are...
severely impaired, requiring intensive social and psychiatric support. Second, after the first few years of illness there is little evidence of further progressive decline. Third, child- and adolescent-onset schizophrenia has a worse outcome than either adolescent-onset affective psychoses or adult-onset schizophrenia. Fourth, social functioning, in particular the ability to form friendships and love relationships, appears to be very impaired in early-onset schizophrenia. Taken together, these findings confirm that schizophrenia presenting in childhood and adolescence lies at the extreme end of a continuum of phenotypic severity.

**Prognostic Factors**
The predictors of poor outcome in adolescent-onset affective psychoses include premorbid social and cognitive impairments (Fleischhaker, Schulz, Tepper et al., 2005; Hollis, 1999), a prolonged first psychotic episode (Schmidt, Blanz, Dippe et al., 1995), extended duration of untreated psychosis and the presence of negative symptoms (Hollis, 1999). Premorbid functioning and negative symptoms at onset provide better prediction of long-term outcome than categorical diagnosis (Fleischhaker, Schulz, Tepper et al., 2005; Hollis, 1999).

**Mortality**
The risk of premature death is increased in child- and adolescent-onset psychoses. In the Maudsley study (Hollis, 1999), there were nine deaths out of the 106 cases followed-up (8.5%), corresponding to a 12-fold increase in the risk of death compared to an age and sex matched general UK population over the same period. Of the nine deaths in the cohort, seven were male and seven had a diagnosis of schizophrenia. Three subjects suffered violent deaths, two died from self-poisoning and three had unexpected deaths from previously undetected physical causes (cardiomyopathy and status epilepticus) and were possibly associated with high-dose antipsychotic medication.

**Epidemiology**

**Incidence and Prevalence**
Good population-based incidence figures for child- and adolescent-onset schizophrenia are lacking, although there are data for broader categories of psychosis, with diagnoses made without the benefit of standardized assessments. Gillberg, Wahlstrom, Forsman, Hellgren, and Gillberg (1986) calculated age-specific prevalence for all psychoses (including schizophrenia, schizophreniform psychosis, affective psychosis, atypical psychosis and drug psychoses) in the age range 13–18 years using case-register data from Goteborg, Sweden. Of the cases, 41% had a diagnosis of schizophrenia. At age 13 years, the prevalence for all psychoses was 0.9 in 10,000, showing a steady increase during adolescence, reaching a prevalence of 17.6 in 10,000 at age 18 years.

**Sex Ratio**
Males are overrepresented in many clinical studies of childhood-onset schizophrenia (Russell, Bott, & Sammons, 1989; Spencer & Campbell, 1994). However, other studies of predominantly adolescent-onset schizophrenia have described an equal sex ratio (Gordon, Frazier, McKenna et al., 1994; Hollis, 2000; Werry, McClellan, Andrews et al., 1994). The interpretation of these studies is complicated by the possibility of referral biases to clinical centers. In an epidemiological study of first admissions for schizophrenia and paranoia in children and adolescents there was an equal sex ratio for patients under the age of 15 (Galdos, van Os, & Murray, 1993). The finding of an equal sex distribution with adolescent-onset is intriguing as it differs from the consistent male predominance (ratio 2:1) reported in incident samples of early adult-onset schizophrenia (Castle & Murray, 1991). Clearly, future studies require population-based samples free from potential referral biases.

**Etiology and Risk Factors**

**Pregnancy and Birth Complications**
Pregnancy and birth complications (PBC) have long been implicated as a risk factor in schizophrenia, although the evidence is mixed (Geddes & Lawrie, 1995; Kendall, McInneny, Juszczak, & Bain, 2000). In two independent case-control studies of childhood-onset schizophrenia, Matsumoto, Takei, Saito et al. (1999); Matsumoto, Takei, Saito et al., 2001 reported an odds ratio of 3.2–3.5 for PBC, suggesting a greater risk in very early-onset cases. However, in the National Institute of Mental Health (NIMH) study of childhood-onset schizophrenia, PBCs were no more common in cases than in sibling controls (Nicolson, Giedd, Lenane et al., 1999). Insofar as there is a significant association, it seems likely that PBCs are consequences rather than causes of abnormal neurodevelopment (Goodman, 1988). This view is supported by the finding that people with schizophrenia have smaller head size at birth than controls (McGrath & Murray, 1995), which is likely to be a consequence of either defects in genetic control of neurodevelopment or earlier environmental factors such as viral exposure.

**Prenatal Famine**
Severe maternal intrauterine nutritional deficiency may increase the risk for schizophrenia in adult life. Evidence of a two-fold increase for schizophrenia in children born to the most malnourished mothers comes from studies of the 1944–1945 Dutch Hunger Winter (Susser & Lin, 1992) and the Chinese famine of 1959–1961 (St. Clair, Xu, Wang et al., 2005).

**Cannabis and Schizophrenia**
There is little doubt that acute intoxication with cannabis and other illicit substances such as stimulants and hallucinogens can precipitate psychotic symptoms or exacerbations of existing psychotic illness. However, there is controversy whether cannabis use in particular is a risk factor for the development of schizophrenia. A meta-analysis of four well-conducted longitudinal population-based studies from Sweden (Swedish conscript cohort), the Netherlands (NEMESIS) and New Zealand
(Dunedin and Christchurch cohorts) concluded that, at an individual level, cannabis confers an overall two-fold increased risk for later schizophrenia (Arseneault, Cannon, Witton, & Murray, 2004). In the Dunedin cohort, Arseneault, Cannon, Poulton et al. (2002) showed that the association was strongest for the youngest cannabis users (after controlling for prior psychotic symptoms), with 10.3% of the cannabis users at age 15 developing schizophreniform disorder at age 26. So far, cannabis use has not been directly implicated in child- and adolescent-onset schizophrenia – possibly because of the relatively lower prevalence of cannabis use in younger adolescents and a short duration between exposure and psychotic outcome. However, cannabis use is associated with earlier age of onset of schizophrenia in adults (Arendt, Rosenberg, Foldager, Perto, & Munk-Jorgensen, 2005).

The mechanism and causal direction for this association remain unclear. It is possible that subtle social and developmental impairments that precede schizophrenia are also risk factors for cannabis use (reverse causality or a third factor). Perhaps a more plausible explanation is a gene x environment interaction effect whereby cannabis exposure causes schizophrenia only in those with a pre-existing susceptibility. Caspi, Moffitt, Cannon et al. (2005) provided evidence for such a gene x environment interaction specific to adolescent cannabis exposure: The COMT val158met polymorphism moderated the link between psychosis and adolescent-onset cannabis use, but not adult-onset cannabis use. The COMT val allele is associated with greater COMT activity (relative to the COMT met allele) and reduced dopamine transmission in the prefrontal cortex. These results, taken together with human (Dean, Bradbury, & Copolov, 2003) and animal (Pistis, Perra, Pillolla et al., 2004) neuropharmacological studies suggest that cannabis may enhance the risk of schizophrenia in vulnerable individuals during a critical period of adolescent brain development.

Psychosocial Risks
Expressed Emotion
High levels of expressed emotion (EE) among relatives of adults with schizophrenia predict psychotic relapse and poor outcome (Leff & Vaughn, 1985), raising the question of whether high EE might act to “bring forward” the onset of the disorder in a vulnerable individual. Goldstein (1987) reported that measures of parental criticism and overinvolvement taken during adolescence were associated with an increased risk of schizophrenia spectrum disorders in young adulthood. However, a causal link was not proven, and the association may reflect either an expression of some common underlying trait or a parental response to premorbid disturbance in the preschizophrenic adolescent. More direct comparisons between the parents of adult- and childhood-onset cases of schizophrenia fail to support the hypothesis of higher parental EE in childhood-onset cases. Asarnow, Thompson, Hamilton et al. (1994) used the Five Minute Speech Sample to measure parental EE and found that people with childhood-onset schizophrenia were no more likely to have “high EE” parents than normal controls. It appears that, on average, the parents of children with schizophrenia generally express lower levels of criticism and hostility than parents of adult-onset patients, because of a greater tendency to attribute their children’s behavior to an illness that is beyond their control (Hooley, 1987).

Migration and Social Class
Two variables, migration and social class, are associated with significant variation in the incidence of schizophrenia. First and second generation migrants have a 2–4 times greater risk of schizophrenia (Cantor-Graae & Selten, 2005). The relative risk is highest in migrants from developing countries and where the majority population is Black. Adjustment for social class reduces, but does not eliminate, the effects of migration. Migrants living in deprived inner cities are exposed to a range of psychosocial adversities including increased exposure to drugs, violence and crime. The mechanisms linking social adversity to psychosis are unclear – but one suggestion is that experience of social defeat and isolation increases liability to dopamine dysregulation and cognitive distortions (Broome, Woolley, Tabraham et al., 2005).

Childhood Abuse and Neglect
A causal link between child abuse and psychosis, in particular hallucinations, in adult life has been proposed (Read, van Os, Morrison, & Ross, 2005). While strong claims have been made for this link, the evidence to date remains inconclusive, with most studies supporting the link having serious methodological weaknesses (Morgan & Fisher, 2007).

Concepts of Schizophrenia
Neurodevelopmental Model
Over the last two decades, the concept of schizophrenia as a neurodevelopmental disorder has been the dominant explanatory model with a tension between “early” and “late” versions of the model. However, more recently these positions have converged as it has been recognized that both early events (during pre- and perinatal brain development) and late events (during adolescent brain maturation) contribute to schizophrenia (Hollis & Taylor, 1997; Rapoport, Addington, & Frangou, 2005).

The “early” neurodevelopmental model views the primary cause of schizophrenia as a static “lesion,” either neurogenic or environmental in origin, occurring during fetal brain development (Weinberger, 1987). Two main lines of evidence support this model. First, Roberts, Colter, Lofthouse et al. (1986) reported an absence of gliosis, suggesting aberrant neurodevelopment rather than neurodegeneration. Second, schizophrenia is associated with premorbid social and cognitive impairments (Jones, Rogers, Murray et al., 1994), pregnancy and birth complications (Lewis & Murray, 1987) and minor physical anomalies (Gualtieri, Adams, & Chen, 1982). According to this “early” model, during childhood this lesion is relatively silent, giving rise only to subtle social and cognitive

SCHIZOPHRENIA AND ALLIED DISORDERS
impairments. However, in adolescence, or early adult life, the lesion interacts with the process of normal brain maturation (e.g., myelination of cortico-limbic circuits, and/or synaptic pruning and remodeling) and leads to psychotic symptoms.

A limitation of the “early” model is that a neurodevelopmental insult on its own cannot account for the finding of increased extracerebral (sulcal) cerebrospinal fluid (CSF) space in schizophrenia. Diffuse loss of brain tissue limited to the preor perinatal periods would result in enlargement of the lateral ventricles but not increased extracerebral CSF space (Woods, 1998).

The “late” neurodevelopmental model, first proposed by Feinberg (1983), argues that the key neuropathological events in schizophrenia occur as a result of abnormal brain development during adolescence. The current formulation of the “late” neurodevelopmental model posits that excessive synaptic and/or dendritic elimination occurring during adolescence produces aberrant neural connectivity (McGlashan & Hoffman, 2000; Woods, 1998). This “late” model characterizes schizophrenia as a progressive late-onset neurodevelopmental disorder and predicts that progressive structural brain changes and cognitive decline will be seen in adolescence around the onset of psychosis. Excessive synaptic pruning is regarded as an amplification of the normal process of progressive pruning and elimination of synapses that begins in early childhood and extends through late adolescence (Purves & Lichtmen, 1980). In the “late” model, premorbid abnormalities in early childhood are viewed as non-specific risk factors rather than early manifestations of an underlying schizophrenic neuropathology.

Both the “early” and “late” models suppose that there is a direct and specific expression of the eventual brain pathology as schizophrenic disorder. A third viewpoint, the neurodevelopmental “risk” model, proposes that early and/or late brain pathology acts as a risk factor rather than a sufficient cause, so that its effects can only be understood in the light of an individual’s exposure to other risk and protective factors (Holli & Taylor, 1997). This latter formulation provides a probabilistic model of the onset of schizophrenia in which aberrant brain development is expressed as neurocognitive impairments that interact with environmental risk factors to produce psychotic symptoms.

Over the last decade, further evidence has emerged to refine the neurodevelopmental model of schizophrenia. Data from premorbid social and developmental impairments, brain morphology, neuropsychology and genetics all suggest an aberrant neurodevelopmental process resulting from an interplay of genetic and environmental factors that is set in train before the onset of psychotic symptoms and continues into late adolescence.

Neurobiology of Schizophrenia

Neuropathology

In the postmortem brains of people with schizophrenia there is an absence of gliosis, which is the necessary hallmark of neurodegeneration (Roberts, Colter, Lothhouse et al., 1986). The prominent neuropathology in schizophrenia is not the classic form involving neuronal cell death, but instead a loss or reduction in dendritic spines and synapses, which are the elements of neural connectivity (Glantz & Lewis, 2000). As a result, the brain in schizophrenia is characterized by increased neuronal density, decreased intraneuronal space and reduced overall brain volume. Furthermore, the decrease in dendritic spine density appears to be both region- and disease-specific, being found in the dorsolateral prefrontal cortex (layer 3 pyramidal cells), but not in the visual cortex (Glantz & Lewis, 2000). These findings are compatible with the hypothesis of reduced cortical and/or thalamic excitatory inputs to the dorsolateral prefrontal cortex in schizophrenia. However, early postmortem findings of aberrant neuronal migration have not been replicated. Hence, while there is a broad consensus that reduced dendritic arborization and synaptic density are core neuropathological features in schizophrenia, there is much less certainty regarding the timing of these changes during development.

Structural Brain Abnormalities

Neuroimaging and postmortem studies have shown that the brain as a whole and the frontal and temporal cortices in particular are smaller than normal in people with schizophrenia (Nopoulos, Torres, Flaum et al., 1995). Brain volume reductions are specific to gray matter (Gur, Turetsky, Cowell et al., 2000b), which supports neuropathological findings of increased neuronal density and reduced intraneuronal neuropil rather than neuronal loss (Selemon, Rajkowska, & Goldman-Rakic, 1995).

The volume of the hippocampus and amygdala is reduced bilaterally by 4.5–10% (Gur, Turetsky, Cowell et al., 2000b; Nelson, Saykin, Flashman, & Riodan, 1998), and prefrontal gray matter volume is reduced by about 10% (Gur, Cowell, Latshaw et al., 2000a). Enlargement of the third and lateral ventricles is a consistent finding, with ventricular volume increased by about 40% bilaterally (Lawrie & Abukmeil, 1998). Ventricular enlargement and frontal gray matter abnormalities are associated with neuropsychological impairment and negative symptoms (Vita, Dieci, Giobbio et al., 1991).

The brain changes reported in childhood-onset schizophrenia appear to be very similar to those described in adult schizophrenia, supporting the idea of an underlying neurobiological continuity. In the NIMH study of childhood-onset schizophrenia (onset less than 13 years of age), subjects had smaller brains than controls, with larger lateral ventricles and reduced prefrontal lobe volume (Jacobsen & Rapoport, 1998). As in adult studies, reduced total cerebral volume is associated with negative symptoms (Alaghband-Rad, Hamburger, Giedd, Frazier, & Rapoport, 1997). Midsagittal thalamic area is decreased while midsagittal area of the corpus callosum is increased (Giedd, Castellanos, Rajapakse, Vaituzis, & Rapoport, 1996) suggesting that the reduction in total cerebral volume in childhood-onset schizophrenia is caused by relative reduction in gray matter with relative sparing of
white matter. Childhood-onset patients have a higher rate of developmental brain abnormalities than controls, including an increased frequency of an enlarged caudate pellucidum (Nopoulos, Giedd, Andreasen, & Rapoport, 1998). Abnormalities of the cerebellum have also been found, including reduced volume of the vermis, mid-sagittal area and inferior posterior lobe (Jacobsen, Giedd, Berquin et al., 1997a). Associated with reports of reduced cortical thickness are gyrification abnormalities including more flattened curvature in the sulci and more peaked or steep curvature in the gyri (White, Andreasen, Nopoulos, & Magnotta, 2003), consistent with a neurodevelopmental origin of cortical abnormalities. In adolescent-onset schizophrenia patients, there is evidence of ventricular enlargement and reduced volume of the prefrontal cortex and reduced thalamic volume (Dasari, Friedman, Jesberger et al., 1999; James, Smith, & Jayaloes, 2004).

Progressive Brain Changes

Two different types of progressive brain change have been described in schizophrenia. First, treatment with traditional antipsychotics appears to cause progressive enlargement of the basal ganglia, with these structures returning to their original size when patients are transferred to the atypical antipsychotic clozapine (Frazier, Giedd, Kaysen et al., 1996). Second, there is evidence of progressive volume reductions in the temporal and frontal lobes during the first 2–3 years after the onset of schizophrenia (Gur, Cowell, Turetsky et al., 1998). In the NIMH study of childhood-onset schizophrenia, longitudinal repeated magnetic resonance imaging (MRI) scans through adolescence revealed a progressive increase in ventricular volume and progressive decrease in cortical volume with frontal (11% decrease), parietal (8.5% decrease) and temporal lobes (7% decrease) disproportionately affected (Rapoport, Giedd, Blumenthal et al., 1999; Sporn, Greenstein, Gogtay et al., 2003). Overall, this represents a four-fold greater reduction in cortical volume than in healthy adolescents. A similar progressive loss in cerebellar volume has been reported in the same NIMH childhood-onset schizophrenia sample (Keller, Castellanos, Vaituzis et al., 2003). Age-related volume reduction across adolescence has also been reported for the anterior cingulate gyrus (Marquardt, Levitt, Blanton et al., 2005). Progressive changes appear to be time-limited to adolescence, with the rate of volume reduction in frontal and temporal structures associated with premorbid developmental impairment and baseline symptom severity (Sporn, Giedd, Blumenthal et al., 2003) and declining as subjects reach adult life (Giedd, Jeffries, Blumenthal et al., 1999). The pattern of progressive cortical volume reduction described in the NIMH childhood-onset schizophrenia sample appears to be an exaggeration of the normal “back to front” pattern of cortical volume reduction seen during adolescence (Gogtay, Sporn, Clasen et al., 2004). At present, it is unclear whether the dramatic findings from the NIMH childhood-onset schizophrenia sample, which is atypical in terms of very early onset (<13 years) and neuroleptic treatment resistance, can be generalized to other samples of children and adolescents with schizophrenia (cf. James, Javaloyes, James, & Smith, 2002).

Because progressive brain changes have been described after the onset of psychosis, it is possible that they are a consequence of neurotoxic effects of psychosis. Evidence that progressive brain changes precede the onset of psychosis is very limited. Pantelis, Velakoulis, McGorry et al. (2003) have reported brain MRI findings in high-risk subjects scanned before and after the transition into psychosis. The baseline cross-sectional comparison found that those about to develop psychosis had reduced cortical gray matter in the right temporal, inferior frontal cortex and cingulate bilaterally. When rescanned, those subjects who developed psychosis had further volume reductions in gray matter in the left parahippocampal, fusiform, orbitofrontal, and cerebellar cortices and cingulate gyri. The only significant longitudinal changes in cases who remained non-psychotic were in the cerebellum. These are important findings, and if replicated would provide strong support for the idea that excessive developmental reductions in gray matter both predate and accompany the onset of psychotic symptoms.

Functional Brain Imaging

The emergence of functional brain imaging technology has provided a unique opportunity to link symptoms and cognitive deficits in schizophrenia to underlying brain activity. In studies of adults with schizophrenia, there are associations between:

1. Negative symptoms, cognitive executive function deficits and abnormal frontal activity;
2. Disorganization symptoms (thought disorder and inappropriate affect) and anterior cingulate activity; and

Reduced activity of the anterior cingulate cortex in schizophrenia is associated with impaired ability to monitor response errors and response to conflict (Kerns, Cohen, MacDonald et al., 2005), which may underlie psychotic symptoms (Frith, 1994). Reduced activity in the right dorsolateral prefrontal cortex has also been associated with working memory impairments and disorganization symptoms (Perlstein, Carter, Noll, & Cohen, 2001).

The notion of “hypofrontality” has been proposed to account for schizophrenia, but is certainly an oversimplification. Evidence suggests that frontal activation is diminished only when processing load is high and task performance diminishes (Perlstein, Carter, Noll et al., 2001). In contrast, baseline resting frontal activation may be increased in acute schizophrenia relative to healthy subjects as a result of abnormal self-generated mental activity associated with psychotic symptoms. When an external task places an increased processing load on an individual with psychosis, the prefrontal cortex may be unable to meet the demand, resulting in reduced performance and activation (Liddle & Pantellis, 2003).

In a positron emission tomography (PET) study in childhood-onset schizophrenia using the Continuous Performance Test (CPT), Jacobsen, Hamburger, Van Horn et al. (1997b) reported...
reduced activation compared to healthy controls in the mid and superior frontal gyrus, and increased activation in the inferior frontal, supramarginal gyrus and insula. Clearly, a simple description of “hypofrontality” does not capture the complex pattern of changes involving interconnected frontal areas. Older, localizationist, models based on focal cerebral dysfunction in schizophrenia have tended to give way to models of cerebral disconnectivity (Bullmore, O’Connell, Frangou et al., 1997) that fit well with both neuropathological and functional neuroimaging findings. This may be one reason for inconsistent neuroanatomical findings in schizophrenia, as “lesions” in different areas of a widely distributed neural system could produce similar functional disturbance.

Magnetic Resonance Spectroscopy: Abnormal Neuronal Metabolism

Magnetic resonance spectroscopy (MRS) is an imaging technique that can be used to extract in vivo information on dynamic biochemical processes at a neuronal level. Proton (1H) MRS focuses on changes in the neuronal marker N-acetylaspartate (NAA). Studies in adult schizophrenic patients have shown reductions in NAA in the hippocampal area and dorsolateral prefrontal cortex (DLPFC). Similar reductions in NAA ratios specific to the hippocampus and DLPFC (Bertolino, Kumra, Callicott et al., 1988) and frontal gray matter (Thomas, Ke, Levitt et al., 1998) have been reported in childhood-onset schizophrenia, suggesting neuronal damage or malfunction in these regions.

Pettegrew, Keshavan, Panchalingam et al. (1991) used 31P MRS with non-medicated patients during a first episode of schizophrenia and found reduced phosphomonoester (PME) resonance and increased phosphodiester (PDE) resonance in the prefrontal cortex. This result is compatible with reduced synthesis and increased breakdown of connective processes in the prefrontal cortex. A similar finding of reduced PME and increased PDE resonance has been reported in adults with autism, although they showed increased prefrontal metabolic activity, which was not seen in people with schizophrenia (Pettegrew, Keshavan, Panchalingam et al., 1991). Keshavan, Stanley, Montrose et al. (2003) reported reduced PME moieties (e.g., synaptic vesicles and phosphorylated proteins) in the prefrontal cortex using 31P MRS in a sample of children and adolescents at genetic high risk for schizophrenia. These findings suggest that abnormal synaptic structure and function in the prefrontal cortex is a marker of schizophrenia risk. Further follow-up is required to determine if these findings have predictive value.

Implications for Neurodevelopmental Models of Schizophrenia

Taken together, the neuropathological and brain imaging findings provide considerable support for the idea of progressive neurodevelopmental changes in schizophrenia including excessive synaptic elimination resulting in aberrant neural connectivity. The progressive nature of brain volume reductions in adolescence, and the fact that reduced brain volume is not accompanied by reduced intracranial volume, suggests that a static pre- or perinatal brain insult is insufficient to account for this process. While early random events in fetal neurodevelopment (e.g., hypoxia, viruses) may affect baseline synaptic density, genetically determined excessive synaptic elimination as proposed by the “late” neurodevelopmental model may be the neurobiological process underlying disorders in the schizophrenia spectrum (McGlashan & Hoffman, 2000). What is unclear is whether excessive synaptic elimination in the prefrontal cortex (and possibly other brain regions) is a sufficient cause for psychosis to occur, or whether it provides a vulnerable neurocognitive substrate that must interact with environmental stressors (e.g., cannabis exposure or cognitive or social stressors) to produce psychotic symptoms.

Genetics of Schizophrenia

Multigene Models of Risk

Twin studies have suggested the heritability of schizophrenia to be as high as 83% (Cannon, Kaprio, Lonnqvist, Huttunen, & Koskenvuo, 1998). However, one of the most significant implications of twin, adoption and family studies in schizophrenia has been the challenge the results pose to traditional qualitatively distinct categories of disorder (Rutter & Plomin, 1997). Quantitative genetic studies have shown that the genetic liability to schizophrenia extends to schizotypal personality disorders and other conditions viewed as lying on the broader schizophrenia spectrum (Erlenmeyer-Kimling, Squires-Wheeler, Adamo et al., 1995; Kendler, Neale, & Walsh, 1995). These results suggest that what is inherited in schizophrenia is likely to be quantitative traits that determine liability to disorder.

While the mode of inheritance in schizophrenia remains unknown, most evidence supports a multilocus or multifactorial threshold model. This model proposes that schizophrenia results from the combined action of multiple genes of small effect that confer susceptibility to the schizophrenic phenotype, with the disorder being expressed above a particular liability threshold. Susceptibility to the disorder is expressed as a dimension in the population (i.e., the risk of schizophrenia in the population is distributed normally, not bimodally). Because there are likely to be multiple genes involved, the genetics of schizophrenia is moving away from the rather simplistic notion of finding a single major gene for the disorder, towards a search for genes that confer susceptibility traits. Susceptibility alleles may be quite common in the population and hence the predictive value of any individual allele alone will be low.

It is commonly assumed that genes affecting brain development in schizophrenia are only expressed during fetal neurodevelopment. However, it is quite possible that while some susceptibility genes for schizophrenia may affect fetal brain development, other genes do not exert their effect until adolescence, possibly causing excessive or aberrant synaptic pruning with reduction in temporal and frontal lobe volume (Feinberg, 1997).
Linkage Studies

Two meta-analyses of schizophrenia linkage studies have supported a multilocus model with several chromosomal regions implicated. Lewis, Levinson, Wise et al. (2003) found the strongest evidence for linkage on 2q, with weaker support obtained for regions on chromosomes 5q, 3p, 11q, 6p, 1q, 22q, 8p, 20q and 14p. Meanwhile, Badner and Gerstein (2002) found evidence supporting susceptibility genes on chromosomes 8p, 13q and 22q. Hence, both studies converged on two regions: 8p and 22q, with nine other regions being supported by only one metaanalysis. While failure to replicate genetic findings has plagued schizophrenia research, this is to be expected if schizophrenia is an etiologically (and genetically) heterogeneous disorder.

Positional Candidate Genes and Neurobiology

Convergent findings from linkage studies have led to mapping of implicated regions and identification of putative susceptibility genes. A number of replicated associations have recently been reported between DNA polymorphisms of various positional candidate genes and schizophrenia. The positional candidate genes most clearly implicated are associated with either dysbindin on 8p21–p22.3 and neuroregulin (NRG1) (8p21–p22). There is also promising but less compelling evidence for catecholamine-O-methyltransferase (COMT), D-amino-acid oxidase (DAO), its activator DAOA (previously known as G72) and regulator G protein signaling 4 (RGS4). The high-risk COMT Val allele associated with schizophrenia is hypothesized to have its effect by reducing dopaminergic transmission in the prefrontal cortex. Dysbindin may affect the uptake of glutamate into synaptic vesicles, NRG1 is released from glutamate terminals and regulates N-methyl-D-aspartate (NMDA) glutamate receptors and DAO, activated by DAOA, is an indirect modulator of NMDA receptors. The actions of many of these genes converge on a shared pathophysiological process that suggests that abnormalities of synaptic signaling, in particular at the glutamatergic synapse, may be a primary abnormality in schizophrenia (Harrison & Owen, 2003). The strongest evidence favors dysbindin (DTNBP1) (6p22.3) and neuroregulin (NRG1) (8p21–p22). There is also promising but less compelling evidence for catecholamine-O-methyltransferase (COMT), D-amino-acid oxidase (DAO), its activator DAOA (previously known as G72) and regulator G protein signaling 4 (RGS4). The high-risk COMT Val allele associated with schizophrenia is hypothesized to have its effect by reducing dopaminergic transmission in the prefrontal cortex. Dysbindin may affect the uptake of glutamate into synaptic vesicles, NRG1 is released from glutamate terminals and regulates N-methyl-D-aspartate (NMDA) glutamate receptors and DAO, activated by DAOA, is an indirect modulator of NMDA receptors. The actions of many of these genes converge on a shared pathophysiological process that suggests that abnormalities of synaptic signaling, in particular at the glutamatergic synapse, may be a primary abnormality in schizophrenia (Harrison & Owen, 2003; Mirnics, Middleton, Lewis, & Levitt, 2001). At a simple conceptual level, these genes are all thought to influence information processing (via synaptic signaling) in cortical circuits. The clinical correlates of these candidate genes are more likely to be neurodevelopmental and cognitive impairments than fluctuating positive symptoms of schizophrenia.

Candidate Genes in Childhood-Onset Schizophrenia

The DAOA polymorphism (13q33.2) was associated with childhood-onset schizophrenia (COS) in the NIMH sample (Addington, Gornick, Sporn et al., 2004). Interestingly, in the same NIMH sample DAOA was associated with later age of onset and lower scores for premorbid autism symptoms. Another intriguing finding in the NIMH COS sample is an association between dysbindin (DTNBP1) (6p22.3) and poor premorbid social and academic adjustment (Rapoport, Addington, & Frangou, 2005). Finally, a polymorphism of the GAD1 (glutamic acid decarboxylase) gene has been associated with both childhood-onset schizophrenia and abnormal frontal gray matter loss (Addington, Gornick, Duckworth et al., 2005).

Cytogenetic Abnormalities

The association between schizophrenia and chromosomal deletions offers another possible route to locating candidate genes (Hennah, Thompson, Peltonen, & Porteous, 2006). The velocardiofacial syndrome (VCFS) microdeletion on chromosome 22q11 (which includes the COMT gene plus two candidates, PRODH and ZDHHC8) is associated with adult schizophrenia, occurring at a rate of 2% compared to 0.02% in the normal population (see chapter 24; Karayiorgou, Morris, Morrow et al., 1995). The association with schizophrenia is not specific, as the VCFS microdeletion is also linked with higher rates of other psychiatric disorders (e.g., affective disorder, ADHD). In the NIMH COS study, a high rate of previously undetected cytogenetic abnormalities was found, including 4 of 80 (5%) with VCFS (Sporn, Addington, Reiss et al., 2004b). The 22q11DS is associated with progressive cortical gray matter loss in children and adolescents who are not yet psychotic, suggesting that a gene or genes mapping to 22q11 is responsible for a high-risk phenotype (Sporn, Addington, Reiss et al., 2004b).

Another major finding based on a chromosomal abnormality comes from an extended Scottish pedigree where a balanced translocation (1:11)(q42;q14.3) showed linkage with a phenotype including schizophrenia, bipolar disorder and depression (Hennah, Thompson, Peltonen et al., 2006). The translocation disrupts two genes on chromosome 1: DISC1 and DISC2. There is some evidence that DISC1 is linked to the regulation of neural migration, which may have a role in the pathogenesis of schizophrenia. Two studies found mutations or polymorphisms of DISC1 associated with schizophrenia, while two other studies have failed to find an association (Owen, Craddock, & O’Donovan, 2005).

Overlap with Bipolar Disorder

Several genes influence susceptibility to both schizophrenia and bipolar disorder, including NRG1, DISC1 and G72 (DAOA; Owen, Craddock, & O’Donovan, 2005). These findings suggest that the two disorders share pathogenic mechanisms and challenge the long-held Kraepelinian dichotomy that views schizophrenia and bipolar disorder as separate diagnostic entities. Prototypic schizophrenia and bipolar disorder can be seen as lying at the extreme ends of a spectrum of psychosis with mixed or intermediate phenotypes lying in between. Within this spectrum of psychosis, dysbindin (DTNBP1) predisposes predominantly to schizophrenia with negative symptoms, DAOA and BDNF predispose predominantly to mood disorder, and NRG1 and DISC1 predispose to both prototypic forms of disorder (Craddock, O’Donovan, & Owen, 2005).
Neuropsychology of Schizophrenia

Pattern of Cognitive Deficits

There is growing awareness that cognitive deficits in schizophrenia are a core feature of the disorder and cannot simply be dismissed as secondary consequences of psychotic symptoms (Breier, 1999). The degree of cognitive impairment is greater in child- and adolescent-onset than in adult-onset patients. These findings raise several important questions.

1. Are the cognitive deficits specific or general (i.e., are some aspects of cognitive functioning affected more than others)?
2. Which deficits precede the onset of psychosis and could be causal, and which are consequences of psychosis?
3. Is the pattern of deficits specific to schizophrenia or shared with other developmental and psychotic disorders?
4. Are cognitive impairments progressive or static after the onset of psychosis?

Children with schizophrenia have specific difficulties with cognitive tasks that make demands on short-term working memory and selective and sustained attention and speed of processing (Asarnow, Brown, & Stranberg, 1995). These deficits are similar to the deficits reported in adult schizophrenia (Saykin, Shtasel, Gur et al., 1994). Deficits of attention, short-term and recent long-term memory have also been reported in adolescents with schizophrenia (Friedman, Findling, Buch et al., 1996). In contrast, well-established “over learned” rote language and simple perceptual skills are unimpaired in child- and adolescent-onset schizophrenia. Asarnow, Granholm, & Sherman (1991), Asarnow, Brown, & Stranberg (1995) have shown that children with schizophrenia have impairments on the span of apprehension task (a target stimulus has to be identified from an array of other figures when displayed for 50 ms). Performance on the task deteriorates markedly when increasing demands are made on information processing capacity (e.g., increasing the number of letters in the display from 3 to 10). Furthermore, event-related potential (ERP) studies using the span of apprehension task in both children and adults with schizophrenia, when compared with age-matched controls, show less negative endogenous activity measured 100–300 ms after the stimulus. Similar findings of reduced ERPs (processing negativity Np, and P2 components) have been found during the CPT in both childhood- and adult-onset schizophrenia (Strandburg, Marsh, & Brown, 1999). These findings indicate a deficit in the allocation of attentional resources to a stimulus (Asarnow, Brown, & Stranberg, 1995). As with adults, children and adolescents with schizophrenia show high basal autonomic activity and less autonomic responsivity than controls (Gordon, Frazier, McKenna et al., 1994), with attenuated increases in skin conductance following the presentation of neutral sounds (Zahn, Jacobsen, Gordon et al., 1997). Childhood-onset patients, like adults, show increased reaction times with a loss of isomodal advantage compared to healthy controls (Zahn, Jacobsen, Gordon et al., 1998).

Eye tracking dysfunction (ETD) – a proxy of frontal lobe dysfunction – as indexed by abnormal-indices in smooth pursuit eye movements (SPEM) has also been found in childhood-onset schizophrenia (Kumra, Sporn, Hommer et al., 2001). Similar ETD has been reported in adult schizophrenia (Iacono & Koenig, 1983). ETD is also a potential genetic endophenotype trait marker for schizophrenia that has been detected in healthy siblings of COS and parents of adult-onset schizophrenia patients (Sporn, Greenstein, Gogtay et al., 2005). Non-psychotic relatives of schizophrenic patients also show eye-tracking deficits that correlate with subtle frontal lobe dysfunction (O’Driscoll, Benkelfat, Florencio et al., 1999).

Finally, children with schizophrenia also show similar impairments to adult patients on tests of frontal lobe executive function such as the Wisconsin Card Sorting Test (WCST; Asarnow, Thompson, Hamilton et al., 1994). Hence, reduced prefrontal activation may be one expression of a genetic susceptibility to schizophrenia.

In summary, while basic sensorimotor skills, associative memory and simple language abilities tend to be preserved in children with schizophrenia, deficits are most marked on tasks that require focused and sustained attention, flexible switching of cognitive set, high information processing speed and suppression of prepotent responses (Asarnow, Brown, & Stranberg, 1995). The diverse cognitive processes described here have been integrated under the cognitive domain of “executive functions”, which are presumed to be mediated by the prefrontal cortical system. Executive function skills are necessary to generate and execute goal-directed behavior, especially in novel situations. Goal-oriented actions require that information in the form of plans and expectations are held “online” in working memory, and flexibly changed in response to feedback. Similar deficits have also been found in children genetically at “high risk” for schizophrenia (Erlemeier-Kimling & Comblatt, 1978) and non-psychotic relatives of schizophrenic probands (Park, Holzman, & Goldman-Rakic, 1995). This strengthens the argument that cognitive deficits cannot be simply dismissed as non-specific consequences of schizophrenic symptoms, but rather are likely to be indicators of underlying genetic and neurobiological risk. Several candidate susceptibility genes (dysbindin-1 and COMT) have been linked to impaired working memory and may provide molecular mechanisms underlying this intermediate (endophenotype of schizophrenia (Egan, Goldberg, Kolachana et al., 2001). However, executive functions deficits are probably not a primary or sufficient cause of schizophrenia given that they also occur in other neurodevelopmental disorders including autism and ADHD (Pennington, 1997).

Course of Cognitive Deficits

Kraepelin’s term “dementia praecox” implied a progressive cognitive decline as part of the disease process. Jones, Rogers, Murray et al. (1994) described how academic performance becomes progressively more deviant during adolescence in those individuals destined to developed schizophrenia in adult life. A similar finding of IQ decline from childhood through adolescence which precedes the onset of schizophrenia in adult life has been reported from a large Israeli population-based cohort (Reichenberg, Weiser, Rapp et al., 2005). There is some
tentative evidence for a small decline in IQ following the onset of psychosis in childhood-onset schizophrenia (Alaghband-Rad, McKenna, Gordon et al., 1995), followed by a stabilization of cognitive function despite progressive cortical gray matter loss during adolescence (Gochman, Greenstein, Sporn et al., 2005). However, without longitudinal control data this is difficult to evaluate, given that, in typically developing samples, most IQ tests will show improved scores with repeated administration. Furthermore, the small drop in IQ after the onset of psychosis could possibly be caused by the effect of psychotic symptoms on performance. In so far as there is an effect, it looks like premature arrest, or slowing, of normal cognitive development in child- and adolescent-onset schizophrenia, rather than a progressive dementia.

**Assessment**

The assessment of a child or adolescent with possible schizophrenia should include a detailed history, mental state and physical examination. In addition, a baseline psychometric assessment is desirable. A detailed understanding of specific cognitive deficits in individual cases of adolescent schizophrenia can be particularly helpful in guiding education and rehabilitation. In the physical examination, particular attention should be given to detecting dysmorphic features that may betray an underlying genetic syndrome. The neurological examination should focus on abnormal involuntary movements and other signs of extrapyramidal dysfunction. Spontaneous abnormal involuntary movements have been detected in a proportion of drug-naïve first-episode schizophrenic or schizoaffective patients as well as in those receiving typical antipsychotics (Gervin, Browne, Lane et al., 1998).

**Developmental Issues**

The cognitive level of the child will influence their ability to understand and express complex psychotic symptoms such as passivity phenomena, thought alienation and hallucinations. In younger children, careful distinctions have to be made between developmental immaturity and psychopathology. For example, distinguishing true hallucinations from normal subjective phenomena such as dreams and communication with imaginary friends may be difficult for young children. Developmental maturation can also affect the localization of hallucinations in space. Internal localization of hallucinations is more common in younger children and makes these experiences more difficult to differentiate subjectively from inner speech or thoughts (Garralda, 1984). Formal thought disorder may also appear very similar to the pattern of illogical thinking and loose associations seen in children with immature language development. Negative symptoms can appear very similar to non-psychotic language and social impairments and can also be easily confused with anhedonia and depression.

**Differential Diagnosis**

Psychotic symptoms in children and adolescents are diagnostically non-specific, occurring in a wide range of functional psychiatric and organic brain disorders. A summary of physical investigations in children and adolescents with suspected schizophrenia is listed in Table 45.1. Referral for a neurological opinion is recommended if neurodegenerative disorder is suspected (see chapter 30).

**Affective, Schizoaffective and “Atypical” Psychoses**

The high rate of positive psychotic symptoms found in adolescent-onset major depression and mania can lead to diagnostic confusion (Joyce, 1984). Affective psychoses are most likely to be misdiagnosed as schizophrenia if a Schneiderian concept of schizophrenia is applied with its emphasis on first-rank symptoms. Because significant affective symptoms also occur in about one-third of first-episode patients with schizophrenia, it may be impossible to make a definitive diagnosis on the basis of a single cross-sectional assessment. In DSM-IV the distinction between schizophrenia, schizoaffective disorder

and affective psychoses is determined by the relative predominance of psychotic symptoms (hallucinations and delusions) and affective symptoms (elevated or depressed mood). Given the difficulty in applying these rules with any precision, there is a need to identify other features to distinguish between schizophrenia and affective psychoses.

Irrespective of the presence of affective symptoms, the most discriminating symptoms of schizophrenia are an insidious onset and the presence of negative symptoms (Hollis, 1999). Similarly, complete remission from a first psychotic episode within 6 months of onset is the best predictor of a diagnosis of affective psychosis (Hollis, 1999). Schizoaffective and atypical psychoses are diagnostic categories with low predictive validity and little longitudinal stability (Hollis, 2000).

**Autistic Spectrum and Developmental Language Disorders**

Some children on the autistic spectrum or with Asperger syndrome have social and cognitive impairments that overlap closely with the premorbid phenotype described in schizophrenia. Furthermore, children on the autistic spectrum can also develop psychotic symptoms in adolescence (Volkmar & Cohen, 1991). Towbin, Dykens, Pearson, and Cohen (1993) have labeled another group of children who seem to belong within the autistic spectrum as having “multiplex developmental disorder.” An increased risk for psychosis has also been noted in the adult follow-up of childhood developmental receptive language disorders (Clegg, Hollis, & Rutter, 2005). In the NIMH COS sample, 19 cases (25%) had a lifetime diagnosis of autism spectrum disorder (ASD), one had autism, two had Asperger syndrome and 16 had pervasive developmental disorder not otherwise specified (PDD-NOS; Sporn, Addington, Gogtay et al., 2004a). The COS-ASD subgroup did not differ from the rest of the COS sample on a range of measures including age of onset, IQ, response to medications and familial schizotypy. However, the rate of cortical gray matter loss was greater in the ASD group. While the authors concluded that ASD was more likely to be a severe form of premorbid social impairment rather than true comorbidity, an unexplained finding was the occurrence of two cases of autism in the siblings of the COS-ASD subgroup. While some children on the autistic spectrum can show a clear progression into classic schizophrenia, others show a more episodic pattern of psychotic symptoms without the progressive decline in social functioning and negative symptoms characteristic of childhood-onset schizophrenia.

Often it is only possible to distinguish between schizophrenia and disorders on the autistic spectrum by taking a careful developmental history that details the age of onset and pattern of autistic impairments in communication, social reciprocity and interests/behaviors. According to DSM-IV, schizophrenia cannot be diagnosed in a child with autism/PDD unless hallucinations/delusions are present for at least 1 month. DSM-IV does not rank the active phase symptoms of thought disorder, disorganization or negative symptoms as sufficient to make a diagnosis of schizophrenia in the presence of autism. In contrast, ICD-10 does not include autism/PDD as exclusion criteria for diagnosing schizophrenia.

**“Multidimensionally Impaired Syndrome” and Schizotypal Personality Disorder**

Multidimensionally impaired syndrome (MDI) is a label applied to children who have brief transient psychotic symptoms, emotional lability, poor interpersonal skills, normal social skills and multiple deficits in information processing (Kumra, Jacobsen, Lenane et al., 1998c). The diagnostic status of this group remains to be fully resolved. Short-term follow-up suggests that they do not develop full-blown schizophrenic psychosis. However, they have an increased risk of schizophrenia spectrum disorders among first-degree relatives and the neurobiological findings (e.g., brain morphology) are similar to those in childhood onset schizophrenia (Kumra, Jacobsen, Lenane et al., 1998c). At 11 year follow-up, 38% (12 of 32) of patients met criteria for bipolar 1 disorder, 12% (4 of 32) for major depressive disorder (MDD), and 3% (1 of 32) for schizoaffective disorder. The remaining 47% of patients (15 of 32) were divided into two groups on the basis of whether they were in remission and neuroleptic-free (“good outcome,” n = 5) or still severely impaired and/or psychotic regardless of pharmacotherapy (“poor outcome,” n = 10; Stayer, Sporn, Gogtay et al., 2005).

Children with schizotypal personality disorder (SPD) lie on a phenotypic continuum with schizophrenia and have similar cognitive and social impairments and are prone to magical thinking, mood disturbances and non-psychotic perceptual disturbances. Distinction from the prodromal phase of schizophrenia is particularly difficult when there is a history of social and academic decline without clear-cut, or persisting, psychotic symptoms. A follow-up of children with SPD found that 25% developed schizophrenia spectrum disorders (schizophrenia and schizoaffective disorder), suggesting that SPD may be a precursor of schizophrenia (Asarnow, 2005). It has been reported that negative symptoms and attention in SPD improve with a low dose of risperidone (0.25–2.0 mg; Rossi, Mancini, Stratta et al., 1997).

**Epilepsy**

Psychotic symptoms can occur in temporal and frontal lobe partial seizures (for a description of these seizures see chapter 30). A careful history is usually sufficient to reveal an aura followed by clouding of consciousness and the sudden onset of brief ictal psychotic phenomena accompanied often by anxiety, fear, derealization or depersonalization. However, longer-lasting psychoses associated with epilepsy can occur in clear consciousness during postictal or interictal periods (Sachdev, 1998). In epileptic psychoses, hallucinations, disorganized behavior and persecutory delusions predominate, while negative symptoms are rare. Children with complex partial seizures also have increased illogical thinking and use fewer linguistic-cohesive devices which can resemble formal thought disorder (Caplan, Guthrie, Shields, & Mori, 1992). A PET study showed hypoperfusion in the frontal, temporal
and basal ganglia in psychotic patients with epilepsy compared with non-psychotic epileptic patients (Gallhofer, Trimble, Frackowiak, Gibbs, & Jones, 1985).

Epilepsy and schizophrenia may co-occur in the same individual, so that the diagnoses are not mutually exclusive. The onset of epilepsy almost always precedes psychosis unless seizures are secondary to antipsychotic medication. In a long-term follow-up of 100 children with temporal lobe epilepsy, 10% developed schizophrenia in adult life (Lindsay, Ounstead, & Richards, 1979).

An electroencephalogram (EEG) should be performed if a seizure disorder is considered in the differential diagnosis or arises as a side effect of antipsychotic treatment. Ambulatory EEG monitoring and telemetry with event recording may be required if the diagnosis remains in doubt.

**Neurodegenerative Disorders**

Rare neurodegenerative disorders with onset in late childhood and adolescence (see chapter 30) can mimic schizophrenia. The most important examples are Wilson’s disease (hepato- lenticular degeneration), and metachromatic leukodystrophy. These disorders usually involve significant extrapyramidal symptoms (e.g., tremor, dystonia and bradykinesia) or other motor abnormalities (e.g., unsteady gait) and a progressive loss of skills (dementia), which can aid the distinction from schizophrenia. Suspicion of a neurodegenerative disorder is one of the clearest indications for brain MRI in adolescent psychoses. Adolescents with schizophrenia show relative gray matter reduction with white matter sparing. In contrast, metachromatic leukodystrophy is characterized by frontal and occipital white matter destruction and demyelination. In Wilson’s disease, hypodense areas are seen in the basal ganglia, together with cortical atrophy and ventricular dilatation. The pathognomonic Kayser–Fleisher ring in Wilson’s disease begins as a greenish-brown crescent-shaped deposit in the cornea above the pupil (this is most easily seen during slit lamp examination). In Wilson’s disease there is increased urinary copper excretion, and reduced serum copper and serum ceruloplasmin levels. The biochemical marker for metachromatic leukodystrophy is reduced arylsulfatase-A (ASA) activity in white blood cells. This enzyme deficiency results in a deposition of excess sulfatides in many tissues including the CNS.

**Drug Psychoses**

Illicit drug use is increasingly common among young people (see chapter 36), so the frequent co-occurrence of drug use and psychosis is to be expected. Psychotic symptoms can occur as a direct pharmacological effect of intoxication with stimulants (amphetamine, ecstasy and cocaine), hallucinogens (lysergic acid diethylamide “LSD,” phencyclidine, psilocybin “magic mushrooms” and mescaline), cannabis (Poole & Brabbins, 1996) and ketamine, an NMDA receptor antagonist and anesthetic (Krystal, Perry, Gueorguieva et al., 2006). The psychotic symptoms associated with drug intoxication are usually short-lived and resolve within a few days of abstinence from the drug. These drugs can have surprisingly long half-lives, with cannabinoids still measurable up to 6 weeks after a single dose. Psychotic symptoms in the form of “flashbacks” can also occur after cessation from chronic cannabis and LSD abuse. These phenomena are similar to alcoholic hallucinosis and typically involve transient vivid auditory hallucinations occurring in clear consciousness.

It is often assumed that there is a simple causal relationship between drug use and psychosis, with any evidence of drug use excluding the diagnosis of a functional psychosis. However, this is a naive approach, as drug use can be either a consequence of psychosis with patients using drugs to “treat” their symptoms in the early stages of a psychotic relapse or, with cannabis, a cause of schizophrenia in susceptible individuals (Arseneault, Cannon, Witton et al., 2004). Overall, there is very little evidence to invoke a separate entity of “drug-induced” psychosis in cases where psychotic symptoms arise during intoxication but then persist after the drug is withdrawn (Poole & Brabbins, 1996). Patients whose so-called “drug-induced” psychoses last for more than 6 months appear to have more clear-cut schizophrenic symptoms, a greater familial risk for psychosis and greater premorbid dysfunction (Tsuang, Simpson, & Kronfold, 1982). DSM-IV takes the sensible position that a functional psychosis should not be excluded unless there is compelling evidence that symptoms are uniquely associated with drug use.

**Other Investigations**

Whether any physical investigations should be viewed as routine is debatable (see chapter 22). However, it is usual to obtain a full blood count and biochemistry including liver and thyroid function and a drug screen (urine or hair analysis). The high yield of cytogenetic abnormalities reported in childhood-onset schizophrenia (Nicolson, Giedd, Lenane et al., 1999) suggests the value of cytogenetic testing including karyotyping for sex chromosome aneuploidies and fluorescent in situ hybridization (FISH) for 22q11DS (velocardiofacial syndrome). The evidence of progressive structural brain changes (Rapoport, Giedd, Blumenthal et al., 1999) indicates the value of obtaining a baseline and annual follow-up brain MRI scans, although this is not a diagnostic test.

**Assessment Interviews and Rating Scales**

Structured diagnostic investigator-based interviews that cover child and adolescent psychotic disorders include the Schedule for Affective Disorders and Schizophrenia for School-Age Children (K-SADS; Ambrosini, 2000), the Child and Adolescent Psychiatric Assessment (CAPA; Angold & Costello, 2000) and the Diagnostic Interview for Children and Adolescents (DICA; Reich, 2000). The DSM and ICD definitions of schizophrenia do not provide symptom definitions so the detailed glossaries that accompany these interviews are particularly useful.

Rating scales give quantitative measures of psychopathology and functional impairment. Scales to assess psychotic symptoms include the Scale for Assessment of Positive Symptoms (SAPS;
CHAPTER 45

Andreasen, 1984), the Scale for Assessment of Negative Symptoms (SANS; Andreasen, 1983) and the Positive and Negative Syndrome Scale (PANSS; Kay, Opler, & Lindenmayer, 1987). The 30-item Kiddie-PANSS has been developed for use in children and adolescents, and contains three subscales: positive syndrome, negative syndrome and general psychopathology (Fields, Grochowski, Lindenmayer et al., 1994). The Children’s Global Assessment Scale (C-GAS) provides a rating of functional impairment on a 0–100 scale (Shaffer, Gould, Brasic et al., 1983). These scales can be used to record the longitudinal course of illness and treatment response. The Kiddie Formal Thought Disorder Story Game and Kiddie Formal Thought Disorder Scale (Caplan, Guthrie, Tanguay, Fish, & David-Lando, 1989) are research instruments produced for the assessment of thought disorder in children. Assessments of extrapyramidal symptoms and involuntary movements can be made using the Abnormal Involuntary Movements Scale (AIMS; Rapoport, Conners, & Reatig, 1985) and the Simpson–Angus Neurological Rating Scale (Simpson & Angus, 1970).

Treatment Approaches

General Principles

While antipsychotic drugs remain the cornerstone of treatment in child and adolescent schizophrenia, all young patients with schizophrenia require a multimodal treatment package that includes pharmacotherapy, family and individual counseling, education about the illness, and provision to meet social and educational needs (AACAP, 2001; Clark & Lewis, 1998).

Prevention and Early Detection

In theory at least, the onset of schizophrenia could be prevented if an intervention reduced the premorbid “risk” status or exposure to causative risk factors. The difficulty with the premorbid phenotype as currently conceived (i.e., subtle social and developmental impairments) is its extremely low specificity and positive predictive value for schizophrenia in the general population. The premorbid psychopathology in childhood-onset schizophrenia is equally non-specific with a range of diagnoses (e.g., conduct disorder, ADHD, anxiety states, depression and ASD preceding schizophrenia; Schaeffer & Ross, 2002). Future refinement of the premorbid phenotype is likely to move from the traditional phenomenological approach to include genetic and neurocognitive markers in order to achieve greater sensitivity and specificity.

An alternative approach is to target putative environmental risk factors such as cannabis exposure. If a direct causal relationship between cannabis and schizophrenia is assumed, then the population attributable fraction for the Dunedin cohort is 8% (Arseneault, Cannon, Witton et al., 2004). Put another way, removal of cannabis use from 15-year-olds in the Dunedin cohort would have resulted in an 8% reduction in the incidence of schizophrenia. Given the rising prevalence of cannabis use in younger adolescents – a group who may be particularly sensitive to its effects – an important public policy intervention would be to delay the onset of cannabis use in young people.

In contrast to primary prevention, the aim of early detection is to identify the onset of deterioration in vulnerable individuals with a high predictive validity. Follow-up of the Australian Early Psychosis Prevention and Intervention Centre (EPPIC) “ultra high risk” sample over 12 months found 40.8% developed a psychotic disorder. Significant predictors of transition to psychosis included long duration of prodromal symptoms, poor functioning at intake, low-grade psychotic symptoms, depression and disorganization (Yung, Phillips, Yuen et al., 2003). A key question is whether early intervention in an “ultra high risk” or prodromal group can prevent the transition to psychosis. The EPPIC group conducted a randomized controlled trial of combined low-dose risperidone (mean 1.3 mg.day−1) and cognitive–behavioral therapy (CBT) compared to standard needs-based intervention in the “ultra high risk” group (McGorry, Yung, Phillips et al., 2002). The risperidone/CBT intervention significantly reduced transition to psychosis at 6 months (3 of 31 vs. 10 of 28 developed psychosis) but there was no significant difference by 12 months. These findings suggest that aggressive early intervention in a population presenting with high-risk mental states and attenuated psychotic symptoms may delay the onset of frank psychosis (prevalence reduction) but may not necessarily reduce the incidence of psychosis. A pragmatic stance would be to monitor children and adolescents with a strong family history and/or suggestive prodromal symptoms to ensure prompt treatment of psychosis.

A key argument used to support early intervention in psychosis has been the finding that a long duration of untreated psychosis is associated with poor long-term outcome in schizophrenia (Loebel, Lieberman, Alvir et al., 1992; Wyatt, 1995). A similar association has been found in child- and adolescent-onset psychoses (Hollis, 1999). While the association between duration of untreated psychosis and poor outcome seems secure, the causal connection is far less certain. A long duration of untreated psychosis is also associated with insidious onset and negative symptoms, which could confound links with poor outcome. While there are good a priori clinical reasons for the early treatment of symptoms to relieve distress and prevent secondary impairments, as yet it remains unproven whether early intervention actually alters the long-term course of schizophrenia.

Pharmacological Treatments

Because of the very small number of trials of antipsychotics conducted with child and adolescent patients, it is necessary to extrapolate most evidence on drug efficacy from studies in adults. This seems a reasonable approach given that schizophrenia is essentially the same disorder whether it has onset in childhood or adult life. However, it should be noted that children and adolescents show a greater sensitivity to a range of antipsychotic-related adverse events including extrapyramidal side effects (EPS) and treatment resistance with traditional antipsychotics (Kumra, Jacobsen, Lenane et al., 1998b) and
weight gain, obesity and metabolic syndrome with the newer atypical antipsychotics (Ratzoni, Gothelf, Brand-Gothelf et al., 2002).

Antipsychotics can be broadly divided into the traditional “typical” and newer “atypical” drugs. The typical drugs include haloperidol, chlorpromazine and trifluoperazine, which block D2 receptors, produce catalepsy in rats, raise plasma prolactin and induce EPS. The newer atypical drugs are effective antipsychotics that are “atypical” in the sense that they do not produce catalepsy, do not raise prolactin levels and produce significantly fewer EPS. Not all atypicals neatly fit this definition; for example, risperidone raises prolactin levels and may cause EPS at higher doses (>4 mg·day⁻¹) with “atypicality” resulting from antagonism of 5HT receptors rather than reduced D2 receptor blockade. The atypicals were introduced during the 1990s and currently include clozapine, risperidone, olanzapine, quetiapine, zotepine and amisulpride. More recently, aripiprazole, a partial dopamine agonist, has been introduced. The pharmacological profile of the atypicals is diverse, involving various combinations of 5HT and dopamine receptor blockade. Aripiprazole acts as a dopamine antagonist at hyperdopaminergic sites (e.g., mesolimbic system in schizophrenia) and as a dopamine agonist at hypodopaminergic sites (e.g., prefrontal cortex in schizophrenia). Interestingly, the therapeutic effects of clozapine (potent affinity for D4 and 5HT₁A receptors) is independent of D2 receptor occupancy, previously thought to be essential for antipsychotic action.

The typical antipsychotic haloperidol has been shown to be superior to placebo in two double-blind controlled trials of children and adolescents with schizophrenia (Pool, Bloom, Miele, Roniger, & Gallant, 1976; Spencer & Campbell, 1994). It is estimated that about 70% of patients show good or partial response to antipsychotic treatment although this may take 6–8 weeks to become apparent (AACP, 2001; Clark & Lewis, 1998). The main drawbacks concerning the use of high-potency typicals such as haloperidol in children and adolescents is the high risk of EPS (produced by D2 blockade of the nigrostriatal pathway), tardive dyskinesia and the lack of effect against negative symptoms and cognitive impairment. Clozapine (the prototypic atypical) has been shown to be superior to haloperidol in a double-blind trial of 21 cases of childhood-onset schizophrenia (Kumra, Frazier, Jacobsen et al., 1996). Larger open clinical trials of clozapine confirm its effectiveness in child- and adolescent-onset schizophrenia (Remschmidt, Schultz, & Martin, 1994). Similar, although less marked, benefits of olanzapine over typical antipsychotics in childhood-onset schizophrenia have been reported (Kumra, Jacobsen, Lenane et al., 1998a).

Recent head-to-head comparisons of atypicals (risperidone and olanzapine) vs. typicals (haloperidol) in adolescents with schizophrenia have reported broadly similar efficacy against psychotic symptoms (with a non-significant trend in favor of atypicals) but a differing profile of adverse effects (Gothelf, Apter, Reidman et al., 2003; Sikich, Hamer, Bashford, Sheitman, & Lieberman, 2004). These finding broadly replicate results from the large NIMH-CATIE pragmatic trial that found no overall difference in effectiveness between typical and atypical antipsychotics in adults, whereas there were differences in tolerability and side effect profiles (Lieberman, Stroup, McEvoy et al., 2005). The UK CUlTASS study compared effects after randomization to either typical or atypical antipsychotics following a clinical decision to change medication in adults with chronic schizophrenia (Jones, Barnes, Davies et al., 2006). There were no differences in outcome (quality of life, symptoms and adverse events) measured at 1 year when comparing the broad classes of typical and atypical antipsychotic. While similar pragmatic clinical effectiveness studies are needed in children and adolescents with schizophrenia, we know that younger and first-episode patients are more sensitive to both therapeutic and adverse effects of antipsychotics. Furthermore, individual drugs within both classes differ importantly in terms of tolerability and side effect profiles when prescribed to children and adolescents. In younger patients (children and adolescents), EPS are more common with haloperidol and high-dose risperidone than olanzapine. Weight gain and obesity are more common with olanzapine (most), then risperidone and least with haloperidol. Sedation is greater with olanzapine and haloperidol than risperidone (Toren, Ratner, Laor, & Weizman, 2004). Further evidence is emerging that children and adolescents experience more rapid and serious weight gain on olanzapine and risperidone than do adults (Ratzoni, Gothelf, Brand-Gothelf et al., 2002). Morbid obesity (body mass index [BMI] >90th percentile) is found in up to 30% of adolescents and young people chronically treated with atypical antipsychotics (Theisen, Linden, Geller et al., 2001). Complications of obesity include hyperglycemia (type 2 diabetes), hyperlipidemia and hypercholesterolemia. It is recommended that dietary advice (reducing carbohydrate intake) combined with regular exercise should be prescribed before initiating atypicals in children and adolescents.

Drawing this evidence together, a strong case can be made for the first-line use of atypicals in child and adolescent schizophrenia (clozapine is licensed in the UK only for treatment-resistant schizophrenia). Treatment resistance in child and adolescent patients should be defined as follows:

1. Non-response with at least two antipsychotics (drawn from different classes and at least one being an atypical), each used for at least 4–6 weeks; and/or
2. Significant adverse effects with conventional antipsychotics. The recommended order of treatment for first-episode schizophrenia in children and adolescents is as follows: atypical as first line, if inadequate response change to a different atypical or conventional antipsychotic, if response is still inadequate or side effects are intolerable then initiate clozapine.

While atypicals reduce the risk of EPS, they can produce other troublesome side effects (usually dose-related) including weight gain (olanzapine, clozapine, risperidone), hyperlipidemia (olanzapine), sedation, hypersalivation and seizures (clozapine, olanzapine, quetiapine) and hyperprolactinemia (risperidone, amisulpride). The risk of blood dyscrasias on clozapine is effectively managed by mandatory routine blood monitoring.
CHAPTER 45

However, knowledge about potential adverse reactions with the newest atypicals is still limited in child and adolescent patients. Baseline investigations and follow-up monitoring every 6 months are recommended when prescribing antipsychotics. Baseline monitoring should include height, weight, blood pressure, full blood count, liver function and creatine kinase, fasting glucose, prolactin (risperidone, amisulpride), lipids (olanzapine, clozapine) and electrocardiogram (ECG) (zotapine). A further consideration is the greater cost of newer atypicals compared to traditional antipsychotics. Although economic studies of cost-effectiveness have suggested that the costs of the atypicals are recouped in reduced in-patient stays and indirect social costs (Aitcheson & Kerwin, 1997), the high cost of these drugs may limit availability, particularly in developing countries.

The UK National Institute for Health and Clinical Excellence (NICE, 2002) has recommended the use of atypicals (risperidone, olanzapine, quetiapine, amisulpride and zotapine) in all first-episode, newly diagnosed patients with schizophrenia and those on established treatment showing resistance to typical antipsychotics. Clinical trial evidence suggests that clozapine is the most effective antipsychotic in child- and adolescent-onset schizophrenia, although its use is restricted to treatment-resistant cases. In summary, atypicals such as olanzapine or risperidone should be used as a first-line treatment given that child- and adolescent-onset schizophrenia is characterized by negative symptoms, cognitive impairments, sensitivity to EPS and relative resistance to traditional antipsychotics. However, a growing awareness of adverse effect profiles of different drugs and greater sensitivity to these effects in children and adolescents means drug choice should be a collaborative exercise, tailored to the needs and preferences of the young person and their family.

Psychosocial Interventions

Psychosocial interventions range from CBT targeted at symptoms, problem-solving skills and stress reduction, to patient and family psychoeducation, family therapy, counseling and support, social skills training and remedial education.

Psychoeducation and Family Interventions

The rationale for psychosocial family interventions follows from the association between high EE and the risk of relapse in schizophrenia (Dixon & Lehman, 1995). The overall aim is to prevent relapse (secondary prevention) and improve the patient’s level of functioning by modifying the family atmosphere. Psychosocial family interventions have a number of principles in common (Lam, 1991). First, it is assumed that it is useful to regard schizophrenia as an illness as patients are less likely to be seen as responsible for their symptoms and behavior. Second, the family is not implicated in the etiology of the illness. Instead, the burden borne by the family in caring for a disturbed or severely impaired young person is acknowledged. Third, the intervention is offered as part of a broader multimodal package including drug treatment and out-patient clinical management.

An important issue when working with parents of children and adolescents with schizophrenia is to recognize that the illness typically results in a bereavement process for the loss of their “normal” child. Parents will often value a clear diagnosis of schizophrenia as it can provide an explanation for previously unexplained perplexing and disturbed behavior. Understanding schizophrenia as a disorder of the developing brain can also relieve commonly expressed feelings of guilt among parents and carers.

Lam (1991) conducted a systematic review of published trials of psychoeducation and more intensive family interventions in schizophrenia and drew the following conclusions. First, education packages on their own increase knowledge about the illness but do not reduce the risk of relapse. Second, more intensive family intervention studies with high EE relatives have shown a reduction in relapse rates linked to treatment by lowering of EE. Third, family interventions tend to be costly and time-consuming with most clinical trials employing highly skilled research teams. Whether these interventions can be transferred into routine clinical practice is uncertain. Fourth, interventions have focused on the reduction of EE in “high-risk” families. Whether low EE families would also benefit from these interventions is less clear. This is particularly relevant to the families of children and adolescents with schizophrenia as, on average, these parents express lower levels of criticism and hostility than the parents of adult-onset patients (Asarnow, Thompson, Hamilton et al., 1994).

Cognitive–Behavioral Therapy

In adult patients, cognitive-behavioral therapy (CBT) has been used to reduce the impact of treatment-resistant positive symptoms (Tarrer, Beckett, Harwood et al., 1993). CBT has been shown to improve the short-term (6 month) outcome of adult schizophrenic patients with neuroleptic-resistant positive symptoms (Turkington & Kingdom, 2000). Whether CBT is equally effective with younger patients, or those with predominantly negative symptoms, remains to be established.

Cognitive Remediation

Cognitive remediation is a relatively new psychological treatment that aims to arrest or reverse the cognitive impairments in attention, concentration and working memory associated with negative symptoms and poor functional outcome in schizophrenia (Greenwood, Lardau, & Wykes, 2005). The results of an early controlled trial in adults are promising, with gains found in the areas of memory and social functioning (Wykes, Reeder, Williams et al., 2000). The severity of cognitive executive impairments in child and adolescent patients suggests that early remediation strategies may be a particularly important intervention in younger patients. Helpful advice can also be offered to parents, teachers and professionals such as breaking down information and tasks into small manageable parts to reduce demands on working memory and speed of processing.

Organization of Treatment Services

It is a paradox that patients with very early-onset schizophrenia
have the most severe form of the disorder yet they often receive inadequate and poorly co-ordinated services. Possibly, this is because the responsibility for schizophrenia is seen to lie with adult psychiatric services with a remit that typically does not extend to patients under age 18. In the UK, community-based child and adolescent mental health services (CAMHS) provide the first-line assessment and care for child and young adolescent psychoses, with only about half of these cases referred to in-patient units (Slavsek, Hollis, & Bramble, 1998). Whereas adolescent in-patient admission is often inappropriate, generic CAMHS services are usually unable to provide the mix of assertive outreach, early intervention and crisis resolution services that have developed over the last decade in UK adult mental health services for psychoses and severe mental illness. Young people with schizophrenia are not generally well served by a separation of services and professional responsibilities at age 16 or 18 (see chapter 13). An alternative model is a community-based young person’s psychosis service spanning ages 14–25 with access to dedicated adolescent and young adult beds. Such a service would provide early intervention, assertive outreach, intensive home treatment and crisis resolution. It would integrate professional expertise from CAMHS (in particular, addressing family, developmental and educational issues) and adult mental health services.

Conclusions

The last decade has seen a dramatic growth in our understanding of the clinical course and neurobiological underpinnings of schizophrenia presenting in childhood and adolescence. It is now clear that adult-based diagnostic criteria have validity in this age group and the disorder has clinical and neurobiological continuity with schizophrenia in adults. Childhood-onset schizophrenia is a severe variant of the adult disorder associated with greater premorbid impairment, a higher familial risk, more severe clinical course and poorer outcome. The poor outcome of children and adolescents with schizophrenia has highlighted the need to target early and effective treatments and develop specialist services for this high-risk group. Unraveling neurocognitive and clinical heterogeneity should lead to improvements in our ability to deliver individually targeted treatments, as well as the ability to identify those “at risk” in order to prevent the onset of psychosis.

CHAPTER 45

CHAPTER 45

Autism spectrum disorders (ASD; or Pervasive Developmental Disorders, PDD) are a group of conditions characterized by three cardinal clinical features: qualitative impairments in social interactions; qualitatively impaired verbal and non-verbal communication; and restricted range of interests. Additional characteristics include onset early in life, delay and/or deviance of development of key psychological functions, multifactorial etiology in which several as yet unknown genetic risk factors interact with each other and with environmental factors, change and mitigation of symptomatic expression by age and, despite this, a chronic course with strong persistence of handicaps over time. However, it is equally true that ASD are clinically very heterogeneous conditions. A main factor that determines diversity is variation in level of cognitive functioning and language skills. There is a large difference between a severely intellectually impaired person with autism who is unable to speak and who engages in motor stereotypies and self-injury, and a highly skilled computer engineer with Asperger disorder or with high functioning autism who is fluent in his one-sided exchange of excessive and obsessive preoccupations about, for example, the constellation of the planets and stars. Other aspects of diversity concern age, severity of cardinal features, coexisting somatic conditions including epilepsy, and coexisting psychiatric conditions.

Over the past decades, clinical and research interest has moved from a focus on a more narrowly defined group of subjects with severe manifestations of the three cardinal features (i.e., “typical autism”) to a broader and more prevalent category with more subtle and less severe symptoms, usually classified as atypical autism or pervasive developmental disorder not otherwise specified (PDD-NOS). Although most of our knowledge about ASD is still derived from research in typical autism, this chapter takes a perspective on the whole range of severity of ASD.

Recent findings indicate that ASD can be conceptualized as disorders of early brain development. Functional and morphological abnormalities of the brain, induced by both static persistent processes that started in utero and dynamic processes that change over time and continue to change in postnatal life, underlie the complex behavioral and cognitive manifestations of ASD.

History

Kanner (1943) first described a syndrome of “autistic disturbances” with case histories of 11 children who presented between the ages of 2 and 8 years and who shared unique and previously unreported patterns of behavior including social remoteness, obsessiveness, stereotypy and echolalia. After its initial description, autism was poorly ascertained during the middle decades of the 20th century. In DSM-I, autism was classified as a childhood type of schizophrenia. Despite this early view of autism as a psychosis, several prominent research groups had formulated the first set of diagnostic criteria for this disorder by the 1970s (Ritvo & Freeman, 1978; Rutter & Hersov, 1977). With DSM-III, the term Pervasive Developmental Disorders (PDD) was first used to describe disorders characterized by distortions in the development of multiple basic psychological functions that are involved in the development of social skills and language, such as attention, perception, reality testing and motor movement. The term PDD was selected because it described most accurately that many basic areas of psychological development are severely affected at the same time. This new PDD umbrella included, for the first time, the term Infantile Autism (with onset prior to age 30 months) as well as Childhood Onset Pervasive Developmental Disorder (with onset after age 30 months). In DSM-III, autism was also clearly differentiated from childhood schizophrenia and other psychoses for the first time, and the absence of psychotic symptoms, such as delusions and hallucinations, became one of the six diagnostic criteria.

In 1944, Asperger wrote the first paper (in German), on what has come to be known as his disorder (translated into English in Frith, 1991). He outlined the clinical picture of four children with normal IQ who were socially odd, naive and inappropriate, had good grammar and extensive vocabularies, poor non-verbal communication, circumscribed interests and poor motor coordination. However, this paper was virtually unnoticed until it was extensively discussed in an English publication (Wing, 1981). Asperger syndrome was first included as a diagnostic category in DSM-IV (American Psychiatric Association, 2000) and ICD-10 (World Health Organization, 1996).

Clinical Characteristics

The diagnostic frameworks currently used, DSM-IV and ICD-10, include a very similar list of disorders under ASD or PDD.
Qualitative Impairment in Social Interactions

The emphasis is on the qualitative impairment in reciprocal social interactions and not on the absolute lack of social behaviors. There is wide variation in social symptoms, which range from a total lack of awareness of another person to intrusive social approaches that are inappropriate to context. In the first year of life, some children with autism do not lift up their arms or change posture in anticipation of being held. Some children do make eye contact, often only in brief glances, but the eye contact is usually not used to direct attention to objects or events of interest. Other children make inappropriate eye contact, by turning someone else’s head to gaze into their eyes, or tend to stare at other people’s faces. Some children make indiscriminate approaches to strangers (e.g., may climb into the examiner’s lap before the parent has even entered the room).

The capacity to make social connections and engage in relationships appropriate to age level is limited. Young children may demonstrate lack of interest, or even lack of awareness of other children. Older children with autism have no age-appropriate friends, are socially isolated and may be teased or bullied. Nonetheless, they may express social interest by saying they want “friends.” Tragically, they do not understand the principles of the reciprocity and sharing of interests inherent in friendship and they lack the pragmatics of “how socially to do what, when and where.” More verbally able children may have one “friend” but the relationship is usually very limited and based on a similar circumscribed interest, such as dinosaurs or a particular computer game. They often do not point things out or use eye contact to share the pleasure of seeing something with another person, which is called joint attention. There are often deficits in reading social cues in body language and facial expressions of others. Some children tend to have a more passive type of social interaction characterized by a lack of social initiative and an observing and compliant style of simply following the directions of others.

Qualitative Impairment in Communication

In a similar way, the communication impairments seen in ASD are diverse, and vary from simple speech delay to muteness, to fluency with subtle peculiarities of intonation and inability to adjust vocabulary and conversational style to social context. As a result, fluency is often accompanied by many semantic (word meaning) and verbal pragmatic errors. Young autistic children, even if verbal, almost universally have comprehension deficits, in particular deficits in understanding higher order complex questions. Some children with autism do not respond to their names when called by a parent or other favored caretaker, and often they are initially presumed to be severely hearing-impaired. A characteristic behavior of many children with autism is mechanically to use another person’s hand to indicate the desired object, often called “hand over hand pointing.” Other “independent” children make no demands or requests of the parents, but rather learn to climb at a young age and acquire the desired object for themselves. When language is present, children with autism seem unable or unwilling to initiate or sustain conversation in a give-and-take fashion.

Speech tends to be in a monotone without the usual emphasis to support meaning of phrases. The autistic child may also use neologisms, echoing or pronoun reversal. Remember that immediate echolalia is a crucial aspect of normal language development under the age of 2 years. It becomes pathological when it is still present as the sole and predominant expressive language after the age of about 24 months, and can often be present throughout the preschool or school-age years in children with autism. ASD are also associated with deficits in non-verbal communication, including the use of gestures such as pointing, showing and nodding. Some children with autism do not use miniature objects, animals or dolls appropriately in pretend play. Others use the materials in a repetitive mechanical fashion without evidence of flexible representational play. Some highly verbal children may invent a fantasy world which becomes the sole focus of repetitive play. Imitation skills are weak or absent, as is the ability to engage in social play, such as peek-a-boo or hide and seek.

Restricted, Repetitive and Stereotypic Patterns of Behaviors, Interests and Activities

Some children show an unusual and intense preoccupation with a topic of private interest such as washing machines, trains or railway schedules. Other children are absorbed in fixed daily routines and rituals. Many children with autism are so preoccupied with “sameness” in their home and school environments, or with routines, that little can be changed without prompting a tantrum or other emotional disturbance. For example, some insist on taking only a certain route to school, entering the supermarket only by one specific door, or never stopping or turning around once the car starts moving. Repetitive behaviors commonly observed in children with autism may include motor mannerisms such as hand-flapping, rocking, flipping objects or lining up toys in a fixed fashion. Some display sensory abnormalities, and are preoccupied by auditory, visual, tactile, haptic or kinesthetic stimuli and apparently are hypo- or hyper-responsive to these. These repetitive and sensory abnormalities can be a source of pleasure or self-stimulation, which differentiates these behaviors from those seen in obsessive-compulsive disorder.

Classification

The prototype of ASD, autistic disorder, is defined by the presence of marked symptoms in all three of the key domains of qualitative impairments in social interactions, qualitatively impaired communication and restricted range of interests. In addition, at least some of these features must have been manifest by the age of 3 years (APA, 2000; WHO, 1996). Asperger syndrome is defined by the presence of social impairment and repetitive behaviors and restricted interests, as in autism. However, in contrast to autism, there is no overall delay in language development, as indexed from the use of single words by age 2 and communicative phrases by age 3 years. Normal or near-normal IQ is also the rule. The lack
of clear language deviance usually leads to later clinical recognition than with other ASD, which is presumably a result of the normal or near-normal adaptive behavior early in life (Volkmar & Cohen, 1991). Yet the language in Asperger disorder is clearly not typical or normal. Individuals usually have pedantic and poorly modulated speech, poor non-verbal pragmatic or communication skills, and intense preoccupations with circumscribed topics such as the weather or railway timetables. They often have both fine and gross motor deficits, including clumsy and uncoordinated movements and odd postures.

In spite of the consensus definition of Asperger disorder in DSM-IV and ICD-10, the validity of Asperger disorder as a discrete diagnostic entity distinct from high-functioning (verbal) autism has remained controversial (Klin, McPartland, & Volkmar, 2005a; Schopler, Mesibov, & Kunce, 1998). Researchers have adopted various diagnostic schemes which differ by whether the focus was on onset of any concerns before age 3, on the presence of speech delay by age 2–3 or by the application of unique investigator-based criteria (Klin, Pauls, Schultz et al., 2005b).

The diagnosis of PDD-NOS (or atypical autism) is appropriate when a subject exhibits impairments in social interactions, impaired communication or restricted range of interests, but does not meet the full criteria for autistic disorder or Asperger disorder. This would apply when the number of criteria met is subthreshold, age of onset is after age 3 years, atypical symptoms are present or more than one of these are present. Balancing sensitivity and specificity in differentiating PDD-NOS from both autism and non-ASD conditions, diagnostic algorithms have been proposed that describe PDD-NOS as a lesser variant of autism, requiring that at least 4 of the 12 DSM-IV criteria of autism are met, including at least one of the social interaction criteria (Buitelaar & van der Gaag, 1998; Buitelaar, van der Gaag, Klin, & Volkmar, 1999a).

Epidemiology

Whereas the first epidemiological studies of autism reported the population prevalence at around 4 per 10,000 (Lotter, 1966), recent large systematic surveys indicate a much higher rate. The current estimates are 30–100 per 10,000 for all ASD, including 13–30 per 10,000 for autism and 3 per 10,000 for Asperger disorder (Baird, Simonoff, Pickles et al., 2006; Fombonne, 1999, 2003). Estimates from single studies vary widely, because of differences in screening and ascertainment procedures, sample size, publication year and geographic location. The increase in reported rates of ASD is largely a consequence of two factors (Rutter, 2005). First, recent studies used systematic standardized and often multiple screenings of total populations or birth cohorts, and by consequence have missed fewer children with ASD than older studies that were more focused on special populations or case registries. Second, over the years the diagnostic concept of ASD has broadened considerably and has included a much better recognition of the expression of autistic symptoms in individuals with near-normal or normal non-verbal intelligence, along with insights from family genetic and twin studies that the genetic liability of autism extends well beyond the traditional categories into more subtle social and communicative abnormalities (Bolton, Macdonald, Pickles et al., 1994; Le Couteur, Bailey, Goode et al., 1996).

However, it is unclear whether there is also a rise in the true incidence of ASD, and whether – if so – this is a result of some as yet unknown environmental factor. The increase, particularly since the early 1980s, has led to claims that specific environmental factors such as the use of mumps–measles–rubella (MMR) triple vaccine are a major factor (Roger, 2000; Wakefield, Murch, Anthony et al., 1998). However, empirical evidence for these claims is absent (Rutter, 2005). For example, a total population study in the Yokohama district, Japan, was able to examine the cumulative incidence of ASD before the introduction of the MMR vaccination and after its withdrawal (Honda, Shimizu, & Rutter, 2005). The findings indicated a continuing rise in incidence of ASD even after the withdrawal of the vaccination. Further, the incidence pattern of ASD associated with regression was similar to that of ASD as a whole. It is also relevant that an independent study of Wakefield’s claims on finding the measles virus in body tissues has not confirmed the findings (D’Souza, Fombonne, & Ward, 2006). Finally, in particular the incidence of ASD with high IQ showed a significant increase. The use of thimerosal, a vaccine preservative that contains ethyl mercury, has in a somewhat similar way been linked to a rise in incidence of ASD. Because mercury, in high dosage, can cause neurodevelopmental sequelae, there is greater biological plausibility in this argument. However, discontinuation of the thimerosal-containing vaccines in Denmark was followed by an increase in the incidence of ASD and not by the predicted decrease (Atladóttir, Parner, Schendel et al., 2007; Madsen, Lauritsen, Pedersen et al., 2003).

Recent surveys continue to indicate associations of ASD with gender, IQ and other medical disorders (Fombonne, 2003). Males are about four times more often affected than females, with gender differences even more pronounced in the normal range of intellectual functioning, up to a male : female ratio of 6:1. The gender difference in ASD is poorly understood. Although Baron-Cohen, Knickmeyer, and Belmonte (2005) have speculated that autism may represent an extreme male brain, there is a paucity of supporting evidence and the suggestion side-steps the important finding that most early-onset neurodevelopmental disorders (such as attention deficit/hyperactivity disorder [ADHD] and dyslexia) show a marked male preponderance (see chapter 3; Rutter, Caspi, & Moffitt, 2003a). It may be more profitable to ask why males are more vulnerable to this range of disorders, rather than to view autism as a special case.

The rate of coexisting severe to profound intellectual impairment is about 40%, mild to moderate cognitive impairments are found in 30% and normal intellectual functioning in another 30%. Potentially causal medical associations are found in about 5–10% of the cases. The strongest connection is found for tuberous sclerosis (Smalley, 1998); approximately 20% of
patients with tuberous sclerosis also have autism, although, in contrast, tuberous sclerosis is found only in a small percentage of cases with autism. Other medical conditions that may be associated with autism are cerebral palsy, fragile X, phenylketonuria, neurofibromatosis, congenital rubella and Down’s syndrome (Fombonne, 2003). These associations with intellectual impairment and known medical conditions are much stronger for typical autism than more broadly defined ASD.

**Course of Autism**

Most children with autism are identified by their parents as showing abnormalities or delays in the second year of life, and many parents suspect problems long before this (Zwaigenbaum, Bryson, Rogers, 2005). Parents who have already had a child tend to recognize social deficits earlier than parents of firstborns, and social deficits are often less recognizable in very young children than when they are older (De Giacomo & Fombonne, 1998).

Often, the problems noticed are not specific autistic features, but rather concerns that the child is less socially responsive and has difficulties in settling, eating and sleeping (Dahlgren & Gillberg, 1989). Home videos similarly show that by the age of 12–18 months (or even earlier) there may be manifestations of abnormal development, but often the indications are quite subtle (Rutter, 2005). Many autistic children under the age of 3 years do not yet show clear examples of restricted or repetitive behaviors (Cox, Klein, Charman & Gillberg, 1999).

It has long been noted that about one-quarter to one-third of all children with ASD appear to lose previously acquired language skills (usually between 18 and 24 months; Rogers & DiLalla, 1990; Rutter, 2005). Surprisingly, the phenomenon has been subject to remarkably little systematic study. Some of these apparent developmental regressions are minor and probably of little significance but there is no doubt that a marked loss of skills does occur in a substantial minority of children with ASD. In one well-documented study (Pickle, Simonoff, Conti-Ramsden et al., submitted), the phenomenon was shown to be common in children with ASD but did not occur in those with specific language impairment (SLI). If confirmed, this would suggest that developmental regression is of some diagnostic significance. However, its meaning remains obscure. Despite claims to the contrary (in relation to MMR), it does not imply any environmental cause and there is no evidence that ASD with regression is becoming more frequent (Rutter, 2005).

When children with ASD enter school, many of them are described as more flexible and socially directed. Data from 13 follow-up studies extending into adult life show a general pattern of modest improvement over time (Howlin, 2005). Some adults with ASD experience real behavioral and social improvements in their late 20s and early 30s (Mesibov, 1984). However, autism is a lifelong disorder, and the likelihood of complete independence is low. Individuals with both autism and intellectual disability require supervised living and working situations throughout their lives. Opportunities within communities, rather than in institutions, have increased in the last decades. Most adults with ASD, even those with average or greater intelligence, require some help in finding and keeping jobs and coping with responsibilities and social demands. Comparisons of outcome studies over the last 30 years suggest that among those of intelligence within the normal range, there has been some increase in the proportion obtaining employment. Admissions with institutional care have also fallen. Nevertheless, even in individuals with an IQ above 70, only about one-quarter show good social functioning. Early reports commented on apparent cognitive deterioration in adolescence in some individuals, but true cognitive decline seems uncommon.

In a recent large follow-up study with a low attrition rate and using systematic interviews to obtain clinical information, Hutton, Goode, Murphy et al. (in press) found that 16% of the autistic participants developed a definite new psychiatric disorder that was not just a worsening of pre-existing autistic features. Five out of 135 developed an obsessive-compulsive disorder and/or catatonia; a further eight developed affective disorders with marked obsessional features; and seven developed complex or straightforward affective disorders. There was no case of schizophrenia in this study, indicating a lack of continuity between autism and schizophrenia (Volkmar & Cohen, 1991). However, there are reports of autistic individuals who show isolated psychotic symptoms, including hallucinations and delusional thoughts (Clarke, Littlejohns, Corbett, & Joseph, 1989; Szatmari, Bartolucci, & Bremmer, 1989; Vorstman, Staal, van Daalen et al., 2006; Wing & Shah, 2000). Hutton, Goode, Murphy et al. (in press) found that one-fifth of individuals with ASD followed into adult life experience one or more epileptic attacks and that about two-thirds of these had their onset in adolescence or adult life.

There are a number of largely anecdotal reports of offending by people with autism or Asperger syndrome. Inappropriate social responses, especially to strangers, may result in police involvement and crimes may also be linked to obsessional interests. Because of this, offending may well be of an unusual or even bizarre nature (Baron-Cohen, 1998; Chesterman & Rutter, 1994). Scragg and Shah (1994) assessed the entire male population of Broadmoor Special Hospital and identified three cases of autism and six with Asperger syndrome out of a total of 392 (just over 2%), clearly a much higher figure than the rates for autism or Asperger syndrome in the general population. In their review of offending by people with Asperger syndrome, Ghaziuddin, Tsai, and Ghaziuddin (1991) found that only 3 out of a total of 132 cases had a clear history of violent behavior. Estimates on the prevalence of violence in people with ASD can only be made on the basis of community studies; these are lacking so far.

**Predictors of Outcome**

Predictors of outcome from preschool to later childhood and adolescence have included joint attention (Sigman, Ruskin,
Arbeile et al., 1999), verbal imitation (Smith & Bryson, 1994) and social communicative aspects of adaptive skills (Lord & Schopler, 1989). However, non-verbal IQ and language are the most powerful predictors. A non-verbal IQ below 50 in preschool years is associated with a reduced likelihood that the child will acquire a useful level of spoken language and a very low probability of good social functioning in adolescence or adulthood (Lockyer & Rutter, 1969). Variations in non-verbal IQ in the range of 50–70 have a somewhat similar effect, but those within the normal range do not. In children with autism but without severe intellectual disability, language skills (and verbal IQ) are the strongest predictors of social outcome. A child who does not have fluent speech by the age of 5 years will make significant gains, but the later these gains come, the less likely the child’s language will be flexible and complex, and the more likely language delays of some sort will reduce his or her level of independence (Szatmari, Bryson, Streiner et al., 2000). Although intrinsic factors such as high IQ and good language abilities are important for outcome, these alone are not enough to ensure a positive outcome. External factors, including appropriate junior and secondary school provision, improved transitional programs for entry into college and supported employment schemes, are also crucial (Howlin, Alcock, & Burkin, 2005; Keel, Mesibov, & Woods, 1997; Smith, Belcher, & Juhrs, 1995).

It is clear that a considerable minority of individuals with ASD, although continuing to be affected by their condition, can find work, live independently and maintain relationships with others. However, such achievements do not come easily. While some individuals have access to specialist support systems, in many cases jobs are found only with the support of families, and opportunities to live independently depend heavily on local provision – and often too on parental determination and persistence.

**Differential Diagnosis**

In daily practice it is often not simple to distinguish autistic syndrome from other pervasive developmental disorders, developmental language disorder, intellectual impairment, sensory defects and severe emotional neglect. Each of these syndromes is briefly described below, and possible differential diagnostic characteristics mentioned.

**Atypical Autism/Pervasive Developmental Disorder Not Otherwise Specified**

These terms refer to non-specific patterns that seem to involve the same deficits as those associated with autism, although they do not fulfill all the accepted diagnostic criteria (Buitelaar, van der Gaag, Klin et al., 1999a). The atypicality may lie in the symptom pattern, its severity or age of first manifestation. Epidemiological analyses (Wing & Gould, 1979) and clinical investigations indicate the frequency of these atypical patterns but they have been subject to little systematic research. It is likely that they reflect variations in the ways in which ASD may present, rather than a separate category (Rapin, 1997; Wing, 1997). The service needs are similar to those for autism, and it remains unknown whether the apparent atypicality has any implications for etiology.

**Asperger Syndrome**

In the last two decades, the concept of Asperger syndrome as used by researchers (Frith, 1991; Gillberg, 1989; Klin, Volkmar, & Sparrow, 2000) and clinicians (Attwood, 1997; Wing, 1981) has served to highlight the occurrence of ASD in individuals who are intellectually able and verbally fluent (Grandin & Sciarino, 1986). It has not proved easy to produce satisfactory diagnostic criteria, and differences in both definition and sampling have led to conflicting findings (Green, Gilchrist, Burton, & Cox, 2000; Klin, Volkmar, & Sparrow, 2000; Szatmari, Bryson, Streiner et al., 2000). In keeping with the lack of language delay, the diagnosis tends to be made substantially later than in autism as such, and the diagnosis of Asperger syndrome tends to be associated with a higher verbal than non-verbal IQ (Klin, Volkmar, Sparrow, Cicchetti, & Rourke, 1995). It remains uncertain whether Asperger syndrome and autism differ in pattern of neuropsychological deficits (Ozonoff, Pennington, & Rogers, 1991a,b) and outcome (Howlin, 2003).

**Rett Syndrome**

Rett syndrome is a progressive developmental disorder that affects 1 in 10,000–15,000 girls (Kozinetz, Skender, MacNaughton et al., 1993) and is the only pervasive developmental disorder with a known genetic cause (see chapter 24). Rett syndrome is brought about by mutations in the X-linked gene encoding methyl-CpG-binding protein 2 (MECP2; Moretti & Zoghbi, 2006). It is characterized by a relatively normal general and psychomotor development through the first 6–18 months of life, followed by stagnation of developmental acquisitions and a rapid deterioration of behavior and mental status, resulting in dementia with apparently autistic-like features within less than 18 months; loss of purposeful use of the hands following the earlier acquisition of normal grasp function; jerky ataxia of the trunk and limbs, awkward, unsteady gait and acquired microcephaly; followed by a protracted period with a relatively stable mental status, marked by the emergence over years of other neurological abnormalities – especially spasticity of the lower limbs and epilepsy (Hagberg, Aicardi, Dias, & Ramos, 1983). Because of its crucial prognostic significance, its diagnosis is most important. The acquired microcephaly (after a normal head circumference at birth), associated with the loss of purposive hand movement and often a midline “handwashing” stereotypy, may be most crucial. There are no specific treatments currently available, although recent animal studies suggest that, potentially, the neural degeneration might ultimately prove to be reversible (Guy, Gan, Selfridge, Cobb, & Bird, 2007).

**Childhood Disintegrative Disorder**

Childhood disintegrative disorder (previously termed Heller
with an intellectual disability, found that half of all children with an IQ lower than 50 also had disturbances of social communication, stereotyped behavior and/or disorders of language development. These three symptoms are similar to the diagnostic core criteria of autism, and these children are usually classified as having PDD-NOS. In daily practice it is not always easy to determine whether a child has a “pure” intellectual disability or intellectual impairment that is part of ASD (see chapter 49).

Sensory Deficits
The parents of a child with autism often approach their general practitioner with the suspicion that their child is deaf, because the child does not react to his or her name or to doors slamming shut, etc. A careful history should clarify the situation, but this does not obviate the need to carry out auditory testing, if necessary supplemented with monitoring of brainstem-evoked responses. As babies, children with autism are often noticeable for not making eye contact – they stare into space or fixedly gaze at something, such as a lamp. This sometimes makes parents think that their child is blind. Extensive ophthalmological investigations may provide information regarding the differential diagnosis.

Emotional Neglect
Children who have experienced very severe institutional deprivation can show language delay, abnormal social behavior and marked circumscribed interests and preoccupations (Rutter, Anderson-Wood, Beckett et al., 1999). In early childhood the clinical picture is rather like autism, although there is usually more social reciprocity than typical with autism, and the course is different, so that by middle childhood it is social disinhibition and circumscribed interests that tend to predominate.

Assessment
Because no single symptom is pathognomonic for ASD, the essence of the diagnostic process is to recognize a particular pattern of social and communicative symptoms and of rigidity that was first manifest early in life, is rather stable over development and cannot better be attributed to other conditions. Assessment requires sufficient expertise with the wide range of expression of the symptoms of ASD by age and level of cognitive and language skills, and is best performed systematically and in a stepwise fashion. Extensive information about assessment of ASD can be found in recent practice parameters (American Academy of Pediatrics, 2000; Volkmar, Cook, Pomeroy, Realmuto, & Tanguay, 1999).

The interview with the parents or caregivers should cover both the core features of ASD as well as comorbid symptoms such as aggression, tantrums, hyperactivity, inattention, impulsivity, sleep problems and self-injury. In older children and adolescents, it is often helpful to focus on age 4–5 years, when the expression of symptoms of ASD is most typical. Necessary components of the interview are a family history...
with probes for ASD, intellectual disability, fragile X syndrome, tuberous sclerosis, and more subtle language, learning and communication problems (see chapter 22). The child’s medical history-taking should explore signs of deterioration, seizure activity, brain injury, gastrointestinal disease, pica and other medical conditions. The observation or interview of the child is best conducted in conditions of both high-structure and low-structure, and by using several strategies varying from direct and intrusive approach and probes for engagement to passive observation while the child wanders around or is with others. It allows the clinician to document behaviors reported in the interview and explore the responses of the child to intrusiveness and structure.

**Diagnostic Instruments**

Several standardized diagnostic instruments are available to facilitate the assessment of ASD. These instruments are commonly used in research and also increasingly in clinical practice. The Autism Diagnostic Interview–Revised (ADI-R) is a comprehensive diagnostic interview conducted by a trained clinical interviewer (Le Couteur, Lord, & Rutter, 2003; Rutter, Le Couteur, & Lord, 2003b). It focuses both on the period between 4 and 5 years of age and on current symptoms, encompasses 92 questions and takes about 120 min to administer. The ADI-R is reliable and valid, and has a scoring algorithm for DSM-IV and ICD-10 diagnoses of autism, but not for PDD-NOS or Asperger disorder.

Less often used is the Diagnostic Interview for Social and Communicative Disorders (DISCO) which also provides a broad base of information on developmental and behavioral issues (Leekam, Libby, Wing, Gould, & Taylor, 2002; Wing, Leekam, Libby, Gould, & Larcombe, 2002). The Vineland Adaptive Behavior Scale is a semi-structured interview with parents or caregivers to measure functional ability in everyday life on three domains: communication, daily living and socialization (Sparrow, Balla, & Cicchetti, 1984). The interview has US norms for age and gender. Individuals with autism often have Vineland scores that are 2 standard deviations below their measured IQ. Rating scales that can be used to assess a broader spectrum of behavioral problems in ASD are the Aberrant Behavior Checklist (ABC; Aman, Singh, Stewart, & Field, 1985) and the Developmental Behavior Checklist (DBC; Einfeld & Tonge, 1995).

Rating scales that have been developed to measure the core symptoms of autism but also more subtle manifestations that characterize subjects with the broad autism phenotype are the Social Responsiveness Scale (SRS; Constantino, Gruber, Davis et al., 2004) and the Child Social Behavior Questionnaire (CSBQ; Hartman, Luteijn, Serra, & Minderaa, 2006). A rating scale to be completed by parents, based on items from the ADI-R and developed to be used as a screening instrument, is the Social Communication Questionnaire (SCQ; Berument, Rutter, Lord, Pickles, & Bailey, 1999). The scale has good validity in differentiating ASD from non-ASD in children of 4 years and older, relatively independently from IQ, but has not been studied sufficiently below age 4 years.

The most often used standardized observation schedule is the Autism Diagnostic Observation Schedule (ADOS; Lord, Rutter, DiLavore, & Risi, 2001). It is built on a series of structured and semi-structured scenarios for interaction with the child by a well-trained interviewer. The presentation of the modules varies according to the child’s verbal skills and the modules have been developed to optimally elicit the core symptoms of ASD. The ADOS takes about 40 min to administer, after which the scoring sheet should be completed.

The selection of specific IQ tests depends on the chronological age, mental age, verbal skills and level of cooperation, and should be carried out by an experienced psychologist. The same applies to the selection of language tests. A summary of available tests can be found elsewhere (Howlin, 1998).

A comprehensive physical examination is an indispensable component of the assessment. Particular attention should be paid to the presence of identifiable clinical syndromes, such as tuberous sclerosis (including the use of Wood’s light to assess any skin lesions) or neurofibromatosis, dysmorphic features and any localizing neurological impairments (see chapter 22). Most experts agree that there is no indication in the clinical setting for routine magnetic resonance imaging (MRI) of the brain or lumbar punctures or metabolic screens, except when neurological abnormalities or clear major regression are present (Filipek, Accardo, Ashwal et al., 2000). Given the increased rate of chromosomal anomalies in ASD, there is a need for routine DNA testing, including high-resolution chromosome testing, fluorescent in situ hybridization testing for Williams syndrome and subtelomeric deletions, and testing for the fragile X anomaly. There is a possibility that the premutation status (with an increase in trinucleotide repeats compared to the general population but below the full mutation expansion) has an increased risk for either ASD or other cognitive or behavioral problems (Hagerman, 2006). Lead levels should be obtained for children with developmental delays, even in the absence of a clear history of pica. About 30% of subjects with autism develop seizures, with a first manifestation either before age 5 years or in adolescence (Volkmar & Nelson, 1990). Sudden unexplained behavioral changes that are outside of the context of autistic symptoms should alert the clinician to this possibility. Assessment procedures that cannot be recommended as a routine are allergy testing, hair analysis, chelation challenge testing, gut permeability studies and stool analysis (Filipek, 2005).

**Early Detection**

Early identification of ASD is now considered to be clinical best practice, because it enables avoidance of unnecessary medical shopping for parents with clinical concerns, provides for early guidance and genetic counseling and starting early interventions (Charman & Baird, 2002; Rutter, 2006). A large proportion of subjects with ASD will nowadays be diagnosed around age 3–4 years, but somewhat later when early cognitive and language development are intact (Howlin & Moore, 1997).

Systematic analysis of video home movies of children in the first 2 years of their life and later diagnosed with ASD has
shown that manifestation of ASD as early as 9–12 months may include difficulties orienting to social stimuli (e.g., less looking at people or faces and less responsiveness to name). This tends to be accompanied by less babbling, a limited understanding of spoken language and a paucity of gestures to express social interest or to draw attention to some object of interest in the environment (as distinct from gestures pointing to an object that the child wants). These difficulties tend to become more obvious in the second year of life, and extend to differences in joint attention and verbal communication. Prospective studies in high-risk siblings report consistent results (Zwaigenbaum, Bryson, Rogers et al., 2005). The frequent association with intellectual impairment makes the early differentiation between ASD and intellectual disability problematic, and only a reduced frequency of looking at people and responding to name appears to differentiate ASD. The discriminative value of other behaviors is less clear, such as increased frequency of unusual visual inspection of objects, abnormal sensory reactions, and decreased flexibility and variety of play (Swinkels, Dietz, van Daalen et al., 2006).

In contrast to this early-onset type of autism, 20–40% of children with ASD manifest an early regression of language and behavior, most often between 18 and 24 months (Werner & Dawson, 2005). Although there is no accepted definition of regression, parents report loss of using words or phrases, together with the loss of sociability and loss of interest in playing with toys, and in some cases the appearance of stereotypes and rigid behavior patterns. Home movies have confirmed the reality of developmental regression and shown that children who regress in the second year of life nonetheless tend to show subtle pre-existent social and regulatory problems (Werner & Dawson, 2005). It is unknown whether early regression represents a specific genetic or neurobiological subtype of ASD. The clinical and prognostic meaning of early regression is also unclear.

At this stage, the wide range of individual differences in both typical and atypical development in the first years of life makes effective screening for ASD below 18 months in normal populations not useful when parents have no clinical concerns (Dietz, Swinkels, van Daalen, van Engeland, & Buitelaar, 2006). Screening is possible and worthwhile after 18 months, particularly in cases of high-risk status or clinical concerns by parents or health care professionals, and is recommended as part of more comprehensive surveillance programs to identify children in need of further assessment. In addition to parental concerns about poor communication, socialization or other behavioral problems, absolute indications for further specialist referral are the absence of babbling by 12 months, the absence of gesturing (pointing, waving bye-bye, etc.) by 12 months, no single words by 16 months, no two-word spontaneous (not just echolalic) phrases by 24 months, and any loss of any language or social skills at any age (Filipek, Accardo, Baranek et al., 1999). A number of instruments are available to be used around 18–30 months such as the Checklist for Autism in Toddlers (CHAT; Baron-Cohen, Allen, & Gillberg, 1992, Baron-Cohen, Wheelwright, Cox et al., 2000), Modified Checklist for Autism in Toddlers (M-CHAT; Robins, Fein, Barton, & Green, 2001) and Early Screening for Autistic Traits (ESAT; Swinkels, Dietz, van Daalen et al., 2006).

Cognitive Theories

Cognitive models have been developed in an attempt to explain the heterogeneous clinical manifestations of ASD by a so-called core deficit (i.e., a basic impairment that is primary and underlies the clinical social symptoms).

Mentalizing Ability

The theory of mind hypothesis proposes that individuals with ASD have a fundamental problem in attributing mental states such as feelings, desires, intentions, fantasies, dreams and beliefs to others and oneself. This leads to “mind-blindness,” a failure to perceive others as social agents, and therefore results in deficient social, emotional and communicative actions and responses, and a failure of imagination. This hypothesis has stimulated a body of experimental psychological work in individuals with ASD that has revealed widespread problems in mentalizing and empathizing ability (Baron-Cohen, 1995; Baron-Cohen, Tager-Flusberg, & Cohen, 1993; Frith, 2003). The spin-off has also been studies into the neural substrate of mentalizing skills in normal subjects and in ASD (Baron-Cohen, Ring, Wheelwright et al., 1999; Castelli, Frith, Happe, & Frith, 2002). Important components of the so-called “social brain” are the amygdala, the orbitofrontal and medial frontal cortex, and the superior temporal sulcus and gyrus in these regions have shown abnormalities in autism.

However, there are several arguments against a core deficit in theory of mind in autism. Social dysfunction in autism is typically present prior to the time at which even the earliest precursors of a theory of mind emerge (Klin, Volkmar, & Sparrow, 1992). The theory of mind hypothesis is less able to explain the lack of spontaneous and original activity of persons with autism, their repetitive behavior, their impairment in understanding conversation (Yirmiya, Sigman, Kasari, & Mundy, 1992) and their executive dysfunctioning (Hughes, Russell, & Robbins, 1994). Impairments in theory of mind do not seem to be specific, nor are they universally present in ASD (Buitelaar, van der Wees, Swaab Barneveld, & van der Gaag, 1999b). Relatively able individuals with ASD, such as those with Asperger disorder, can solve theory of mind problems, albeit often by idiosyncratic and alternative strategies, and still present with major social handicaps in everyday life (Bowler, 1992; Ozonoff & McEvoy, 1994; Zias, Durkin, & Pratt, 1998).

The mentalizing account of ASD was later extended to the empathizing–systemizing (E-S) theory (Baron-Cohen, 2002). In addition to weak mentalizing–empathizing skills, systemizing is either intact or superior. Systemizing is the drive to analyze systems in terms of their underlying rules and regularities. Good systemizing skills would explain islets of abilities, the content...
of obsessional symptoms and repetitive behavior. Such predictions have yet to be adequately tested.

Central Coherence Theory
The central coherence theory originally suggested that a core deficit in processing information for meaning and for global (gestalt) form would explain the social symptoms in ASD (Frith, 1991). Weak central coherence, with an undue focus on details, would lead to a disregard to contextual issues, and to fragmented perceptions of the external world. This was illustrated remarkably well by performances on the Block Design test of the Wechler’s Intelligence Scales and on the Embedded Figures test. Both tests require “field independence,” that is, the ability to disregard context (Frith & Happé, 1994). However, later work has challenged this view in the following ways (for review see Happé & Frith, 2006). Weak global extraction of information may be the result of a superior performance in local processing of details, rather than vice versa. Further, many individuals with ASD seem able to pay sufficient attention to global information when specifically directed to do so. This means that the strong preference for local detailed information is a cognitive style or processing bias rather than a cognitive deficit. Weak central coherence characterizes a subsample of the ASD population and seems to be an aspect of their cognitive set-up of ASD, but does not serve as the all-explaining core deficit.

Executive Functioning
Executive functions (EFs) are mental control processes that enable the self-control necessary for the attainment of a future goal (Pennington & Ozonoff, 1996). EF refers to cognitive functions mediated by the prefrontal cortex (Fuster, 1997), such as inhibition, working memory, cognitive flexibility or set-shifting, planning and verbal fluency (Pennington & Ozonoff, 1996). The EF account of ASD assumes that the weak performance of one or more of these cognitive functions (poor attentional regulation, inability to shift attention) on the basis of some form of neurological abnormality of the prefrontal cortex, leads to the perseverative inflexible problem-solving strategies commonly observed in ASD and ultimately to the other social and communicative symptoms. Multiple studies have identified EF deficits in preschoolers, children and adolescents as well as adults with autism (Geurts, Verte, Oosterlaan, Roeyers, & Sergeant, 2004; Williams, Goldstein, Carpenter, & Minshew, 2005), although inconsistent findings have also been reported (Griffith, Pennington, Wehner, & Rogers, 1999; Ozonoff & Strayer, 1997; Russell, Jarrold, & Hood, 1999).

However, it would be simplistic to assume that autism can be explained by poor EF, because:
1 Poor EF is also found in other disorders such as ADHD, although EF deficits were much more widespread in ASD than in ADHD in a direct comparison (Geurts, Verte, Oosterlaan et al., 2004);
2 EF deficits are not always seen in ASD;
3 Children with early frontal lesions do not all appear to be autistic (Ozonoff, Pennington, & Rogers, 1991a,b); and
4 The correlation between EF deficits and social impairment is not very strong (Dawson & Osterling, 1997).

Treatment
The main aims of the treatment of ASD are (Rutter, 1985):
1 As much as possible to facilitate and stimulate the normal development of cognition, language and socialization;
2 To decrease autism-bound maladaptive behaviors such as rigidity, stereotypy, and inflexibility;
3 To reduce or even eliminate non-specific maladaptive behaviors such as hyperactivity, irritability and impulsivity; and
4 To alleviate stress and burden for the family.

Further information about treatment of ASD is available in recent US practice parameters (American Academy of Pediatrics, 2000; Volkmar, Cook, Pomeroy et al., 1999). The treatment of individuals with ASD should be multimodal, with a combination of family counseling, structured and special educational techniques, individual behavior modification, home training, and placement in special schools or daycare centers. So far, ASD are chronically disabling conditions for which no effective evidence-based cure exists. This does not detract from the great benefits that can be brought by a comprehensive and intensive treatment plan to patients and their families in terms of improvement in quality of life. Recent research suggests that the most effective results stem from early intensive behavioral interventions. Medication treatment has not been shown to influence the core symptoms of ASD, but may be considered when troublesome target and comorbid symptoms such as aggression, temper tantrums, irritability, hyperactivity, self-injurious behavior, rigidity, anxiety and sleeping problems do not respond to behavioral interventions or seriously interfere with the application of these interventions.

There are some general principles of treatment of ASD that are important. Individuals with ASD reach a higher level of social functioning in highly structured than in unstructured situations. For example, the daily routines of a classroom provide structure, whereas anxiety, social isolation and rigidities may emerge rapidly during free time and lunch breaks. In relation to this, the social functioning of those with ASD is usually better in an environment with moderate levels of expression of emotions and symbolic meanings. For example, the difficulty for individuals with ASD to grasp the symbolic meaning of special events and ceremonies such as a birthday party or Christmas can easily make them anxious or lead to aggressive reactions when pushed too much. The intensity of social stimulation offered should be adjusted to the level that can be handled. When a child has reached an equilibrium in interacting with one or two other children as buddies at school, this should first be consolidated before other classmates are to be involved. Every treatment plan should accommodate for the often profound limitations in communication of individuals with ASD. This could be addressed by some form of speech and language therapy, and for very young or non-verbal subjects by the Picture Exchange Communication System.
CHAPTER 46

(Bondy & Frost, 1998, 2001), Social Stories, which is the use of cartoon-type illustrations to help children understand how to respond in social situations, or peer-mediated intervention (Roeyers, 1996). Training and interventions should be performed as much as possible in daily-life situations, in an attempt to overcome the problems of the transfer of skills mastered in one setting to another.

Counseling for Parents and Family Support
It is very important to inform parents about the diagnosis and implications for the future of the child. Parents may have difficulty in accepting the diagnosis. Once a family has a child with ASD, the risk of recurrence of ASD in subsequent children rises to 3–7%. Therefore, parents need appropriate counseling on genetic issues. During the different stages of development, the child and parents have different needs. For example, placement in a school that provides a specialized education can be enough for the first years, but when behavior management problems occur, more intensive counseling, behavioral therapy and/or medication may be an option. In some countries, patients and their families are organized into National Autistic Societies which hold information evenings where parents can meet each other and where “non-professional” support is given. Most parents benefit from training courses aimed at skills building and reduction of problematic behavior. In adolescence, attention should be paid to sexuality issues that may be relevant to ASD – such as masturbation, inappropriate touching, privacy issues and public exposure.

Early Intervention
There are great expectations in the field from the benefits of intensive early interventions for children with ASD (Butter, Wynn, & Mulick, 2003). Typically, these interventions would be started shortly after diagnosis and continued up to kindergarten or primary school, depending on the child’s progress and areas of handicap. Work on early intensive treatment has started with claims about significant gains in IQ and outcome in a sample of 19 young autistic children (Lovaas, 1987). However, this promising result and that of a related study (McEachin, Smith, & Lovaas, 1993) have been questioned because of methodological problems (Campbell, Schopler, Cueva, & Hallin, 1996). There are now a number of positive studies of intensive early intervention which indicate that a subsample of children with ASD make considerable progress and nearly all children show some benefits (Medical Research Council, 2001; National Research Council, 2001). However, observations also indicate that some young children with ASD improve rapidly with relatively little intervention, and others show very little progress despite very intensive and comprehensive multimodal treatments. It is claimed that effective early interventions include the following important components (Kabot, Masi, & Segal, 2003):

1. Provision at the earliest possible age;
2. High intensity, with the suggestion of a threshold of at least 20 h per week spent one-to-one with the child;
3. Strongly based on parent involvement, training and support;
4. Various modules and training schemes to stimulate social and communicative functioning of the child in a developmentally oriented way;
5. Systematic instruction with individual goals, based on applied-behavioral analysis (ABA) and stepwise approach; and
6. Investment in attempts to generalize acquired skills to other settings of daily life.

Further research is needed to test these claims.

Education
Opportunities for adequate education are essential, as follow-up studies have indicated that children who complete some form of education have a better outcome (van der Gaag, 1993). It is necessary for the teacher to be informed about the nature of autism and the child’s needs. An autistic child at school needs extra individual attention, a very structured approach and special education programs, such as the Treatment and Education of Autistic and related Communication-handicapped Children program (TEACCH; Mesibov, Shea, & Schopler, 2004). This program emphasizes extensive collaboration with and training of the parents, so that they become knowledgeable about their child’s disorder and needs. This program provides a highly structured approach for autistic children at school. Based on principles from cognitive–behavioral theory, a system is developed with stepwise visualization of the actions needed to fulfill a task. Through this system the life-environment can be structured, and parents can act as co-therapists and continue with the principles of TEACCH at home.

Skills Training and Behavioral Therapy
Depending on clinical needs, a number of specific treatment modalities may be helpful. In cases of clumsiness or delays in motor development, there is an indication for sensorimotor training. Language and communication skills can be facilitated by means of language training. Occupational therapy and play therapy may be of use in some cases. For high-functioning autistic children, individual therapy can be an option, for instance when the child is suffering from the awareness of being different. Social skills training programs, delivered on an individual or on a group basis, are being offered to children and adolescents with ASD at an increasing rate (Bauminger, 2002; Koegel & Frea, 1993). Recently, social skills training programs have been nurtured with ideas from research on theory of mind and emotion recognition deficits in autism (Howlin, Baron-Cohen, & Hadwin, 1999). Although the benefits may be an improvement of social awareness and the acquisition of routine social skills, the merits on a long-term basis are often disappointing because of a lack of generalization of skills.

Behavioral treatment based on classic and operant conditioning is the most studied and publicized form of non-medical treatment. There is a clear indication for specific behavioral interventions in cases of severely interfering and maladaptive behaviors such as stereotopies, self-injury and negativism. Also, the acquisition of normal behaviors, such as toileting, may benefit from behavioral interventions. These interventions should be based on a detailed analysis of the functional
relationship between the child and the environment (Campbell, Schopler, Cueva et al., 1996), which can then give rise to an individual treatment plan designed for the child.

Vocational Training
ASD are lifelong disorders that impact on the ability of individuals to obtain employment, care for themselves and live independently. As a result, many individuals with autism require some form of community support. Projects have been established that involve autistic people living with more or less intensive supervision by a professional. Specialist-supported employment services have been designed for high-ability adults with autism; approximately 68% of clients found employment (Howlin, Alcock, & Burkin, 2005; Mawhood & Howlin, 1999).

Medication
There is no drug that has been shown to have a consistent and worthwhile effect on the core symptoms of autism. Accordingly, treatment plans should not involve any presupposition that medication should be used. Nevertheless, drugs can be useful in modifying some specific behaviors and hence we review the findings accordingly. When using medication, it is important to select appropriate targets of treatment and to monitor efficacy and side effects on a regular basis. Potential benefits of any medication should be weighed against side effects and risks.

Concern over side effects such as tardive dyskinesia and extrapyramidal symptoms (EPS) of conventional antipsychotics has led to increased use of the newer atypical antipsychotics. Risperidone, the best studied and most often used atypical antipsychotic, has shown superiority to placebo in short-term randomized controlled trials in children and adolescents with ASD (McCracken, McGough, Shah et al., 2002; Shea, Targay, Carroll et al., 2004) and in adults (McDougle, Holmes, Carlson et al., 1998). Maintenance of effect of risperidone over a period of 6 months has been established in placebo-controlled discontinuation studies (RUPP, 2005b; Troost, Lahuis, Steenhuis et al., 2005). Risperidone in low daily doses (0.5–1.5 mg for most subjects) appears to be effective in decreasing irritability, temper tantrums, hyperactivity, aggression and self-injurious behavior in ASD, but without convincing positive effects on the core symptoms. Although risperidone is usually well tolerated, except for mild initial sedation, and the risk of EPS is low, a serious limitation of the use of risperidone is the risk of significant weight gain. Weight gain should be monitored each week, and an increase of 3 kg or more in the first month of treatment should lead to discontinuation. Less well studied in ASD are other atypical antipsychotics such as olanzapine, quetiapine, ziprasidone and aripiprazole.

Fluoxetine treatment has been studied in children and adults with ASD and was shown to be effective in reducing compulsive and repetitive behaviors, stereotypes and rituals (DeLong, Teague, & McSwain, 1998; Hollander, Phillips, Chaplin et al., 2005). Fluoxetine was generally well tolerated; adverse effects included agitation, hyperactivity, hypomania and disinhibition. Similar treatment effects were obtained with fluvoxamine in a controlled trial in adults with autism (McDougle, Naylor, Cohen et al., 1996b). However, a trial with fluvoxamine in children and adolescents with autism was unable to establish a significant treatment response but documented a high rate of side effects and adverse behavioral activation (McDougle, personal communication).

A recent large controlled trial with methylphenidate in children with ASD and symptoms of ADHD found that the clinical response was lower and that the risk for adverse effects such as irritability was increased, compared to that in children with typical ADHD. When using low dosages (0.125–0.5 mg·kg$^{-1}$ per day) and careful clinical monitoring, treatment with stimulants none the less may be of substantial clinical value in individuals with ASD and symptoms of ADHD (RUPP, 2005a).

Mood stabilizers such as lithium and valproic acid have been used to treat affective instability, impulsivity and aggression in individuals with ASD (Hollander, Dolgoff-Kaspar, Cartwright, Rawitt, & Novotny, 2001; Kerbeshian, Burd, & Fisher, 1987; Plioplys, 1994). Anticonvulsants are important in the management of the seizure disorders in ASD.

Buspirone, an agonist of the serotonin 5T$_{1a}$ receptor, may be useful in improving anxiety, temper tantrums, and aggression associated with ASD in regimens of 10–45 mg·day$^{-1}$ (Buitelaar, van der Gaag, & van der Hoeven, 1998). Propranolol, a lipophilic beta-blocker, may be used to treat aggression, self-injury and impulsivity in developmental disorders (Ratey, Bemporad, Sorgi et al., 1987a; Ratey, Mikkelson, Sorgi et al., 1987b). It is necessary to obtain an electrocardiogram (ECG) before treatment starts and to monitor pulse rate and blood pressure regularly because of the risk of bradycardia and hypotension.

Ineffective or Unproven Treatments
Probably more often than in any other psychiatric condition of childhood and adolescence, parents of children with ASD tend to seek out complementary and alternative medical (CAM) treatments both for the core symptoms and for comorbid symptoms (Levy & Hyman, 2003). It is important to respect parents’ views, critically discuss the merits and risk–benefit ratio of these treatments and advise the family on treatments with and without supporting evidence, and for families choosing CAM treatments, assisting to determine if the treatment is helpful by gathering clinical outcome data (Aman, 2005). Among the ineffective or unproven treatments are facilitated communication, administration of secretin (a gastrointestinal peptide hormone with putative effects on the brain), auditory integration training, treatment with vitamin B$_6$ and magnesium, gluten- and casein-free diets, essential fatty acid treatment, Son-Rise Program and cranial osteopathy (Aman, 2005; Howlin, 2005).

Etiology
Environmental Risk Factors
Although the high heritability of ASD might seem to imply that environmental risk factors will be unimportant, this does...
not necessarily follow (Rutter, 2006; Rutter, Moffitt, & Caspi, 2006). If the rise in the rate of diagnosed ASD represents a true rise in incidence (which remains quite uncertain), there would be the implication that some new (or increased) environmental risk factor was operative. If so, it is likely that the risks would stem from some prenatal or early postnatal factor, most likely of a physical nature. The large-scale Norwegian prospective longitudinal study of a cohort of some 100,000 being followed from pregnancy provides the possibility of identifying any such risks (Magnus, Irgens, Haug et al., 2006; Rønningen, Paltiel, Meltzer et al., 2006). They could be in toxins, pollutants, diet or immunological abnormalities.

An area of uncertainty includes the possibility of abnormalities in the immune system in ASD. Studies of immunological function reveal a wide range of abnormalities, including decreased cellular immune capacity, decreased plasma complement component C4b, and increased humoral immunity and autoantibody responses (Hornig & Lipkin, 2001). These abnormalities of the peripheral immune system have been linked to the hypothesis that children with ASD are predisposed to abnormal responses to viral infections either through the establishment of persistent infections or a virally triggered autoimmune diathesis. However, immune dysfunction in ASD has not been established or corroborated by measures more directly related to the brain, such as by studies of cerebrospinal fluid (CSF) or at autopsy. Thus, it is unclear whether systemic immune dysfunction is truly common in ASD (Murch, 2005).

With respect to possible environmental risk factors, it will also be necessary to consider the possible role of gene–environment interaction (Hornig, Chian, & Lipkin, 2004; Rutter, 2006; Rutter, Moffitt, & Caspi, 2006).

There is a long-standing interest in obstetric risk factors, and recent studies have confirmed that individuals with autism have more obstetric risk factors than controls, as evidenced, for example, by the presence of fetal distress, being delivered by elective or emergency Cesarean section, more frequent breech presentations, and lower Apgar scores at 1 or 5 min (Glasson, Bower, Petterson et al., 2004; Larsson, Eaton, Madsen et al., 2005). Cases with PDD-NOS or Asperger disorder had lower risk scores than subjects with typical autism, and higher than controls (Glasson, Bower, Petterson et al., 2004). However, because unaffected siblings of cases were more similar to cases than to control subjects in their profile of complications, the higher rate of obstetric complications may reflect underlying genetic vulnerability or an interaction between genetic factors and the environment. Other data support the view that obstetric hazards are, at least in part, consequences of genetically influenced abnormal prenatal development rather than independent etiological factors (Bolton, Murphy, Macdonald et al., 1997). For example, postmortem studies of autism have not detected lesions typical of perinatal brain damage, and studies of autistic singletons have found that the number of minor congenital anomalies is higher in probands than in siblings or normal controls, which suggests that the early in utero development of autistic individuals may be suboptimal (Bailey, Phillips, & Rutter, 1996).

**Developmental Perturbations**

Traditionally, studies of non-genetic influences on causal pathways for disorders have focused on specific environmental hazards of some kind. However, as Molenaar, Boomsma, and Dolan (1993) pointed out, it is also necessary to consider the possibility of chance causing developmental perturbations that increase the risk of some maladaptive outcomes. Three sets of findings suggest that such perturbations may contribute to the liability to autism. First, surveys indicate that 5–10% of individuals with ASD have some form of chromosomal anomaly (Autism Genome Project Consortium, 2007). However, apart from duplications of 15q11–q13, typically of maternal origin (which occur in 1–3% of cases), the anomalies span virtually all chromosomes and offer no good leads for the location of susceptibility genes. Nevertheless, the raised rate of anomalies relative to the general population does suggest some type of developmental perturbation. Perhaps the significant feature lies in the suggestion that development has gone awry, rather than the specific form of the anomaly. The parallel would be in the increased rate of minor congenital anomalies associated with an increased risk for many types of psychopathology. Second, the large-scale Autism Genome Project Consortium (2007) study found an increased rate of copy number abnormalities (CNAs) – such as exemplified by the chromosome 15 duplication. For a variety of conceptual and technical reasons, it is difficult to provide a confident quantitative estimate of their frequency, but a figure of about 10% seems likely for families in which all affected individuals share the same possibly detrimental abnormality. Third, a recent large-scale study of Israeli army conscripts found an association between autism and raised paternal age (Reichenberg, Gross, Weiser et al., 2006). The finding has yet to be replicated, but it too suggests that a focus on developmental perturbations might prove profitable.

**Neural Basis of Autism**

The last decade has seen an enormous proliferation of studies seeking to identify the neural basis of autism (for reviews see DiCicco-Bloom, Lord, Zwaigenbaum et al., 2006; Moldin & Rubenstein, 2006; Moldin, Rubenstein, & Hyman, 2006). Attention has been drawn to the possible role of mirror neuron dysfunction because these neurons respond to perceived mental states (Dapretto, Davies, Peifer et al., 2006). A range of animal models has been proposed but, at least so far, their relevance to autism seems quite uncertain. Thus, there was excitement over the social differences between montane and prairie moles, with findings pointing to the role of oxytocin and vasopressin (Young & Wang, 2004) but knockout mice display social amnesia, which is not what is found in autism. Numerous leads are worth following up but they have yet to deliver; accordingly, we focus primarily on human studies.

**Head Circumference**

One of the most consistent anatomical findings in autism research is an enlarged head circumference (Bailey, Phillips, & Rutter, 1996; DiCicco-Bloom, Lord, Zwaigenbaum et al., 2006;
Fombonne, Rogé, Claverie, Courty, & Frémolles, 1999). Brain size is approximately normal at birth but increases in the preschool years so that by 3–4 years of age, the average brain size in individuals with autism increased by about 10%. The evidence with respect to older ages is more limited but it seems that brain size remains increased to some extent (Palmen, Hulshoff Pol, Kemner et al., 2005) but probably to a lesser degree. The available evidence suggests that the increased brain growth affects both gray and white matter, but the findings are inconsistent and inconclusive (Palmen, Hulshoff Pol, Kemner et al., 2005). Whether or not it reflects an excess of neurons, and/or reduced synaptic pruning, remains uncertain (Keller & Persico, 2003). It also remains uncertain how far the macrocephaly is proportionate or disproportionate to overall body growth (Torrey, Dhavale, Lawlor, & Yolkien, 2004). Accordingly, it remains unclear what role the increased rate of brain growth in early life plays in the pathogenesis of autism.

**Neuroimaging**

Structural neuroimaging studies in individuals with autism converge to show that the brain is abnormally large in some, but not all children with autism (Lainhart, 2006; Palmen & van Engeland, 2004). Advances in structural brain mapping have been used to investigate morphological connectivity. Structures in the brain whose functions are tightly coupled grow and develop in unison. Children with autism show evidence of marked disruption in relationships between cortical–subcortical and cortical–cortical gray matter volumes (McAlonan, Cheung, Cheung et al., 2005). Correlations between frontal lobe gray matter volume and temporal lobe, parietal lobe and subcortical gray matter have been found to be aberrant in autistic children.

Functional MRI (fMRI) studies examine functional connectivity in the brain by measuring the correlation between the amount of activation of two brain areas during task performance measuring social attribution, sentence comprehension and working memory (Castelli, Frith, Happe et al., 2002; Just, Cherkassky, Keller, & Minshew, 2004; Koshino, Carpenter, Minshew et al., 2005). Aberrant or reduced connectivity patterns have been found. Other fMRI studies of brain function during tasks or in response to visual and auditory stimuli show evidence that individuals with autism appear to be using different cognitive strategies and some different brain areas to process information (Gervais, Belin, Boddart et al., 2004; Hadjiklani, Joseph, Snyder et al., 2004; Muller, Kleinhans, Kennotsu, Pierce, & Courchesne, 2003; Pierce, Haist, Sedaghaei, & Courchesne, 2004; Piggott, Kwon, Mobbs et al., 2004; Schultz, Gauthier, Klein et al., 2000; Wang, Ting, Dapretto et al., 2004; Williams, Goldstein, Carpenter et al., 2005).

**Neuropathology**

A review of postmortem studies in autism revealed that approximately 40 brains have been studied (Palmen & van Engeland, 2004) with an emerging pattern of increased cell packing in the limbic system, reduced numbers of Purkinje cells in the cerebellum, age-related changes in cerebellar nuclei and inferior olives, cortical dysgenesis and increased brain weight. However, all reported studies had to contend with the problem of small sample sizes, the use of quantification techniques not free of bias and assumptions, and high percentages of autistic subjects with co-occurring intellectual impairment and epilepsy (at least 70% and 40%, respectively).

Cortical minicolumns have been measured in postmortem brains of autistic persons and compared with non-affected controls. Minicolumns consist of approximately 80–100 neurons arranged radially like beads on a string and are believed to comprise the smallest level of functional organization in the cortex cerebri (Mountcastle, 1997). Minicolumnar width, interneuronal distance, peripheral neuropil space and compactness were evaluated and it was found that minicolumns in the brains of autistic persons were more numerous, “narrower” with less peripheral neuropil space and increased spacing among the constituent cells (Casanova, 2004; Casanova, Buchhoeveden, Switala et al., 2002; Casanova, van Kooten, Switala et al., 2006). The authors conjecture that these micro-architectural abnormalities originate during prenatal development and reflect progressive encephalization, defined as a disproportionate increase in white matter relative to gray matter.

**Neurophysiology**

Along with epilepsy (Rutter, 1970), one of the first indications of abnormal brain function in autism came from EEG studies. With repeated or extensive testing, EEG abnormalities are found in about 50% of individuals with autism (Minshew, 1991). Although regional differences in EEG power have been reported, there is no evidence of regional localization of abnormalities (Dawson & Osterling, 1997).

For many years event-related potentials (ERPs) were the only means available to investigate brain function during specific cognitive tasks (Burack, Enns, Stauder, Mottron, & Randolphe, 1997). Event-related evoked potentials and magneto-electro-encephalography provide information about temporal and spatial aspects of brain functioning in autism. Studies using these methods show that individuals with autism have slowed face processing, decreased sensitivity to whether a face is upright or inverted, less effect to repeated presentation of a face, abnormal brain response to eye-gaze detection, abnormal hemispheric lateralization and different localization of processing within the cortex (Bailey, Braeutigam, Jousmaki, & Swithinby, 2003; Grice, Halir, Farroni et al., 2005; McPartland, Dawson, Webb, Panagiotides, & Carver, 2004). Behavioral studies have shown subjects with ASD to have a variety of abnormalities in attentional processing (Allen & Courchesne, 2001). Several ERP studies focused on attentional and perceptual processing of visual stimuli in persons with autism. Although some studies reported that subjects with ASD show less long-latency activity (mostly reflected in P3 peak) in response to infrequently occurring stimuli within an odd-ball paradigm, these findings are not consistent (Kemner & van Engeland, 2006). A serious problem in the interpretation of these studies is that subjects were not matched for IQ and age, and there is evidence that the P3 peak is sensitive to these
variables (Polich & Herbst, 2000; Wahlovd & Fjell, 2003). The only study in which subjects were age and IQ matched (Kemner, Verbaten, Cuperus, Camfferman, & van Engeland, 2004) did not find differences between persons with autism and control groups in this respect. Additionally, there are no indications that individuals with autism have a decreased processing capacity (Hoeksma, Kenemans, Kemner, & van Engeland, 2005). ERP studies of the ability to focus attention on a specific channel of information (selective attention) failed to find consistent evidence of abnormal attentional processing in subjects with autism (Ciesielski, Courchesne, & Elmasian, 1990; Hoeksma, Kenemans, Kemner et al., 2005).

Recently, several studies have indicated that the atypical processing of visual stimuli in autistic children and adolescents might occur at a perceptual level, because ERP studies have provided evidence that activity over the modality-specific cortex is already abnormal at an early stage of processing (Boeschoten, Kemner, Kenemans, & van Engeland, 2007; Hoeksma, Kenemans, Kemner et al., 2005; Kemner, Verbaten, Cuperus et al., 2004; Verbaten, Roelofs, van Engeland, Kenemans, & Slanger, 1991). The authors conjecture that this abnormal brain activation might be related to the spatial frequency content of the visual stimuli and a decreased specialization of the visual brain pathways for spatial frequency processing (Kemner & van Engeland, 2006).

Other studies have examined the processing of auditory stimuli in autism. These studies found evidence that children with autism have neural-based impairments in automatically orienting to speech-like sounds but not to non-speech sounds (Ceponiene, Lepistö, Shestakova et al., 2003). Adults with autism may have impairments in one of the earliest levels of cortical speech processing, automatic detection of change in speech (Kasai, Hashimoto, Kawakubo et al., 2005). In noisy environments, individuals with autism appear to have neural-based deficits in recognizing and understanding speech and attending to socially relevant sounds (Alcantara, Weisblatt, Moore, & Bolton, 2004; Teder-Salajari, Pierce, Courchesne, & Hillyard, 2005). Involuntary orienting to sound depends on neural communication in a widely distributed network, involving auditory cortex, multimodal sensory areas in the parietal lobe, and dorsolateral prefrontal cortex.

**Neurochemistry**

The most robust and well-replicated biological finding is the 25–50% increase in levels of serotonin in blood platelets in subjects with autism (for reviews see Lam, Aman, & Arnold, 2006; McDougle, Erickson, Stigler, & Posey, 2005) and the broader phenotype (Mulder, Anderson, Kema et al., 2004). The mechanism of the alteration remains unknown. Additional factors that may determine serotonin levels in blood are pubertal status, race and use of medication (McBride, Anderson, Hertzig et al., 1998). Abnormalities of central rather than peripheral serotonin systems matter when considering the pathophysiology of ASD. Acute depletion of dietary tryptophan (the dietary precursor of serotonin) leads to a forced lowering of serotonin in the brain and worsening of autistic symptomatology (McDougle, Naylor, Cohen et al., 1996a; McDougle, Naylor, Cohen et al., 1996b), underlining the role of central serotonin in the expression of the syndrome. Further, positron emission tomography (PET) using a tracer for the synthesis of serotonin in the brain found indications for an abnormal serotonin synthesis capacity over time in autism (Chugani, Muzik, Rothermel et al., 1997). Because serotonin acts as a growth factor and regulator of early neuronal development before assuming its role as a neurotransmitter in the mature brain, this suggests that developmentally dysregulation of serotonin synthesis may be involved in the pathogenesis of ASD (Whitaker-Azimitia, 2001).

Research into the dopamine neurotransmitter system by measuring levels of dopamine’s major metabolite homovanillic acid (HVA) in blood, urine and CSF did not reveal significant differences (McDougle, Erickson, Stigler et al., 2005). A PET scan study showed reduced accumulation of dopamine in the prefrontal cortex of subjects with autism (Ernst, Zametkin, Matochik, Pascualvaca, & Cohen, 1997). There are no notable abnormalities in neurochemical indices of the norepinephrine transmitter system in ASD.

Little research has been performed examining the role of glutamate and gamma-aminobutyric acid (GABA) in ASD. Glutamate is the primary excitatory transmitter and is crucially involved in neuronal plasticity and higher cognitive functions (Purcell, Jeon, Zimmerman, Blue, & Pevsner, 2001), whereas GABA is the primary inhibitory transmitter in the brain. Measuring peripheral levels of these transmitters has produced conflicting findings, but postmortem studies found indirect evidence for altered status of glutamate and GABA receptors in the hippocampus (Fatemi, Halt, Stary et al., 2002).

Animal work has led to interest in the role of neuropeptides such as endogenous opioids, oxytocin and vasopressin in regulating social behavior. Nevertheless, neither evaluations of levels of opioids in body fluids nor clinical trials investigating the effects of opioid receptor antagonists lend support for a key role of opioids in the pathophysiology of ASD (Tordjman, Anderson, McBride et al., 1997; Willemsen-Swinkels, Buitelaar, Nijhof, & van Engeland, 1995). Children with autism were shown to have lower plasma levels of oxytocin (Green, Fein, Modahl et al., 2001) but intravenous administration of oxytocin did not lead to changes in the core symptoms of ASD (Holland, Novotny, Hanratty et al., 2003). Research on melatonin and secretin does not support a role of these neuropeptides in the pathophysiology of ASD (Esch & Carr, 2004; Nir, Meir, Zilber et al., 1995).

Findings of early abnormalities in the development of the brain in ASD, and a potential contribution therein of neuropeptides and/or neurotrophins, led to an analysis of peptide concentrations in frozen blood samples of neonates subsequently diagnosed with ASD and control samples (Nelson, Grether, Croen et al., 2001; Nelson, Kuddo, Song et al., 2006). Concentrations of some neurotrophic factors were higher in subjects with ASD and with intellectual disability but they did not differentiate these two groups; these results await replication and extension.
Genetics

Data from several epidemiological twin and family studies provide substantial evidence that ASD are amongst the most heritable complex disorders (Rutter, 2000). The concordance rate in monozygotic (MZ) twins is 60–90% and the autism rate in siblings is about 5% (Bailey, Palferman, Heavey et al., 1998b; Szatmari, Jones, Zwagenbaum, & MacLean, 1998). Folstein and Rutter’s (1977) twin study was remarkable for indicating that the phenotype associated with a genetic predisposition to autistic disorder included cognitive and social difficulties extending beyond autism as traditionally diagnosed. In a follow-up into adulthood of this original sample, the majority of non-autistic MZ cotwins showed social and/or cognitive abnormalities, with the most severely affected individuals having more well-defined ASD (Bailey, Le Couteur, Gottesman et al., 1995). A parallel family history study found similar social and/or cognitive abnormalities at a higher rate in relatives of probands with autism compared to relatives of probands with Down syndrome (Bolton, Macdonald, Pickles et al., 1994). In fact, individuals with autism represented only a small proportion of all the individuals showing phenotypic expression.

Since then numerous family studies have reported mild autism-related behavioral phenotypes manifesting as social, communicative and repetitive impairments, either alone or in combination in first-, second- or third-degree family members of autistic probands (for a review Bailey, Palferman, Heavey et al., 1998b). Some relatives of autistic individuals show a lack of interest in others, or a lack of socioemotional responsiveness, whereas others may show socially odd behavior, a history of language delay, circumscribed interests, rigidity, obsessive-compulsive and repetitive behavior and a lack of seeking change (Bailey, Palferman, Heavey et al., 1998b; Lainhart, 1999; Piven, Palmer, Jacobi, Childress, & Arndt, 1997; Starr, Berument, Pickles et al., 2001). It is estimated that this “broader phenotype” or “milder variant” can be found in 20–30% of the relatives of autistic individuals (de Jonge, 2006; Fombonne, Bolton, Prior, Jordan, & Rutter, 1997). The highest rates of “broader phenotype” characteristics were found in multi-incidence families (Lainhart, 1999; Piven, Palmer, Jacobi et al., 1997; Szatmari, Bryson, Streiner et al., 2000).

Clearly, genetic risk ASD is not conferred in a simple Mendelian fashion. Statistical modeling of the data derived from twin and family studies has implicated the involvement of several genes interacting with one another to produce the clinical phenotype that is a multilocal model with epistasis. Latent class analysis of twin and family data has suggested that as few as 3–4 predisposing genes may be involved (Pickles, Bolton, Macdonald et al., 1995), although the presence of as many as 15 loci has been proposed (Risch, 1999). The clinical complexity and heterogeneity of the autism phenotype are also likely to reflect the presence of genetic heterogeneity (different genes or combination of genes may be implicated in different families). Other factors, such as sex and environmental influences, may also affect phenotypic expression. Moreover, epigenetic mechanisms such as DNA methylation defects or abnormal imprinting have also been proposed as possible factors in the etiology of autism (Abildormaleky, Smith, Faraone et al., 2004; Lamb, Barnby, Bonora et al., 2005).

Although autism and ASD exhibit high heritability, the identification of susceptibility genes has so far been elusive. The major challenges are represented by the complex inheritance pattern, the likely involvement of multiple genes each having a moderate effect on disease risk, the high degree of heterogeneity and the lack of clear pathophysiological clues that could suggest particularly strong candidate genes. Therefore, the typical approach adopted by many research groups has been to perform genome-wide scans for linkage. This entails screening large samples of affected sib pair (ASP) or affected relative pair (ARP) families using microsatellite markers, in order to identify chromosomal regions that co-segregate with the phenotype within families.

During the last decade at least a dozen genome scan studies of ASD have been published (for reviews see Autism Genome Project Consortium, 2007; Bachelli & Maestrini, 2006; Coon, 2006; Trikalinos, Karvouni, Zintzaras et al., 2006), each identifying several chromosomal regions of suggestive linkage. Although no region of strong evidence of linkage has been consistently replicated, the overlap in linkage findings from these international family collections points to a few regions that are likely to harbor autism susceptibility genes. A region on chromosome 7q, designated as AUTs 1, stands out as the region with the greatest concordance of findings (Bachelli & Maestrini, 2006; IMGSAC, 1998; Lamb, Barnby, Bonora et al., 2005). Another region of interest is on chromosome 2q, representing the strongest linkage finding obtained in the expanded IMGSAC data set of 219 ASP (IMGSAC, 2001; Lamb, Barnby, Bonora et al., 2005), which overlaps with linkage results reported by three additional studies (Buxbaum, Silverman, Smith et al., 2001; Philippe, Martinez, Guilloud-Bataille et al., 1999; Shao, Raiford, Wolpert et al., 2002). Similarly, overlapping linkage findings have been reported for a region on chromosome 17q, although these were not confirmed in the large-scale consortium study. However, it did produce suggestive evidence of linkage in the vicinity of 11q12–13 (Autism Genome Project Consortium, 2007).

The overlaps in findings of these scans are somewhat encouraging, providing a first step towards the identification of autism susceptibility loci. However, there are some limitations in the interpretation of these results. Each genome scan has shown little evidence for strong linkage signals, the loci found so far are rather broad, containing many genes, and most of the linkage results do not converge on the same linkage peaks (Bachelli & Maestrini, 2006). The lack of reproducibility between linkage studies suggests that autism may involve extensive genetic heterogeneity and/or many interacting genes of weak effect. The identification of many potential susceptibility loci and the failure to narrow down the chromosomal intervals using linkage or cytogenetic approaches have prompted many groups to undertake association studies of candidate genes.
Candidate genes are genes thought to be involved in relevant pathophysiological processes (functional candidates), or genes within the chromosomal interval identified by linkage analysis or close to cytogenetic rearrangements associated with autism (positional candidates). In the last decade, over 100 positional and functional candidate genes have been studied, such as the neuroligin genes, the serotonin transporter gene, the Reelin gene and several GABAergic genes (for a review see Bachelli & Maestrini, 2006). Up until now the candidate gene studies are characterized by a lack of reproducibility because of similar problems to those encountered in linkage analysis. A clear involvement of any gene in autism has not yet been conclusively identified (Bachelli & Maestrini, 2006).

**Future Directions**

Autism is a disorder with a strong genetic basis. It is unclear whether the 10% variance that is not genetic is due to stochastic factors, measurement error, environmental influence, mitochondrial genomic variation or other non-Mendelian genetic influences. There is no doubt that a feeling of disappointment in the field of autism genetics because definitive answers have not come more easily. However, there are several reasons to put this aside and push forward:

1. Autism remains strongly genetic, and even – if possible – more complex than originally estimated.
2. The development of novel, and more accurate high-throughput approaches, together with access to data from large international patient samples and bioinformatics resources is now providing the opportunity to generate an unprecedented amount of information.
3. Identification of susceptibility genes will lead directly to studies of protein function in single cell systems, and might possibly lead to the development of animal models of autism.
4. These cell systems seen in animal models may provide an opportunity to study the neuropathological and neurophysiological consequences of gene activity in the developing organism and to develop novel psychopharmacological strategies.

There have been significant advances in our understanding of some central aspects of developmental psychopathology in ASD. Nevertheless, there is still a need to identify more accurately those abnormalities that are potentially specific as well as to understand the possible interactions among different processes early in development.

Functional imaging and evoked electrocortical response techniques provide a means to move beyond localization of abnormal brain activity to an understanding of underlying mechanisms such as functional coherence in neuronal networks and connectivity.

There is growing evidence that early detection of ASD at 2 years of age is feasible and there are great expectations from the benefits of intensive early interventions for children with ASD. The available evidence on the effectiveness of early intervention approaches is not conclusive, and further randomized and large-scale studies and follow-up measurements are required. Questions to be answered are about intensity and dosage (is there really a threshold at 20 h per week one-to-one contact with the child?; does this apply to all children, or is there a subgroup for which lower-intensity treatment is sufficient?), timing, cost-effectiveness, feasibility and availability of high-intensity treatment, the specific behavioral domains improved, and the magnitude and persistence of change induced.

In clinical work, difficulties in dissemination and availability of services and facilities are often more limiting than the absence of knowledge. Continued parent and professional advocacy for clinical, educational and vocational services remains necessary, and service models should be modified to address the needs of individuals, from younger children to older adults and their families. The importance of multifaceted individual treatment plans, specific to a particular child and family and supported by knowledgeable clinicians and educators, must continue to be recognized, as models for evidence-based and manualized interventions are disseminated.

Speech, Language and Communication

The distinction between speech, language and communication may be illustrated by three child cases. Emma is a lively and engaging 9-year-old who has difficulty making herself understood because her production of speech sounds is very unclear. However, she demonstrates normal language skills: she understands what others say to her, and can express herself in writing using long and complex sentences. Her ability to communicate is hampered by her speech difficulties, but she enjoys interacting with others, and when people fail to understand her, she supplements her utterances with gesture and facial expression to get her message across.

Thomas is a 6-year-old who has no difficulty in producing speech sounds clearly, but his language skills are limited, as evidenced by his use of simple and immature sentence construction. Instead of saying “I’d like a drink” he says “Me want drink.” However, although his language is far more simple than that of other 6-year-olds, he does use it to communicate with other children and adults. In contrast, 4-year-old Jack produces a great deal of complex, fluent and clearly articulated language, but he does not use it to communicate effectively. Thus, his opening gambit to a stranger might be to say: “In Deep Space Nine you can’t get to level 6 until you have killed all the foot soldiers, but if you get to level 6, you have to first destroy the klingons before you can enter the palace of death.”

One way of depicting the relationship between speech, language and communication is shown in Fig. 47.1, where language is a subset of communication and speech is a subset of language. Communication is defined by McArthur (1992, p. 238) as “the transmission of information (a message) between a source and a receiver, using a signaling system.” The primary means of communication between humans is through language, but communication also encompasses other means of signaling meaning, such as facial expression, bodily gesture and non-verbal sounds. Language differs from these other communicative modes; it is a complex formal system in which a small number of elements are combined in a rule-based manner to generate an infinite number of possible meanings. Most human language is expressed in speech (i.e., meanings are represented by words that are composed of a small set of speech sounds, or phonemes). Where learning of oral language is compromised because a child is deaf, manual (sign) languages have evolved, showing similar structural characteristics to spoken languages. In addition, oral language can be expressed in written form. Language involves more than speech, and communication involves more than language. However, it is possible for someone to speak without producing language (e.g., when a person utters meaningless gobbledegook), and it is possible for someone to produce utterances that obey the formal rules of language, yet communication is not achieved, as in the case of Jack. In evaluating children with impairments, it is important to keep these three levels in mind, and to recognize that a problem at one level does not necessarily entail a problem at another.

In this chapter we make a broad division between disorders affecting speech, and those affecting language and communication. This distinction has some similarity with the distinction made in DSM-IV-TR (American Psychiatric Association, 2000) between phonological disorder (315.39) and language disorder (315.31), but the coverage is broader. Among speech disorders, we cover disorders affecting fluency, voice and prosody as well as problems of speech sound production that may have a neurological basis. For language and communication disorders, we focus heavily on specific language impairment (SLI), which is analogous to the DSM language disorder category, but we also consider other conditions required for a differential
diagnosis, including acquired epileptic aphasia, autistic disorder and selective mutism.

General Principles of Assessment

In most instances, detailed assessment of the speech and language system will be carried out by a specialist speech-language therapist, who will have extensive knowledge of linguistics and language development, the anatomy and physiology that support the language system, and access to a variety of assessment and intervention techniques. With regard to communication, the primary decisions for the practitioner to make at initial assessment are:

1. Is the child’s communication development delayed or disordered?
2. What aspects of communication are causing the most concern?
3. Is referral to speech-language therapy warranted?

The first port of call in the assessment process is the case history. This will give the practitioner an opportunity to explore with the child’s parents who is concerned about communication, and precisely what they are concerned about. Although many parents will be concerned about their child’s language development, others may not be aware of difficulties with communication. These parents may not see language as the central problem, but will voice concerns about behavior, social skills and learning that may be related to underlying language difficulties.

As part of the case history, it is essential to obtain from parents clear examples of what motivates the child to communicate and how the child achieves communication. For example, does the child communicate only to get his or her basic needs met? Does the child communicate to show others things that interest him or her? Does the child use words or phrases? If not, does the child gesture, vocalize and/or point in an effort to get the message across? In addition to concrete examples of the types of communication the child produces, it is also important to ascertain the types of communication the child can understand. Does the child follow an adult’s point or eye gaze? Can he or she follow simple verbal instructions out of context? For more able children this may not pose a problem, but they may have difficulty following a story or getting the point of a joke.

Once the practitioner has gained an impression of the child from the parents, it will be necessary to determine directly the child’s current level of functioning. Throughout the rest of this chapter, we give specific signposts to impairment in speech, language and broader communication, and suggest standardized assessments in each of these domains that can assist in the diagnostic process (Table 47.1). However, it is usually preferable to start by observing the child’s communication in a less structured setting. This can be achieved by videoing the child playing with his or her parents or siblings in the clinic. If the child has some verbal language, this play session can be supplemented by asking the child to recall a favorite story, computer game or television program.

During these informal tasks, the practitioner can make a number of important observations. The first concerns the child’s expressive language output. How long and grammatically complex are the child’s utterances? How rich is the child’s vocabulary? Does he or she struggle to find the words for common objects? Does he or she use gestures and facial expression? Is the speech fluent, or is the child’s speech peppered with hesitations and repetitions? What is the child’s voice quality like? Is he or she shouting and hoarse, or whispering inappropriately? Is the child intelligible, or are there numerous speech errors that impede understanding? Does the child tell a story as a coherent sequence of events, or does he or she get muddled and leave important events out?

The next set of observations concerns the child’s understanding, which may be more difficult to gauge in this setting. Nevertheless, it can be revealing to observe how the child responds to the questions and comments of others. Are the answers appropriate to the questions? Does the child follow adult directions? Does the child understand the premise of a story or does he or she misinterpret key events? Does the child appear to understand the gestures and facial expressions of others? Can the child listen while engaged with something else, or must the adult focus his or her attention before speaking?

Finally, these informal interactions enable the practitioner to observe other important behaviors. How and why does the child engage with the other people in the room? Does he or she look up when called? Is the child’s play creative and imaginative, or destructive and repetitive? Can the child stick with an activity, or is his or her attention span unduly short? Is the child frustrated when he or she is not understood? Does he or she try again? Does the child recognize when he or she has not understood something and ask for clarification? Is the child anxious, or does he or she quickly adjust to the new situation?

In combination with the case history, this set of observations should provide the practitioner with a working hypothesis of the child’s strengths and weaknesses, which will guide the assessment process (see chapters 19 and 21).

Speech Disorders

Speech refers to the production of oral language, which is achieved by modifications to the vocal tract while a stream of air is breathed out from the lungs. Speech difficulties in children are not difficult to detect, but accurate diagnosis requires specialist assessment by a speech and language therapist. The main types of difficulty that are encountered are those affecting the distinctive production of speech sounds, fluency of connected speech, voice, and prosody (i.e., speech melody and intonation).

Differential Diagnosis of Speech Sound Disorders
All spoken languages encode meaning in terms of a small set of vowels and consonants: in standard British English there are 24 consonants and 20 vowels that can be combined to yield thousands of words. When a child’s speech is difficult

</table>
to understand, analysis of the pattern of errors will be helpful in distinguishing whether the difficulty is the result of a structural or motor impairment affecting the articulatory apparatus (i.e., a dysarthria) or whether other explanations need to be sought (Dodd, 2005). Usually, dysarthria will be accompanied by other evidence of physical or neurological impairment, and the production of speech sounds will be distorted or labored.

**Phonological Disorder**

Contrary to popular belief, most childhood problems with speech production do not have a physical basis. For many years there was a belief that children’s speech difficulties could be caused by “tongue tie,” which could be cured by cutting the frenum. However, surgery is seldom effective in improving speech and it is now recognized that interventions that train children to perceive and produce sounds accurately are more effective. The key point to note is that speech production involves more than articulation: in learning a language, the child has to integrate speech perception with production, and work out which sounds in the language are used to signal contrasts in meaning (i.e., correspond to phonemes). To illustrate the difference between articulation and phonology, consider the following: many native English-speakers have great difficulty in correctly learning to produce the French words “rue” and “roux” distinctively. This is because the vowel contrast in these words does not match the phonemes in English, where there is just one “oo” sound. This has nothing to do with the structure of the articulatory apparatus, and everything to do with perceptual experience of a language, which leads English-speakers to treat all instances of “oo” as one phoneme, where French-speakers divide the vowel space into two phonemes. Most cases of childhood speech production difficulties appear analogous to the problems of the second language-learner: they arise because the child has not learned to categorize speech sounds appropriately, and so may fail to differentiate sounds that are important for signaling contrasts in meaning. Over the years, a variety of terminology has been used to describe such difficulties, including functional articulation disorder and phonological disorder/impairment.

**Developmental Verbal Dyspraxia**

Sitting somewhat uneasily between dysarthria on the one hand, and phonological disorder on the other is the category of developmental verbal dyspraxia, also known as developmental apraxia of speech. An early use of the term was by Morley (1957), who applied it to children in whom the neuromuscular control of the articulators seemed adequate for all purposes except the rapid integrated movements used in speech. Such children might be able to imitate accurately a simple syllable or word, but would make errors if asked to produce longer words or connected sentences. Stackhouse and Wells (1997) noted that production of longer words may be inconsistent as well as inaccurate, so that “caterpillar,” “taperkiller” or “takerpillar.” The term “dyspraxia” is taken from adult neurology where it describes a disorder of planning movement sequences that is not accounted for in terms of lower-level difficulties in executing individual movements. However, it is unclear whether motor programming is at the root of the inconsistent speech difficulties seen in children. Individuals with the clinical picture of developmental verbal dyspraxia often have major problems in perception as well as production of speech sounds, doing poorly on tests that require them to discriminate or classify sounds (Stackhouse & Wells, 1997). Some experts argue that developmental verbal dyspraxia is simply an unusually severe kind of phonological disorder in children, reflecting an underlying difficulty learning the categorization of speech sounds, rather than having motor origins. The jury is still out on this question, not least because different experts use different diagnostic criteria (Forrest, 2003).

One way of bypassing diagnostic difficulties has been to use the more general term “speech sound disorder” (SSD) to encompass all difficulties of speech sound production in children that do not have a physical basis, without needing to specify whether they are motor-based or phonological in origin. Although such “lumping” of disorders might seem likely to obscure important differences between phenotypes, Lewis, Freebairn, Hansen et al. (2004) argued in its favor. They compared family pedigrees of children with verbal dyspraxia and children with other forms of SSD. Verbal dyspraxia showed very high familiality, but the disorder did not “breed true,” and affected relatives were more likely to have other forms of SSD or language impairment than to have verbal dyspraxia themselves. Lewis, Freebairn, Hansen et al. (2004) concluded that the principal difference between children with verbal dyspraxia and those with other SSD was in the degree of genetic loading for disorder.

**Assessment of Speech Sound Disorders**

Coplan and Gleason (1988) provided guidelines to help health professionals decide when to refer a child for speech assessment, based on a parent’s response to the question, “How much of your child’s speech can a stranger understand?” By 2 years, it should be possible to understand at least 50% of what the child says, by 3 years, 75%, and by 4 years the child’s speech should be completely intelligible. Referral should be considered if these cut-offs are not met (see p. 786).

Assessment by the speech-language therapist will involve examination of the articulatory apparatus. A history of difficulty with sucking, chewing, dribbling, licking or blowing should alert the clinician to the possibility of physical impairment, such as submucous cleft palate, or neurological impairment. Where there is facial dysmorphology or evidence of neurological dysfunction, referral to specialist medical services (pediatric neurology, otolaryngology or clinical genetics) is warranted.

The speech-language therapist will construct a phonemic inventory of sounds the child is able to produce and will look for inconsistency of word pronunciations and the presence of “phonological processes” (i.e., consistent error patterns), such as replacing /k/ with /t/ so that “cat” becomes “tat” and
“take” becomes “tate.” Many of these processes are seen in the course of normal phonological development; however, an SSD is diagnosed when such processes continue beyond the normal age, or when there are numerous inconsistencies and atypical phonological processes.

“Phonological processing” is a general term used to cover more subtle difficulties in using phonological information. Phonological awareness in particular is nowadays often targeted in assessment as research has demonstrated links with later literacy difficulties (Snowling & Stackhouse, 2006). This refers to the ability to manipulate the sound segments in the language and includes tasks such as rhyming, segmenting syllables and phonemes in words, identifying initial and final word sounds, and deleting, adding or transposing phonemes in words. Such problems can be seen in children with normal speech sound production but are often also seen in children with SSD, suggesting their difficulties do not involve the physical act of articulating speech, but rather the ability to perceive and categorize different exemplars of the same phoneme (Bird, Bishop, & Freeman, 1995; Stackhouse & Wells, 1997).

An important point to stress is that although speech and language difficulties are not the same thing, they do often co-occur. We therefore recommend that any child who presents with a speech difficulty should have a full assessment of both speech and language.

Prevalence, Causes and Correlates of Speech Sound Disorders

Estimates of prevalence of SSD are hampered by inconsistencies in diagnostic criteria. Gierut (1998) cited a 1994 report from the US National Institute on Deafness and Other Communication Disorders which estimated that phonological disorders affected approximately 10% of preschool and school-aged children, and that in 80% of cases the disorder was severe enough to merit clinical treatment. At 6 years of age, the prevalence of “speech delay” was estimated at 3.8% in a US epidemiological study (Shriberg, Tomblin, & McSweeny, 1999).

Campbell, Dollaghan, Rockette et al. (2003) identified a number of factors that greatly increased the risk of speech sound disorders in preschool children. These included male gender, limited maternal education and a positive family history of speech and language disorder. These authors also suggested that an accumulation of risk factors exerted a greater threat to developmental outcome than individual risks. Children with only one risk factor were 1.7–2.6 times more likely than children who had none of these characteristics to have speech delay at 3 years; children with all three risk factors present were almost eight times more likely to have speech delay at 3 years.

Both family (Lewis, Freebairn, Hansen et al., 2004) and twin studies (Bishop, 2002; DeThorne, Petrill, Deater-Deckard et al., 2006) suggest a strong genetic etiology for SSD. Although verbal dyspraxia can follow an autosomal dominant pattern of inheritance in some families (Hurst, Baraitser, Auger, Graham, & Norell, 1990), in most cases there are numerous genes that contribute to risk of poor speech and language skills, rather than a single genetic mutation. To date, progress in the search for a molecular basis has been limited to one report of linkage to a site on chromosome 3 (Stein, Schick, Taylor et al., 2004).

**Intervention and Prognosis for Speech Sound Disorders**

A variety of techniques may be employed to improve speech intelligibility, and research to date suggests that no single treatment approach is appropriate for all children with SSD (Dodd & Bradford, 2000). Techniques might include using tactile and visual cues to enable children to produce the target sound accurately. This will be combined with repeated practice at producing the target sound in words with corrective feedback. More meta-linguistic approaches involve games and exercises to develop the child’s awareness of meaningful phonemic contrasts (Gierut, 1998).

In a recent meta-analysis of the literature, Law, Garrett, and Nye (2004) found that phonological interventions were generally effective when compared with no treatment. The most effective treatments were those carried out by speech-language therapists, rather than parent-administered treatments, and those that lasted for longer than 8 weeks. Therapist-led treatments may incorporate a variety of techniques, such as “articulation drills” in which the child learns and practices correct production of speech sounds with visual aids such as cued articulation (hand gestures that illustrate the place and manner of articulation) or symbols (pictures of place and manner of articulation). Other techniques (e.g., Metaphon) emphasize a meta-linguistic approach to improving speech production (Howell & Dean, 1994). This treatment teaches sound “concepts” so that children learn, for example, the differences between “short” sounds (/t/ and /d/) and “long” sounds (/s/ and /l/). The therapy also utilizes “meaningful minimal contrasts,” in which the child is required to alter speech production to avoid ambiguity. For instance, if the child is “fronting” (producing /k/ sounds as /t/ sounds), the therapist might construct a game in which the child has to ask for “key” or “tea.” If the child intends to ask for the “key” but the therapist responds with the “tea,” the child is forced to adapt his pronunciation to convey his or her intended meaning. Many therapists will use a combination of techniques depending on the needs of the child, as there is currently no evidence that one method of treatment is more effective than any other method.

The longer-term prognosis for children with isolated phonological impairments is much better than that of language impairment, especially if the phonological difficulties resolve by the time the child starts school. However, the child who starts school with phonological difficulties is at increased risk of long-lasting literacy deficits (Stothard, Snowling, Bishop, Chipchase, & Kaplan, 1998).

Other Types of Speech Disorder

**Fluency Disorders**

Stuttering and stammering are two popular terms for dysfluent speech. Developmental dysfluency is characterized by
involuntary repetitions, blocks or prolongations of sounds, syllables and words in discourse. These may be accompanied by secondary behaviors such as physical tension in the speech musculature, eye blinking or breaking of eye contact, movements of the head and limbs, and emotional reactions to the dysfluency, including anxiety and avoidance of speaking.

Persistent dysfluency is estimated to affect 1% of the population (Yairi & Ambrose, 1999), although many more children produce normal dysfluencies during the preschool years. Like many speech, language and communication disorders, it appears to be strongly familial, and more boys are affected more often than girls (ratio of 1.65:1; Mansson, 2000). Campbell, Dollaghan, and Yaruss (2002) suggest referral to a speech-language therapist if parents report:

1. Frequent part-word dysfluencies;
2. Noticeable physical tension or struggle;
3. Any sign that the child is frustrated or concerned about talking; or
4. Concerns about any other aspect of speech and language development.

The etiology of childhood stuttering appears to be multifactorial, with a significant genetic component (Yairi, Ambrose, & Cox, 1996). An international study by Suresh, Ambrose, Roe et al. (2006) suggested a complex etiology, with the strongest linkages being found when separate analyses were conducted for males (linkage to chromosome 7, LOD score 2.99) and females (linkage to chromosome 21, LOD score 4.5), and when interactions between sites on different chromosomes were considered.

Stuttering has been associated with early difficulties in language formulation (Bloodstein, 2006) and atypical development of the auditory temporal cortex (Foundas, Bollich, Feldman et al., 2004). Furthermore, comorbidity with speech sound disorders is 30% (Yairi & Ambrose, 1999). Therefore, assessment of broader speech and language abilities is warranted.

Approximately 75% of preschoolers will recover from dysfluency without professional involvement (Yairi & Ambrose, 1999). However, prognosis is poor for those who continue to stutter beyond the age of 7 years (Campbell, Dollaghan, & Yaruss, 2002). There is considerable debate regarding the most appropriate form of intervention. One approach, exemplified by the Michael Palin Centre for stammering in London (www.stammeringcentre.org), focuses on modifying the environment to reduce speaking pressure and working with children and families to reduce anxiety about speaking (for a full description see Rustin, Cook, Botterill, Hughes, & Kelman, 2001). An alternative approach, exemplified by the Lidcombe Programme (http://www3.fhs.usyd.edu.au/asrcwww/treatment/lidcombe.htm), provides direct behavioral modification to reinforce fluent speech. There are few, if any, methodologically sound investigations of treatment efficacy and no studies that we are aware of that explicitly compare the two treatment approaches. However, there is some preliminary evidence that behavioral approaches are effective in reducing dysfluent speech in the preschool years (Jones, Onslow, Packman et al., 2005).

Voice Disorders

A voice disorder, dysphonia, should be suspected when a child speaks with abnormal pitch, loudness and/or hoarseness. These features can have profound effects on how a child is perceived by others and adversely affect socialization. Recent prevalence estimates from a population-based study suggest 6–11% of school-aged children present with dysphonia (Carding, Roulstone, Northstone, & Team, 2006). This is considerably higher than would be predicted from clinical referrals, but this probably reflects widespread lack of recognition of the problem (Boyle, 2000). Gender (male) and older siblings were the most significant risk factors in the Carding, Roulstone, Northstone et al. study. Campbell, Dollaghan, & Yaruss (2002) reported unpublished data from their own sample of 427 clinical referrals to a specialist clinic; 93% of these children had abnormal voice quality associated with laryngeal pathology. The most common pathology was vocal nodules (i.e., mechanical trauma caused by one vocal fold making excessive contact with the other). Surgical treatment is not recommended in such cases, as nodules are likely to return if damaging vocal behavior is not altered. Behavioral treatments can be effective and center on modifying the environment (i.e., reducing competing noise) and training the child to use the voice more appropriately.

Prosodic Disorders

Prosody may be defined as the suprasegmental properties of the speech signal that modulate and enhance its meaning (Paul, Shriberg, McSweeny et al., 2005a). Prosody includes variations in pitch, loudness, duration, rhythm, tempo and pausing, and serves a wide range of grammatical, pragmatic and affective functions. For example, variations in stress and intonation may signal the difference between a noun (con vict) and a verb (con vict), highlight elements within the sentence for attentional focus (the blue book, as opposed to the red one), and convey a speaker’s emotional state.

It is frequently reported that impaired prosody is characteristic of verbal individuals with autistic spectrum disorder (ASD), although it may not be universal. Paul, Shriberg, McSweeny et al. (2005a) reported that 47% of the 30 adolescent and adult speakers with ASD they investigated had prosodic abnormalities. Such abnormalities have a negative effect on how listeners perceive social and communicative competence and pose significant obstacles to social integration and employment (Paul, Augustyn, Klin et al., 2005b).

Disorders of Language and Communication

Components of Language

Competent adults produce language so effortlessly that it is easy to forget just what a complex system it is. All spoken languages can be studied in terms of four levels of description: phonology (speech sounds); semantics (meaning); grammar (formal ways of using word order and inflection); and
pragmatics (use of language to communicate). However, there is considerable variation from one language to another at all of these levels. For instance, Chinese does not have word inflections, whereas Turkish has numerous inflections that are appended to word stems in an agglutinative fashion. Clearly, the task confronting the young language learner is going to be very different in these two languages, and in English, which uses inflections, but much more sparsely than many other languages. As well as the different levels of linguistic representation, language can be divided into expressive (production) and receptive (comprehension) aspects. To be a competent communicator, the child must learn to recognize and produce the distinctive speech sounds in the language (the phonology), establish a “mental lexicon” containing representations of words as phoneme sequences linked to meanings, master the grammatical structure of the ambient language, and learn how to select a message to convey meanings economically and effectively to others (pragmatics). Furthermore, language processing has to be carried out at speed.

**Differential Diagnosis of Specific Language Impairment**

When a child presents with language impairment, the clinician needs to establish whether there is any causal factor present that could explain the language difficulty, or whether the language impairment is part of a recognized syndrome. The majority of cases of language impairment in children have no obvious cause (Shevell, Majnemer, Rosenbaum, & Abrhamowicz, 2000), and occur in the context of otherwise normal development. This is known as specific language impairment (SLI) and also as primary language impairment, developmental language disorder or developmental dysphasia. Before considering the characteristics of SLI we briefly discuss other conditions that need to be considered when making a differential diagnosis.

**Low Non-verbal Ability**

An early step in the assessment of a language-impaired child is administration of a non-verbal IQ test. Cases of intellectual disability (non-verbal IQ more than 2 SD below average) are usually straightforward enough to identify (see chapter 49). However, there are many children with slow language development who do not have a syndrome of intellectual disability, but nevertheless have below-average non-verbal IQ. Traditional definitions of SLI usually require that non-verbal IQ is broadly within normal limits. More stringent definitions also require that there should be a significant mismatch between language ability and non-verbal IQ (equivalent to 1 SD in ICD-10). However, there is increasing disquiet about the use of IQ discrepancy criteria, because these exclude large numbers of children who are not intellectually impaired and yet have evident language difficulties. For instance, if we require there to be a 1 SD difference between a language and non-verbal index, then we would exclude a child with a language level 2 SD below the mean and a non-verbal score 1.3 SD below the mean. This child would not meet criteria for intellectual disability and so would be left in a diagnostic limbo and may be denied access to intervention, even though the profile and severity of language difficulty may be similar to those seen in a child who does meet the discrepancy criterion (Tomblin & Zhang, 1999). Furthermore, twin studies suggest the same genetic risk factors operate for children with language difficulties regardless of their non-verbal IQ (Bishop, 1994). Thus, the logic of distinguishing between verbal and non-verbal IQ is questionable.

**Auditory Problems**

Hearing should always be assessed by an audiologist in a child who presents with language impairment. As neonatal screening programs become more widespread, it is unusual to find an undetected sensorineural hearing loss in a language-impaired child, but one needs to be alert to the possibility of screening errors or a progressive hearing loss. Hearing loss restricted to a specific frequency range is easy to miss, because the child appears responsive to sound, yet crucial information may be lost from the speech signal, leading to a profile of impaired language development that may look similar to SLI (Stelmachowicz, Pittman, Hoover, Lewis, & Moeller, 2004).

It is much more common to find conductive losses in young children with language impairments. However, it is not easy to know how to interpret these. Early studies suggested unusually high rates of language and literacy problems in children who had otitis media with effusion (OME; Holm & Kunze, 1969). OME typically causes a conductive loss of up to 40 dB, and it seems plausible that such a loss might assume significance in a child in the early stages of language learning. However, more recent epidemiological studies have questioned whether OME is a major etiological factor in language impairment (Feldman, Dollaghan, Campbell et al., 2003). A substantial number of children under 5 years of age have undetected and asymptomatic middle ear disease, particularly in the winter months. Prospective studies of children with and without prolonged episodes of OME have found little or no impact on verbal skills, suggesting that language development is resilient in the face of the mild associated hearing losses. OME may assume more importance if it is chronic and persistent (Feldman, Dollaghan, Campbell et al., 2003). However, we would recommend caution in assuming that OME is the main causal factor if it is detected in a child with language impairment.

There is a large body of knowledge on assessment of the integrity of the peripheral auditory pathways in children, but much less agreement concerning diagnosis of central auditory processing deficits. In some countries, notably the USA and Australia, the diagnosis of auditory processing disorder (APD – sometimes prefixed with C for central) is frequently made. However, it is far less common in the UK. The principal difficulty with the APD concept is that it is typically diagnosed using tests that use verbal materials (e.g., listening to speech in noise) or being presented with two streams of speech in different ears (Moore, 2006). These tests have demonstrated
Acquired epileptic aphasia (AEA), also known as Landau–Kleffner syndrome, is a rare cause of childhood language impairment which is often misdiagnosed. The typical presentation is one of deterioration in language skills in the preschool years after a period of normal development. Because the child previously spoke normally, the disorder may be misdiagnosed as selective mutism (see p. 791); however, in AEA, there is genuine loss of language skills, with comprehension problems predominating. Deafness is usually suspected but ruled out on the basis of a hearing test. Many children with AEA have relatively selective problems with language in the context of preserved non-verbal ability, but in some children there are associated behavioral disturbances, which further complicate the diagnosis (Deonna & Roulet-Perez, 2005). The epileptic manifestations of AEA are not obvious, because overt seizures are uncommon, and it may be necessary to carry out a sleep electroencephalogram (EEG) to demonstrate EEG abnormalities. These can be marked, and there has been debate as to how far this disorder overlaps with slow wave status epileptics in sleep (SWSS). Some children, particularly those with onset after 6 years of age, can make a good recovery, but the prognosis for those with preschool onset is often poor and substantial receptive language deficits may persist to adulthood. Our recommendation is that any child with language regression accompanied by comprehension problems should be referred to a pediatric neurologist for an evaluation of AEA. Deonna and Roulet-Perez (2005) note that pharmacological interventions can be effective, but there is wide variation in responsiveness to treatment, and in the absence of controlled clinical trials it is difficult to give precise guidelines. Deonna (2000) recommended that when receptive language difficulties persist for more than a few weeks or months, it is crucial to provide the child with an alternative mode of communication. Sign language can be effective and does not interfere with attempts to retrain comprehension of auditory language (Roulet-Perez, Davidoff, Prélaaz et al., 2001).

Delayed Language Development: Late-Talkers

When diagnosing SLI, it is important to determine when a young child’s language delay represents a significant departure from normal variation, which can be difficult when the child is younger than 3 years old. Late-talkers are identified as having severely restricted vocabulary at age 2 years (fewer than 50 words). It is unclear how many late-talkers have similarly impaired receptive language skills, because many studies include only children with normal comprehension (Rescorla, 2005). Many late-talkers meet typical exclusionary criteria for SLI such as normal non-verbal ability and no hearing loss; however, most late-talking 2-year-olds will normalize language function by the time they enter school (Rescorla, 2005), whereas the long-term prognosis for school-aged children with SLI is less optimistic (Stothard, Snowling, Bishop et al., 1998).

Dale, Price, Bishop, and Plomin (2003) followed a large sample of twins from 2 to 4 years of age. Late-talkers were identified as those 2-year-olds with expressive vocabulary scores in the bottom 10th centile (15 words or fewer on a modified version of the MacArthur Communicative Development Inventory). By age 4, 60% had age-appropriate scores on parent-report measures of vocabulary, grammar and use of abstract language.

It appears that gains in language skill are maintained over time. Paul (2000) reported that 84% of late-talkers in her cohort had language scores within the normal range at age 7. Rescorla (2005) followed 28 late-talkers from preschool to age 13 and found that, at this age, all of the children scored within the normal range on standard measures of language and literacy. However, their scores were significantly lower than a comparison group of typically developing children matched for socioeconomic status (cf. Stothard, Snowling, Bishop et al., 1998). Rescorla argued that late-talkers represent a subgroup of SLI characterized by less severe language weakness.
Although 60–85% of late-talking children will improve without direct intervention, a minority will not (Paul, 2000; Dale, Price, Bishop et al., 2003). It is not currently possible to distinguish reliably between those children with transient and persistent impairments. Dale, Price, Bishop et al. (2003) found that severity of language delay at age 2 did not predict language status at age 4. In addition, neither gender nor level of maternal education significantly predicted group outcome. Paul (2000) reported that children with persistent language difficulties tended to have lower non-verbal abilities, although scores on non-verbal assessments were still within the normal range and there was considerable overlap between groups with good and poor outcome. In addition, high socioeconomic status and prosocial adaptive communicative behaviors were associated with good outcome at age 7. A much smaller-scale study by Thal, Tobias, and Morrison (1991) indicated that poor receptive language skills and failure to use gesture were associated with persisting language difficulties.

Given these findings, a dilemma facing practitioners is what to do when language delay is identified during the preschool years. Conventional wisdom posits that early intervention is desirable, but Paul (2000) questioned the ethics of treating children who are otherwise developing normally, having normal language comprehension and do not present with any additional risk factors for a language “disorder” that they may overcome naturally without any professional help. Instead, she advocates initial parent training to optimize language input in conjunction with careful monitoring of language development.

Even though good language outcomes are often seen in late-talkers, there is evidence to suggest they should be monitored because such children may be at risk for other developmental difficulties. In a survey of over 1000 children, Horwitz, Irwin, Briggs-Gowan et al. (2003) found that late-talkers tended to show poor social interaction, which was in turn associated with an increased risk of emotional and behavioral disorders. Furthermore, it would seem prudent to give the child support in the early stages of reading and writing, given a suggestion that there is a risk of weak literacy skills in children who were late-talkers (Rescorla, 2005).

**Autism and Pragmatic Language Impairments**

Delayed language development and poor communication skills are hallmarks of autistic disorder, and the issue of differential diagnosis between autistic disorder and specific developmental language disorder frequently crops up in the clinical setting. Diagnosis of autistic disorder is covered in detail in chapter 46, so in this chapter we focus on areas of diagnostic difficulty.

Autistic disorder should be considered when the child’s language difficulties are accompanied by more pervasive difficulties affecting social interaction, non-verbal communication and play, or if the child shows unusual repetitive or ritualistic behaviors or restricted interests. The clinician needs to consider whether language development is merely delayed, or whether there are deviant features that would not be regarded as normal at any age, such as repetitive use of stereotyped catchphrases, unusual and exaggerated intonation, pronoun reversal or a frequent failure to respond when the parent attempts to attract the child’s attention.

Some higher-functioning children with autistic disorder (i.e., those children with non-verbal IQs within the normal range) resemble our illustrative child Jack in having superficially complex language; they may appear verbose and achieve age-appropriate scores on tests of expressive language or simple vocabulary measures. However, such measures may overestimate true language ability (Mottron, 2004) and the same children usually have significant comprehension deficits in less structured and more naturalistic discourse settings (Adams, Green, Gilchrist, & Cox, 2002).

Textbook cases of autistic disorder and SLI are relatively easy to differentiate, but many children present with a pattern of symptoms that does not fit unambiguously in either category, while showing some features of both. Thus, their difficulties extend beyond the characteristic grammatical deficits seen in SLI, but they do not have the full triad of impairments in severe enough form to warrant a diagnosis of autism. Differentiation between the two disorders may be hampered by a changing clinical picture over time (Charman, Taylor, Drew et al., 2005; Mawhood, Howlin, & Rutter, 2000). Conti-Ramsden, Simkin, and Botting (2006) applied standard diagnostic instruments (Autism Diagnostic Interview – Revised; Lord, Rutter, & Le Couteur, 1994; Autism Diagnostic Observation Schedule – Generic; Lord, Risi, Lambrecht et al., 2000) to 76 adolescents with a history of SLI, none of whom had been regarded as autistic in middle childhood. The majority of individuals did not meet criteria on either measure, but 3.9% met criteria for autistic disorder on both assessments, a prevalence rate more than three times greater than would be expected from the general population (Baird, Simonoff, Pickles et al., 2006). A further 26% met criteria on one or other measure but not both. Similar results were obtained by Bishop and Norbury (2002), who noted that many children with language impairment displayed difficulties with broader aspects of communication and social interaction, although restricted interests and rigid behaviors were less characteristic of this population.

In cases where a child meets criteria in one or two domains of the autistic triad or exhibits subthreshold symptomatology across domains, a diagnosis of “pervasive developmental disorder not otherwise specified” or “atypical autism” is frequently applied. However, there is concern that these terms may be overused, and do not provide helpful information about symptom profile, nor do they facilitate decisions about educational placement. Bishop (2000) suggested that the term “pragmatic language impairment” (formerly “semantic-pragmatic disorder”) might be useful for describing children who do not meet full diagnostic criteria for autistic disorder, but whose language difficulties affect social interaction and the use of language in context. The use of this term was not intended to imply a new and discrete disorder; rather, “pragmatic language impairment” is seen as a variable correlate of both SLI and milder forms of autistic spectrum disorder (Norbury, Nash, Bishop, & Baird, 2004).
In reality, the diagnostic label chosen may reflect the practitioner’s theoretical stance and the practical implications a particular diagnosis brings with regard to accessing appropriate educational and remedial provision. The important point to recognize is that rather than attempting to draw a discrete diagnostic line between SLI and autistic disorder, it is more helpful to think in terms of multidimensional space, with children varying in terms of the severity of impairments in language, social interaction and range of interests.

Selective Mutism
Occasionally, the clinician will encounter a child who is extremely reticent in the clinic setting. In these instances, it is important to establish that the child does speak with others in more familiar situations such as school and home. However, if the child’s communication varies significantly in different settings, the practitioner should consider the possibility of selective mutism.

Selective mutism (SM) is diagnosed in the child who consistently does not speak in certain situations in which there is an expectation for speaking (e.g., school), but can and does speak normally in some situations (e.g., at home; Steinhausen, Wachter, Laimbock et al., 2006). The disorder was previously known as “elective” mutism, but the terminology has been revised to avoid implying that children are being obstinate or oppositional when they remain silent (Cline & Baldwin, 2004; Cohan, Chavira, & Stein, 2006a).

DSM-IV-TR (American Psychiatric Association, 2000) and ICD–10 (World Health Organization, 1996) criteria stipulate that in order to receive a diagnosis, the mutism must persist for more than 1 month (not including the first month of school), and cannot be accounted for by a communication disorder or a lack of familiarity with the ambient language of the social situation. Toppelberg, Tabors, Coggins, Lum, and Burger (2005) further recommend that bilingual children are not diagnosed with SM unless the mutism persists for longer than 6 months and is apparent in both languages.

Prevalence estimates vary depending on the criteria used and the population studied, with higher rates of transient mutism associated with starting school. Cline and Baldwin (2004) estimate 6–8 cases of selective mutism per 1000 through-out childhood, with a preponderance of girls (55–65% of cases), consistent with the results of recent community studies, which have found rates of approximately 75% (Cohan, Chavira, & Stein, 2006a).

The precise cause(s) of SM is unknown; although trauma may precipitate mutism, it is not implicated in the majority of cases (Steinhausen & Juzi, 1996). SM is generally regarded as a variant of anxiety disorder (Steinhausen, Wachter, Laimbock et al., 2006; Vecchio & Kearney, 2005), rather than being categorized with speech and language disorders. Rates of comorbid anxiety and phobic disorders are high, both in affected children and their first-degree relatives, and some success in treatment has been reported using drugs that effectively reduce anxiety (for a review see Cline & Baldwin, 2004). However, it would be wrong to imply that social anxiety is the only problem; other factors are also often implicated, including bilingualism and speech and language impairment, suggesting that self-consciousness about inadequate communication plays a part in maintaining the disorder (Manassis, Fung, Tannock et al., 2003). The consensus of opinion is that SM is the culmination of multiple predisposing, precipitating and perpetuating factors (Cohan, Price, & Stein, 2006b; Johnson & Wintgens, 2001).

Assessment of the child with SM may be particularly challenging, as the assessment process itself might further increase anxiety and reluctance to speak. At first meeting, it is most important to create a relaxed atmosphere in which the child feels little pressure to communicate with an unfamiliar adult. In this session, the clinician may take a detailed case history from the parents, focusing on where, when and with whom the child does speak and obtaining detailed examples of how the child communicates in different settings. During conversation with the parents, the clinician may unobtrusively observe the child playing and, if possible, interacting with parents or siblings.

Direct assessment of expressive language may not be possible at this point, although many children with SM will cooperate with receptive language testing if this just involves carrying out commands or pointing to pictures, and this can give valuable information about general language level (Manassis, Fung, Tannock et al., 2003). Formal assessment may be supplemented by asking parents to record the child’s language skills in a more comfortable arena, perhaps telling a story at home, or keep a diary of what the child says and the contexts in which language occurs. Johnson and Wintgens (2001) provide further examples of techniques for gaining the child’s confidence to enable assessment to proceed.

The most successful treatments are thought to combine behavioral and psychopharmacological interventions, but there appears to be no systematic research on the efficacy of this approach (Cline & Baldwin, 2004). Cohan, Chavira, & Stein (2006a) conducted a critical review of psychosocial treatments published over a 15-year period. The techniques used in these studies included positive reinforcement for speaking to classmates, systematic desensitization to anxiety-provoking situations, language training, family therapy and self-modeling techniques, in which the child with SM listens to recordings of him or herself speaking in situations in which he or she is usually mute. Although the majority of these studies report increases in speaking behavior, the findings are limited by very small participant numbers and a lack of suitable control groups.

A recent longitudinal study demonstrated considerable improvement in symptoms of SM over time, but rates of psychiatric disorder, especially social phobia, remained high (Steinhausen, Wachter, Laimbock et al., 2006). Prognosis is especially poor when a family history of SM is present.

Assessment of Language and Communication
Approximately 50% of children referred for psychiatric evaluation have clinically significant language impairments that
are frequently unsuspected (Cohen, 2001). In many clinical contexts it is not possible to offer the time and expertise necessary for every referral to receive an in-depth assessment of language. However, it can be informative to gain an overview of the child’s language development and current communicative functioning by taking a detailed case history and asking caregivers to complete a screening checklist.

The Children’s Communication Checklist-2 (CCC-2; Bishop, 2003a) is a 70-item checklist for children aged 4 years and over that asks parents to rate the frequency of communicative behaviors in everyday situations, thus providing a naturalistic assessment of functioning. One advantage of this assessment is that it covers both structural aspects of language (phonology and syntax) as well as pragmatic aspects of communication, which are more difficult to measure on face-to-face assessment. The CCC-2 reliably distinguishes children with communication impairment from typically developing children (Norbury, Nash, Bishop et al., 2004) and an earlier version of the checklist identified children at genetic risk for language impairment as effectively as standardized tests (Bishop, Laws, Adams, & Norbury, 2006b). However, it should be noted that CCC-2 is not suitable for children who are not yet speaking in sentences.

More detailed evaluation of language and communicative functioning will typically be undertaken by a speech-language therapist or specialist psychologist. A number of standardized assessments tapping all domains of language are available in English, but this is not necessarily so in other languages. The application of English language assessments to children from non-English speaking backgrounds is not recommended, as test scores may not accurately reflect the child’s competence in his or her native language.

There is evidence that “knowledge-dependent” measures, such as vocabulary tests, exaggerate cultural and socioeconomic differences between children, whereas “processing” measures that vary difficulty by manipulating the amount of material that has to be processed (e.g., nonsense word repetition), provide a culturally unbiased estimate of language ability (Campbell, Dollaghan, Needleman, & Janosky, 1997). Table 47.1 provides a list of commonly used language assessments in the UK, including the domain of language targeted and the age range appropriate for testing.

There is currently no clear consensus on what degree of impairment on standardized assessment constitutes a significant difficulty. A score of –1 SD (equivalent to 16th centile) on a single assessment may not interfere with the child’s educational or social development, whereas consistently low scores across a number of language domains or an extremely low score on one measure (–2 SD or 3rd centile) may be more problematic. Tomblin, Records, and Zhang (1996) used a battery of language tests covering different aspects of receptive and expressive processing, and combined these into five composites: expressive language, comprehension, vocabulary, grammar and narrative. SLI was diagnosed if two or more of these composites fell more than 1.25 SD below age level (10th centile), non-verbal IQ was 87 or more, and no exclusionary conditions were present. In a population sample, this resulted in 0.85 sensitivity (identifying true cases of impairment) and 0.99 specificity (correctly identifying unimpaired cases). Note that the definition of SLI used by Tomblin et al. was considerably less stringent than that of ICD-10 (World Health Organization, 1996), which requires that language test scores must be 2 SD or more below age level. Application of this criterion would give a lower prevalence rate.

In DSM-IV-TR (American Psychiatric Association, 2000) a distinction is drawn between expressive vs. mixed receptive-expressive subtypes of language disorder. The importance of establishing the level of receptive language should not be underestimated: poor comprehension is an important predictor of outcome in a language-impaired child (Stothard, Snowling, Bishop et al., 1998). However, if strictly interpreted, the DSM-IV system is unworkable. This is because it defines Expressive Language Disorder as having an expressive language score that is “substantially below” both non-verbal IQ and receptive language, whereas in Mixed Receptive-Expressive Language Disorder, both expressive and receptive language are “substantially below” non-verbal IQ. This creates a problem of how to categorize a child with average non-verbal IQ and a mild receptive language impairment and a more severe expressive impairment (e.g., receptive language score is 0.8 SD below average and expressive language score is 1.2 SD below average). If we interpret “substantially below” in terms of a 1-SD discrepancy, such a child would not meet criteria for either DSM subtype. Furthermore, the distinction between the two subtypes seems artificial; both genetic and developmental data suggest that they correspond to points on a continuum of severity (Bishop, North, & Donlan, 1995).

**Prevalence, Causes and Correlates of Specific Language Impairment**

Research on SLI is complicated by the variety of diagnostic criteria that have been employed. It is rather unusual to find research that focuses on “pure” SLI in which there is a substantial discrepancy with non-verbal IQ. More commonly, an IQ cut-off is used to establish that children are within broadly normal limits. In addition, as noted in chapter 3, SLI is often accompanied by other neurodevelopmental disorders: rates of co-occurrence of ADHD, developmental coordination disorder and academic difficulties are all high. Studies vary in how far they explicitly include or exclude children with these comorbid conditions, with speech problems or with autistic features. It is likely that estimates of prevalence, comorbidity and etiology will depend on the phenotype that is studied.

**Prevalence**

The most frequently cited prevalence figure for SLI comes from an epidemiological study by Tomblin, Records, Buckwalter et al. (1997), who estimated that 7.4% (95% confidence interval [CI] 6.3–8.5%) of 5- to 6-year-old children in an Iowa sample met diagnostic criteria as defined above. Intriguingly, of those who did meet criteria for SLI, only 29% had previously been identified as having language difficulties. If the
criteria were made more stringent, to include only those with composite language scores more than 2 SD below average, it was still the case that only a minority of affected children (39%) had been identified clinically. This result suggests that the features that lead to a child being identified as having an SLI are different from those that are picked up by standardized tests (Bishop, Laws, Adams et al., 2006b). In general, teachers and parents will notice a child whose speech is unclear or whose language structure is so immature as to sound ungrammatical, but poor verbal memory, limited understanding, weak vocabulary and lack of complex grammar are easier to miss.

As with many other neurodevelopmental disorders, more males than females are affected with SLI, although the male preponderance was far less in the epidemiological study of Tomblin, Records, Buckwalter et al. (1997), who reported 1.33:1 boys to girls, than in samples recruited from clinical sources (e.g., Robinson, 1991, reported a ratio of 3.8:1). There is no evidence that different genetic influences are implicated in causing language impairment in males and females; a comparison of same-sex and opposite-sex twin pairs found a similar magnitude of genetic and environmental influences in both sexes (Viding, Spinath, Price et al., 2004).

As Tomblin, Records, Buckwalter et al. (1997) pointed out, there is an intrinsic difficulty in attempting to compare prevalence in different racial groups, because even if the core language is the same across races, there are likely to be cultural differences in language use that will lead to biased test results. Campbell, Dollaghan, Needleman et al. (1997) suggested such bias could be eliminated by avoiding language tests that were affected by prior knowledge or experience, but we are not aware of any epidemiological studies that used such measures to compare different rates of SLI in different races or cultures.

Correlates of SLI
Although SLI is “specific” insofar as the language disorder is not accompanied by low non-verbal ability, there are frequently accompanying impairments in other aspects of functioning. Literacy problems are found in most but not all children with SLI. The question of what characterizes those children who learn to read and write despite SLI is intriguing but as yet not fully understood; however, poor phonological processing appears a key factor (Bishop & Snowling, 2004; Catts, Adlof, Hogan, & Weismer, 2005). Another frequent accompaniment to SLI is motor impairment, which may not be evident in everyday interactions, but becomes so on formal testing (Hill, 2001; Webster, Majnemer, Platt, & Shevell, 2005).

Comorbidity with Psychiatric Disorder
Early research by Cantwell and Baker (1991) demonstrated a high rate of psychiatric disorder, including but not limited to ADHD, in children referred for speech and language disorders. In one of the few epidemiological studies to address this issue, the Ottawa Longitudinal Study, it was found that language impairment in 5-year-olds was one of the strongest predictors of psychiatric outcome at 12 years of age, even after measures of social background were taken into account (for review see Beitchman, Brownlie, & Wilson, 1996). In this study, ADHD and emotional disorders were the most common psychiatric diagnoses. A series of studies by Cohen, Hodson, O’Hare et al. demonstrated that the converse also applied. Of children referred for psychiatric assessment solely for socio-emotional disturbances, 33% were found to have previously undiagnosed language impairment. When combined with those whose language impairments had already been identified, some 50% of school-aged children referred to out-patient mental health clinics had clinically significant language impairments (for review see Cohen, 2001).

Such co-occurrences raise a host of questions about causation. An obvious possibility is that inability to express one’s needs and ideas leads to a sense of frustration and impotence, and subsequent acting-out behavior. However, if this were the principal route to psychiatric disorder, we would expect the greatest evidence of psychopathology to be seen in children with expressive difficulties, whereas most studies find receptive language difficulties pose substantially greater risk. Failure to comprehend language can lead to inappropriate accusations in the classroom of laziness, willfulness or inattention, and it will also limit the opportunities to form close relationships that would normally exert a protective effect. Redmond and Rice (1998) contrasted this latter type of “social adaptation” account with a “social deviance” model that regards both behavior and language problems as indicators of an underlying trait of disturbed psychosocial development. They argued that parent and teacher ratings of socioemotional status in children with SLI showed little congruence or temporal stability, supporting the idea that behavioral problems were consequences of specific communicative experiences rather than reflecting intrinsic deficits in the child. However, rates of behavior disorder were relatively low in their sample, and the possibility remains that more severely affected children have socioemotional deficits that go beyond what could be reasonably regarded as adaptations to poor communication (see also Bishop, 2000).

Another route from language impairment to psychiatric disorder is through the experience of school failure. Both Beitchman, Brownlie, & Wilson (1996) and Tomblin, Zhang, Buckwalter, and Catts (2000) found that the risk of psychiatric disorder was substantially raised in those children whose language impairment was accompanied by reading disability, and was much lower in those who were experiencing academic success. In both these studies, this association was less evident when the same children’s behavior problems were assessed before they learned to read; this suggests that it is experience of school failure that exacerbates psychiatric risk.

One further mechanism whereby language could affect psychiatric status is through its role in inner speech and self-regulation. Language is a tool for thought as well as a means of communication, and it affects how we structure our experiences, plan for the future and reflect on the past. A child with limited language understanding is anchored more firmly in the here and now, and may find it hard to delay gratification, think
CHAPTER 47

through another person’s motivations or appreciate chains of causality. In the case of autistic disorder, verbal ability is strongly linked to the development of understanding of other minds, which is thought to mediate social understanding and interaction (Happé, 1995), and those children with significantly lower verbal ability in relation to non-verbal ability demonstrate the most severe deficits in social interaction (Joseph, Tager-Flusberg, & Lord, 2002).

We need more research relating specific aspects of language skill to cognitive processes and behavioral outcomes in SLI to evaluate the plausibility of different causal pathways to disorder, compared with other accounts such as one that would regard language impairment and psychiatric disorder as associated with language difficulties. The role of language in thinking has implications for intervention: some children have language problems that could make it difficult to use methods such as cognitive–behavioral therapy. For instance, if the child does not understand what is meant by “if... then”, and has difficulty thinking about events beyond the here and now, then it may be counterproductive to try to use social problem-solving approaches that involve thinking about solutions to hypothetical situations.

Genetic Factors
Twin studies have converged in finding that SLI is a highly heritable disorder (for review see Bishop, 2001). In 1990, excitement was generated by the discovery of a three-generation family, the K.E. family, in which a speech and language disorder appeared to be inherited in an autosomal dominant fashion. The earliest account of this family focused on their verbal dyspraxia (Hurst, Baraitser, Auger et al., 1990), but subsequent reports have drawn attention to coexisting problems with broader oral language skills (Watkins, Dronkers, & Vargha-Khadem, 2002). The mutation responsible for the disorder has since been identified as affecting the function of a transcription factor, the FOXP2 gene, which influences the development of the brain as well as other organs (for an overview see Fisher, 2005). Although other cases of speech and language impairment linked to FOXP2 have been reported (Feuk, Kalervo, Lipsanen-Nyman et al., 2006; Macdermot, Bonora, Sykes et al., 2005), it is evident that this is a rare mutation that cannot account for the majority of cases of SLI. Although it is possible that other single major genes may be involved in the etiology of some cases of SLI (Bishop, 2005), it is likely that for many children the etiology will involve the combined influence of several genes and environmental factors, each of small effect.

Research on the genetics of SLI is moving ahead on three fronts. First, there are molecular studies that have made progress in identifying linkages to sites on chromosomes 3, 16 and 19 (Newbury & Monaco, in press). Second, there are behavioral genetic studies that attempt to refine the phenotype of heritable SLI. In general, these suggest that we will make better progress in molecular genetic studies if we abandon the conventional clinical criteria for SLI and move instead to define the phenotype in terms of measures of underlying cognitive and linguistic processes (Bishop, 2006). One important clinical message to emerge from genetic studies is that genes can increase a child’s risk of SLI, but they do not act in a deterministic fashion. Whether or not a genetic risk is manifest as a language disorder may depend on environmental factors (Bishop, 2001). Finally, there is a recognition that we need to move away from focusing on individual neurodevelopmental disorders, to consider whether there are genetic risks for SLI that also affect related conditions such as developmental dyslexia or autistic disorder. In the case of dyslexia, it is clear that there are some genetic variants that increase the risk for both SLI and reading problems but, nevertheless, there is little overlap in the sites of significant linkage found in whole-genome scans for these two conditions (Fisher, 2006). There has been considerable interest in the idea that a common genetic locus might be found that increases the risk for both SLI and autism (Folstein & Mankoski, 2000), but this has yet to be validated, and behavioral studies suggest that phenotypic similarities between the two disorders may be only superficial (Bishop, Maybery, Wong et al., 2004; Whitehouse, Barry, & Bishop, 2007).

Environmental Factors
There is little evidence that environmental factors alone are sufficient to cause the selective deficits in grammar and phonology that characterize SLI. However, environmental factors may be implicated in early language delay and can have a role in mediating the developmental course of language disorders and the impact of language impairment on the child’s well-being.

Family socioeconomic status (SES) has long been associated with child language development, with children from lower SES environments experiencing protracted rates of language development in relation to peers from more affluent homes. It is suggested that the relationship between SES and language impairment is mediated by maternal education, via the quantity and quality of mothers’ communicative interactions with their children (Hoff & Tian, 2005). However, other studies have found that SES (as measured by income or maternal education) is not a reliable predictor of long-term language impairment (Dale, Price, Bishop et al., 2003; Paul, 2000). Furthermore, even when SES is implicated in language or literacy impairment, one must consider that environments are at least partially genetically influenced (Oliver, Dale, & Plomin, 2005). In other words, a mother may have a limited educational experience and poor career prospects because of her own language limitations. Nevertheless, early language delay in the presence of low SES should alert the clinician of the need to monitor linguistic progress carefully.

In a multicultural society, one must establish whether a child is presenting with a language disorder or a language difference. Two questions must be addressed:

1. Is the child impaired only in his or her ability to learn the ambient language, or are language impairments evident in the child’s home language as well?
2 If the child does have language impairment, does exposure to more than one language exacerbate the child's language learning difficulties?

Studies of SLI in bilingual language learners are in their infancy, and there is a dearth of longitudinal data with which to answer these important questions. For some languages, such as Spanish in the USA, there now exists a range of culturally appropriate, well-standardized assessments with which to assess bilingual children, but the situation is far less satisfactory for many other language communities. It is not safe to assume that a straightforward translation of an English text into the child’s home language will provide an accurate picture of the child’s language ability. In these instances, it will be important to obtain a picture of the child’s communicative competence from the primary caregiver. It may be particularly beneficial to ascertain whether the caregiver is concerned about the child’s communication and how this child’s development compares with other children in the family or community.

The limited research available suggests that experience with two or more languages does not cause or compound SLI (Paradis, Crago, Genesee, & Rice, 2003). Thus, most speech-language clinicians recommend that families continue to provide rich input in the child’s home language and that, where possible, intervention should target both languages. However, there is no systematic research comparing monolingual vs. bilingual therapy in such cases, and it could be argued that the child with SLI may be particularly handicapped by the challenge of mastering two or more languages simultaneously. One recent study by Cheuk, Wong, and Leung (2005) endorsed this view, but focused on preschool children; thus, it is likely that many would achieve normal language outcomes. Longitudinal studies of bilingual children with SLI are clearly needed.

**Neurobiology**

Most children with SLI show no gross abnormalities of the brain on structural imaging. More fine-grained analyses have revealed evidence for four kinds of developmental brain anomaly associated with SLI:

1. Abnormalities in the organization of different kinds of brain cell (ectopias and microgyri; Galaburda, Sherman, Rosen, Aboitiz, & Geschwind, 1985);
2. Additional gyri in frontal or temporal regions (Clark & Plante, 1998; Plante & Jackson, 1997);
3. Unusual proportions of different brain regions (Herbert, Ziegler, Makris et al., 2003; Jernigan, Hesselink, Sowell, & Tallal, 1991; Leonard, Lombardo, Walsh et al., 2002); and
4. Anomalous cerebral lateralization (De Fossé, Hodge, Makris et al., 2004; Gauger, Lombardo, & Leonard, 1997; Herbert, Ziegler, Makris et al., 2003). However, the field is plagued by inconsistent findings: for instance, whereas SLI was associated with small cerebral volume in studies by Jernigan, Hesselink, Sowell et al. (1991) and Leonard, Lombardo, Walsh et al. (2002), it was associated with large cerebral volume in the study by Herbert, Ziegler, Makris et al. (2003). Leonard (1997) noted that such associations as are found are weak and probabilistic, and abnormalities that are more frequent in SLI than in typically developing children may also be seen in other disorders. In her own research, she has had some success in showing clearer relationships between disorder and brain anomaly by distinguishing between cases with language comprehension impairments and those with more restricted phonological deficits (Leonard, Lombardo, Walsh et al., 2002, Leonard, Eckert, Given et al., 2006).

Overall, the picture from structural brain imaging has been confusing and contradictory. The one thing we can conclude is that such anomalies as are found in SLI appear to arise early in neurodevelopment, rather than being brought about by early acquired lesions. This fits with the view of SLI as a disorder in which genetic influences lead to a brain that is wired up in a non-ideal fashion. From a clinical perspective, it is unlikely that brain imaging will provide information of diagnostic or prognostic utility in a child with SLI (Shevell, Majnemer, Rosenbaum et al., 2000).

Few functional imaging studies have been conducted with SLI, and those that have been performed are difficult to interpret. Thus, if one shows underactivation of regions implicated in language processing, it is unclear if this is cause or consequence of the language disorder. Functional imaging can nevertheless be useful in providing evidence for unusual localization of specific functions (e.g., studies of the affected members of the K.E. family have shown that when they perform a verb generation task they have diffuse bilateral brain activation), in contrast to unaffected individuals, who show more focal activation of traditional language regions in the left hemisphere (Vargha-Khadem, Gadian, Copp, & Mishkin, 2005).

Electrophysiological methods have been used to study brain–behavior relationships in children with SLI, but results are characterized by the same level of inconsistency as is seen in the structural imaging studies (see chapter 17; Bishop & McArthur, 2005; Bishop, 2007). Furthermore, research in this field is handicapped by a lack of normative data on typically developing children.

**Cognitive Factors**

Theoretical accounts of SLI have traditionally attempted to explain the disproportionate difficulties with grammar that characterize the disorder. Many of these theories are grounded in a linguistic tradition and propose that SLI results from a delay or disruption of the development of a specialized brain system that serves grammatical computations (Rice, 2004; van der Lely, 2005). Tasks tapping grammatical marking of tense and agreement, as well as comprehension of complex grammatical relations, discriminate children with SLI and typically developing peers (Conti-Ramsden, 2003) and poor performance on grammatical tasks has been put forward as a behavioral marker of heritable forms of SLI (Rice, 2004).

However, a number of researchers have criticized the notion of an innate modular language faculty and suggest that specialized language function is the developmental outcome of a number of domain-general endowments acting in concert (Bates, 2004). Children with SLI are impaired not only on
CHAPTER 47

grammatical tasks, but also on measures of phonological short-term memory. These tasks require children to repeat strings of unfamiliar speech sounds (e.g., “blonterstaping”), an ability that is seen to facilitate the learning of new words (Baddeley, Gathercole, & Papagno, 1998). Attention has also been focused on the abilities of children with SLI to process rapid brief auditory signals (Tallal, 2000); an ability that is argued to underpin the recognition and learning of grammatical contrasts in English (Joanisse & Seidenberg, 2003).

A recent study confirmed that deficits in nonsense word repetition, like deficits in grammatical inflection, are highly heritable and sensitive markers of SLI (Bishop, Adams, & Norbury, 2006a). Intriguingly, there appeared to be little etiological overlap between the two deficits, indicating that different risk genes may be involved in these different aspects of language difficulty. However, auditory processing deficits showed no genetic influence (Bishop, Bishop, Bright et al., 1999) and cannot fully account for the linguistic deficits seen in SLI (Norbury, Bishop, & Briscoe, 2001; van der Lely, Rosen & Adlard, 2004). Thus, auditory impairment may be seen as an environmentally based risk factor that comes into play in those children at genetic risk of the disorder.

The conclusions that we draw from theoretical studies of SLI are that there is unlikely to be a single cognitive or biological factor that can cause the variety of language profiles captured by a diagnosis of SLI. Instead, multiple risk factors in the child’s genetic and biological make-up are likely to interact with factors in the child’s environment to determine the severity and course of language impairment (Bishop, 2006).

Intervention and Prognosis for Specific Language Impairment

Intervention is usually determined by speech and language therapists, who use a wide range of techniques to stimulate language learning. In preschool, intervention may involve working with parents and caregivers to provide optimal language input for the child. Such approaches often involve videotaping parent–child interactions and using these videos constructively to foster better communication techniques (e.g., The Hanen program; Girolametto & Weitzman, 2006; see www.hanen.org for details). The advice given focuses on following the child’s lead in play, talking about what the child is doing rather than asking questions, recasting what the child says in a grammatically correct form, and increasing communication opportunities by giving children choices rather than anticipating their needs.

In a meta-analysis of intervention, Law, Garrett, & Nye (2004) found that treatment for preschool children with expressive language delays was successful when compared with no treatment, and treatments lasting longer than 8 weeks produced the most favorable outcomes. Parent-led interventions were as successful as direct intervention by a speech-language therapist in developing young children’s language; such interventions are cost-effective and encourage generalization of language gains into everyday environments. With such methods, speech-language therapists are instrumental in identifying communicative targets for parents to work on, and supporting parents throughout the intervention program. Nevertheless, as noted by Nelson, Nygren, Walker, and Panoscha (2006), there is a dearth of good-quality research on long-term efficacy of interventions for preschool children, a problem that is compounded by the fact that existing studies are small and heterogeneous.

There is even less research on intervention for children with receptive language difficulties or school-aged children. In general, randomized controlled studies are rare and studies that explicitly compare different treatment approaches for the same language problem simply do not exist. The field is plagued by studies in which the participant numbers are small, the interventions poorly described and methodological problems abound. The studies outlined below are pilot studies in nature, but offer promise for larger-scale investigations of treatment efficacy.

Ebbels (2007) reported preliminary data for a school-based intervention that focuses on grammar. This intervention uses visual cues such as shapes and colors to teach children with language impairment different parts of speech, and how these parts of speech may combine in different grammatical constructions. By situating the intervention in a school setting, classroom materials can be used in therapy to promote generalization. Other approaches advocate developing the child’s linguistic repertoire in more naturalistic settings. Fey, Long, and Finestack (2003) presented 10 principles for facilitating grammar development. Although the authors recognize the need to teach specific grammatical forms, they argue that these forms should rarely be taught in isolation. Instead, the targeted forms should be embedded in natural contexts such as play or story-telling. The role of the therapist in this approach is to manipulate the environment so that the targeted form is salient and frequently occurring, providing ample opportunity for modeling and shaping the child’s production.

Adams (2005) reported a series of case studies detailing treatment for children with pragmatic language impairments. Standardized assessments often lack the sensitivity to detect subtle improvements in social communication and interaction, but using detailed conversational analysis, Adams was able to demonstrate improvement in discourse functioning in school-aged children. These studies lacked a suitable control group necessary to evaluate specific treatment effects, but hold promise for larger-scale studies with school-aged populations with pragmatic deficits.

A radically different approach to treatment was developed by Tallal, Miller, Bedi et al. (1996), who devised a computer-based intervention, FastForWord, which involves prolonged and intensive training on specific components of language and auditory processing. The advantage of computerized presentation is that children may be persuaded to participate in thousands of training trials in a way that would not be possible in standard therapist-based interventions. Unfortunately, after initially promising results using the FastForWord program (Merzenich, Jenkins, Johnston et al., 1996), randomized controlled studies have failed to demonstrate a significant
advantage of this approach over other methods in improving children’s language or literacy skills (Cohen, Hodson, O’Hare et al., 2005; Pokorni, Worthington, & Jamison, 2004; Rouse & Krueger, 2004). Children in these studies had receptive as well as expressive language impairments, which appear particularly resistant to treatment (Law, Garrett, & Nye, 2004).

The limited intervention studies available suggest that there is no cure for SLI. Despite years of intensive specialist training, many children will continue to have language deficits. However, one should bear in mind the broader aims of therapeutic intervention for SLI. One cannot “cure” a sensorineural hearing loss or a physical impairment; in these instances intervention will seek to maximize potential and lessen the impact of the child’s impairment on his or her social well-being and educational experiences.

In the absence of a “quick-fix,” many children with SLI will present with long-term special educational needs. There is a lack of consensus on the most suitable type of provision for children with SLI. Experience in the UK suggests that some children will benefit from a special school or language unit placement where there is access to regular speech and language therapy and where the curriculum may be supported by using signed English or a visual symbol system. Others will benefit from a mainstream placement. Unfortunately, specialist support for children within mainstream settings is limited and almost non-existent by secondary school (Lindsay, Dockrell, Mackie, & Letchford, 2005).

A number of longitudinal studies have shed light on the developmental course of SLI. There is general agreement that the child with severely impaired understanding of language has a poor prognosis, even if the diagnosis is made early. Comprehension problems do not resolve spontaneously and, as they grow older, children with such problems experience increasing difficulties with social cognition and interaction (Clegg, Hollis, Mawhood, & Rutter, 2005; Howlin, Mawhood, & Rutter, 2000); non-verbal reasoning (Botting, 2005; Stothard, Snowling, Bishop et al., 1998) and an increased risk of psychiatric disturbance (Howlin, Mawhood, & Rutter, 2000; Snowling, Bishop, Chipchase, & Kaplan, 2006).

For children with normal non-verbal abilities and expressive language impairments, the outlook is much more positive, particularly if expressive deficits have resolved by school entry (Stothard, Snowling, Bishop et al., 1998). However, there is evidence that literacy skills may remain an area of weakness for these children (Botting, Simkin, & Conti-Ramsden, 2006; Rescorla, 2005); although these “resolved” cases may score within the normal range on standardized assessment, their scores are frequently lower than those of an IQ-matched peer group.

Conclusions

This chapter has considered various factors designed to facilitate clinical decision-making in this complex and difficult area. It is important to realize that cases of “pure” SLI are rare in clinical practice. Rather, children present with a range of co- occurring deficits and challenges that may cloud diagnostic decisions. The most important message for clinicians to remember is that speech, language and communication skills are critical to the cognitive and social development of children, whatever their primary diagnosis. Thus, attention to these aspects of development is fundamental for children presenting to psychiatric clinics.

Further Reading

References

CHAPTER 47

Learning difficulties can occur in the context of global delays in development or where there are circumscribed deficits in specific cognitive processes. It has proven productive in theory and in practice to differentiate these two forms of learning difficulties (Rutter & Maughan, 2005). The term specific learning difficulties is used to refer to poor educational attainment in the absence of general cognitive deficits, whereas the term general learning difficulties (now more appropriately termed intellectual disability; see chapter 49) is used to refer to problems associated with low IQ.

This chapter deals with specific learning difficulties, the major focus being on reading difficulties. More research has been conducted on the nature and causes of reading difficulties than on other learning difficulties, and interventions to ameliorate reading impairments have been evaluated. The chapter also considers specific difficulties in arithmetic and non-verbal learning disabilities including motor impairments; much less is known about the causes and treatments of these other learning disorders.

The assessment of specific learning difficulties is more often the domain of psychologists and educators than of psychiatrists and hence, the term “difficulties” is usually used rather than “disorders” or “disabilities,” which derive from the medical model. According to diagnostic manuals, there is a variety of such difficulties, viz, reading disorder, spelling disorder, mathematical disorder, disorder of written expression and mixed disorder of scholastic skills (DSM-IV, American Psychiatric Association, 2000). However, there is not a one-to-one correspondence between the classifications specified in the diagnostic manuals and those typically used by school systems or researchers in the field. Importantly, “discrepancy definitions” (that prescribe that attainments should be low relative to age and intelligence) are seldom strictly adhered to; in particular, the measurement of IQ is no longer considered central to the diagnosis of reading disorders. The main reason for this is that there are few cognitive differences relevant to reading between poor readers of high and low IQ. Given targeted support, children with specific reading difficulties make similar progress in reading (as measured by decoding) to those with general reading difficulties (Hatcher & Hulme, 1999; Shaywitz, Fletcher, Holahan, & Shaywitz, 1992a).

However, in the absence of such intervention, outcomes for reading and spelling have been reported to differ, children with intellectual disability faring better in literacy although less well in arithmetic (Rutter & Maughan, 2005).

### Disorders of Reading and Spelling

#### Definition, Classification and Incidence

Difficulties in reading accuracy (measured by tasks requiring decoding of single words) are distinct from difficulties with reading comprehension (measured by tasks tapping understanding of text). Whereas problems with decoding inevitably limit reading comprehension, there are a substantial minority of children (perhaps as many as 10%; Nation, 2005) who have difficulties with reading comprehension in the absence of problems with reading accuracy. In English-speaking countries, reading difficulties have been reported to affect 4–8% of school-aged children. Epidemiological studies in England reported prevalence rates of just over 3% (3.1% on tests of reading accuracy and 3.6% on tests of reading comprehension) among 9- and 10-year-olds in a non-metropolitan area using a stringent IQ-discrepancy criterion of 2 standard errors of prediction below expected performance (Rutter & Yule, 1975).

Using exactly comparable assessment procedures, rates were more than doubled (6.3% for reading accuracy and 9.3% for reading comprehension) in an inner city area, suggesting that social factors have a key role in risk for reading disability (Rutter & Maughan, 2005; Yule, Rutter, Berger, & Thompson, 1974). Boys are more likely to be referred for reading difficulties than girls (Shaywitz, Shaywitz, Fletcher, & Escobar, 1990) but this is not simply a matter of referral bias because sex ratios of between 1.5:1 and 3:1 boys to girls have been reported in large-scale community studies (Rutter, Caspi, Fergusson et al., 2004). However, rates of reading difficulties vary with age (Shaywitz, Escobar, Shaywitz, Fletcher, & Makugh, 1992b) with some children falling just below a chosen threshold at one age and just above at another. Problems with word decoding are likely to predominate in the earliest years of schooling, whereas a later-emerging group of poor readers who cope with the initial stages of learning to read fare less well when the school curriculum places heavier emphasis on comprehension. Later still, through into adulthood, individuals may face persisting problems with spelling or written expression (Maughan, Messer, Collishaw et al., submitted).
The language in which children learn to read also affects the likelihood of reading difficulties, although data do not exist to allow fair comparison of prevalence rates. European languages vary in the consistency of their writing systems. Languages such as Italian, German and Greek are regular in the way they map speech sounds onto written forms, whereas others – most notably English (and to a lesser extent Danish and French) are more irregular or opaque. Regular orthographies present children with fewer challenges in learning to read than do opaque writing systems (Seymour, 2005). However, differences in diagnostic practice may have overemphasized the differences between reading difficulties in different languages and played down the similarities (Caravolas, 2005). In both the irregular English and the regular Czech language, the correlates of reading skill and the predictors of reading difficulties have been reported to be similar (Caravolas, Volin, & Hulme, 2005). In line with this, a recent survey of 150,000 Dutch children reported a 9% prevalence of reading and spelling problems among 11- to 12-year-olds, and further assessment revealed that these were specific to literacy (and not more general) for 3.6% of children (Blomert, 2005). The case might be thought different when considering reading difficulties in non-alphabetic languages, such as Chinese, but there is little direct evidence that supports this view (Hanley, 2005).

Normal Literacy Development: A Framework

In an alphabetic language such as English, the foundation of literacy is a system of mappings between orthography (the letters of printed words) and phonology (the speech sounds of spoken words). Learning to read requires the child to abstract the idea that the letters of printed words represent phonemes in spoken words (Byrne, 1998).

More formally, the relationship between oral and written language skills has been simulated in computational models. According to the Triangle model of Plaut, McClelland, Seidenberg et al. (1996; after Seidenberg & McClelland, 1989) depicted in Fig. 48.1, reading involves the interaction of a phonological pathway (mapping from letters to sounds) and a semantic pathway (mapping from letters to meanings and then to sounds). It is thought that beginning readers place more reliance on the phonological pathway (phonics) and then gradually start to use the semantic pathway to gain fluency in their reading. This use of the semantic pathway is important in English for reading exception words that do not conform to English letter-sound rules (e.g. yacht and pint). When children read words they usually occur in a sentence context, context exerts its influence on reading via activation through the semantic pathway.

The Triangle model makes predictions about the cognitive resources that children require in order to learn to read. It is now agreed that early reading development depends on phoneme awareness (the ability to reflect on and manipulate speech sounds in words) and letter knowledge (Bowey, 2005). Later in development, broader language skills (such as vocabulary and grammar) predict gains in reading fluency and are critical foundations for reading comprehension (Catts, Fey, Zhang, & Tomblin, 1999; Muter, Hulme, Snowling, & Stevenson, 2004; Share, 1995). In addition, higher-level skills, such as inference making, are important for some aspects of text comprehension (Yuill & Oakhill, 1991). Thus, reading difficulties can occur for different reasons.

Problems of Decoding

Problems that specifically affect a child’s ability to decode text are commonly referred to as “dyslexia.” Although the term has had a chequered history, international voluntary agencies concerned with children’s specific reading difficulties now provide definitions of the “disorder” that are informed by research (International Dyslexia Association, 2002) and national initiatives (Riddick, 2006) have lent credence to the judicious use of the term.

Theories of Dyslexia

Phonological Deficit Theory

The majority of children with specific reading difficulties have phonological (speech processing) difficulties that affect their decoding skill to some extent (Vellutino, Fletcher, Snowling, & Scanlon, 2004). The predominant theoretical account views the primary cognitive cause of dyslexia as a phonological (speech) processing impairment (Harm & Seidenberg 1999; Ramus, Rosen, Dakin et al., 2003). According to this hypothesis, children with dyslexia have difficulty establishing the phonological reading pathway (Snowling, 2000); the development of the semantic pathway is affected less because the mappings in this pathway do not depend upon identifying the phonemes of speech.

Aside from reading, phonological deficits explain why people with dyslexia typically have difficulties with a wide range of cognitive tasks that engage phonological processes such as limitations of verbal short-term memory, long-term verbal (phonological) learning, slow naming of letters, digits, color and
objects and word finding difficulties. Together, this evidence led Stanovich and colleagues to propose the phonological-core variable-difference model of dyslexia (Stanovich & Siegel, 1994); according to this model poor phonology is related to poor reading performance, irrespective of IQ. It is now believed that this model holds irrespective of language background (Caravolas, 2005; Goulandris, 2003).

Rate Deficits and Double Deficits
Some have argued that the phonological deficit theory does not fully account for the reading problems found in children with dyslexia. Lovett, Ransby, and Barron (1988) differentiated accuracy-impaired and rate-impaired poor readers, and Wolf and Bowers (1999) distinguished between disabled readers with single deficits in either phonological awareness or in naming speed (measured by the speed to retrieve names of digits or letters; Wimmer, Mayringer, & Landerl, 2000) and a subgroup with deficits in both processes.

An alternative to the phonological deficit hypothesis is the automatization hypothesis (Nicolson & Fawcett, 1990). According to this theory, people with dyslexia have difficulty learning skills to the point at which they become completely automatic, and, although they can learn to read, they have difficulty developing reading fluency. This model conceptualizes the phonological deficit in dyslexia as a consequence of problems with speech-articulation. A feature that marks this hypothesis out from the phonological deficit hypothesis is that it places the deficit in dyslexia at a domain-general level—that is, the automatization deficit places similar constraints on the learning of all skills, including basic motor skills, and is associated with cerebellar dysfunction (Nicolson, Fawcett, & Dean, 2001). The theory does not account well for the finding that dyslexia can occur in the absence of motor deficits.

Perceptual Theories of Dyslexia
A large body of research has assessed whether reading difficulties are associated with low-level perceptual processing impairments. Investigations have examined putative impairments in visual, auditory and motor domains as explanations for different manifestations of dyslexia.

Visual Deficits Although most people with reading difficulties have normal visual acuity, there is a raised incidence of abnormalities on psychophysical tasks assessing motion processing and contrast sensitivity (Skoyles & Skottum, 2004). These impairments have been related to a deficit within the magnocellular division of the visual system, which responds strongly to high contrast visual patterns (Lovegrove, Martin, & Slaghuis, 1986; Stein & Talcott, 1999). However, some studies have found no evidence of abnormal sensitivity, whereas others have suggested that group differences may be related to uncontrolled differences in IQ (Hulslander, Talcott, Witton et al., 2004). Problems of visual attention have also been considered a putative cause of dyslexia (Facetti, Turatto, Lorusso, & Mascetti, 2001; Hari, Renvall, & Tanskanen, 2001; Roach & Hogben, 2004) but again the evidence is inconsistent. It has therefore been proposed that phonological and visual attention could be dissociable causes of dyslexia that may co-occur (Valdois, Bosse, & Tainturier, 2004).

Although scientific understanding of how visual deficits might affect reading is limited, the use of colored lenses or filters to reduce visual stress and improve reading performance is recommended by some practitioners. To date, there is no evidence for the effectiveness of such interventions as a treatment for reading impairments in dyslexia.

Auditory Deficits A hypothesis that has attracted considerable research is that the phonological deficit in dyslexia stems from a deficit in basic auditory processing (Tallal, 1980); specifically, an auditory processing deficit affects the perception of consonants, which in turn affects the development of phonological skills (cf. Mody, 2003). The plausibility of this hypothesis is supported by evidence that infants at family risk of dyslexia or language impairment are less sensitive to the speech sounds that signal meaning changes than typically developing children (Leppänen, Eklund, & Lyttinen, 1997), and that behavioral and brain responses to speech sounds in the first year of life correlate with later language and reading development (Guttorm, Leppänen, Poikkeus et al., 2005).

Investigation of auditory deficits has extended to tasks tapping frequency discrimination, frequency modulation, binaural processing, backward masking (for review see Bailey & Snowling, 2002) and amplitude onset sensitivity (Goswami, Thomson, Richardson et al., 2002). However, the findings are inconsistent and typically only 30–40% of people with dyslexia show auditory impairments.

The direct investigation of speech perception in dyslexia has produced some positive findings (Manis, McBride-Chang, Seidenberg et al., 1997). Current evidence comes primarily from performance on categorical perception tasks (e.g., identifying synthetic speech tokens as [ka] or [ga]). As a group, children with dyslexia show fuzzy boundaries between different phonemes, constituting a categorical speech perception deficit (it should be noted that such difficulties are more marked if children have concomitant language impairments; see chapter 47; Joanisse, Mains, Keating, & Seidenberg, 2000). Serniclaes, Van Heghe, Mous’tay, Carré, & Sprenger-Charolles (2004) showed that not only did children with dyslexia show reduced between-category discrimination, but also they were more sensitive to (within category) variations in the acoustic characteristics of individual phonemes than age-matched controls. Such hypersensitivity implies that phoneme categories are not well-defined and this in turn may pose important problems for learning to read in all alphabetic systems that depend on knowledge of how phonemes are related to letters.

Overall, evidence for the involvement of perceptual problems in dyslexia is equivocal; findings suggest that neither auditory nor visual (nor cerebellar) deficits are necessary or sufficient causes of dyslexia (Ramus, Rosen, Dakin et al., 2003; White, Milne, Rosen et al., 2006). However, in the absence of longitudinal data it remains possible that a sensory deficit early
in development (which may resolve by the time children are diagnosed as having reading problems) may still have had a causal role in the etiology of the disorder.

**Spelling Difficulties**

Typically, the spelling difficulties of people with dyslexia are more severe and more resistant to remediation than their reading difficulties (Romani, Olson, & DiBetta, 2005). Such problems may be seen as a direct consequence of difficulties in mastering the mappings between orthography (spelling patterns) and sound within the phonological pathway (Fig. 48.1). The spelling errors made by people with dyslexia include both phonetic spelling errors, where the sound pattern of the word is represented accurately (e.g., biscuit → bikit; chaos → kaos), and phonetically unacceptable spelling errors (e.g., umbrella → unbrl; adventure → afeorl).

The term dyslexia has sometimes been applied to individual who have spelling difficulties in the absence of reading problems. These children (called “dysgraphic”; Frith, 1980) tend to have higher verbal than performance IQ and they make phonetically accurate spelling errors (Nelson & Warrington, 1974; Romani, Olson, & DiBetta, 2005). Evidence from single-case studies suggests they may have subtle visual memory impairments (Goulardis & Snowling, 1991; Romani, Ward, & Olson, 1999). This cognitive profile has also been observed in “unaffected” offspring of parents with dyslexia, suggesting that it may represent a broader phenotype of dyslexia in which good oral language skills have mitigated the risk of reading problems (Snowling, Muter, & Carroll, 2007).

**Reading Comprehension Impairments**

In contrast to children with dyslexia, “poor comprehenders” decode well but have problems understanding what they read. Their difficulties often go unnoticed in the classroom because they can read aloud competently. Poor comprehenders typically have normal non-verbal abilities and good phonology; they do well on phoneme awareness tasks and on simple memory tests (Nation, 2005). However, they have cognitive impairments that encompass poor working memory, problems making inferences and deficits in metacognitive processes, such as comprehension monitoring (Cain, Oakhill, Barnes, & Bryant, 2001; Cain, Oakhill, & Bryant, 2004). Clinically, the profile is often seen in combination with attention deficit/hyperactivity disorder (ADHD).

Within the Triangle model, poor comprehenders have problems both within the semantic pathway and in grammatical processes that feed it. The consequences are a tendency to rely heavily on a “phonic” approach, leading to the tendency to regularize words (e.g., to read broad as “brode” or bread as “breed”), a reduction in the benefit of context (i.e., limited semantic facilitation of word reading) and problems of reading comprehension – their defining characteristic. The reading comprehension impairments shown by these children are related to a range of oral language processing weaknesses (see chapter 47; Nation, Clarke, Marshall, & Durand, 2004).

**Etiology of Reading Difficulties**

**Genetic Influences on Dyslexia**

Prospective studies following the development of children born to parents with dyslexia confirm a heightened risk of literacy impairment in “dyslexic” families (Lyytinen, Erskine, Tolvanen et al., 2006; Scarborough, 1990; Snowling, Gallagher, & Frith, 2003). However, families share environments as well as genes, and twin studies can be helpful in disentangling genetic and environmental influences on reading behavior (see chapter 23).

Twin studies of dyslexia find that the proportion of variance attributable to genetic factors (heritability) is significant (Pennington & Olson, 2005), and heritability appears to be higher among more severely disabled readers (Bishop, 2001) and among those with higher IQ ( Olson, Datta, & DeFries, 1999). Two relatively small-scale British twin studies have reported that shared environment accounted for most of the variance in reading, once IQ had been controlled for (Bishop, 2001; Stevenson, Graham, Fredman, & McLoughlin, 1987), perhaps reflecting more diverse educational experiences in these samples. Moreover, it is important to bear in mind that some of the shared genetic variance between twins may be caused by gene-environment correlation (Rutter, 2006). For example, the home literacy background provided by more literate parents may foster reading skills, and better readers may themselves actively seek out more literary experiences.

Studies of the molecular basis of genetic influences on reading have used a variety of methods (for reviews see Fisher & DeFries, 2002; Grigorenko, 2005). To date, the strongest evidence for linkage with dyslexia (in terms of number of replications) is a site on the short arm of chromosome 6. Other linkages that have been replicated although less frequently are on chromosomes 1, 2, 3, 11, 15 and 18 (Grigorenko, 2005). Recently, some candidate susceptibility genes have been identified within these chromosomal regions, including KIAA0119 on 6p (Cope, Harold, Hill et al., 2005) and DYX1C1 in the 15q21 region (Taipale, Kaminen, Nopola-Hemmi et al., 2003). However, it is important to remember that genetic influences are probabilistic; complex disorders depend on the combined influence of many genes of small effect, as well as on environmental influences. Moreover, the findings of linkage studies depend upon the behavioral phenotype, such that the use of different definitions of dyslexia by different groups will affect the genotypes that are identified (particularly when data are taken from children learning to read in different languages).

To date, there is no comparable analysis of the genetic bases of reading comprehension difficulties. However, work on the genetic basis of specific language impairments is likely to be relevant here (SLI Consortium, 2002, 2004).

**Brain Bases of Dyslexia**

The majority of children with specific reading difficulties do not show any gross structural brain abnormalities, but early neurodevelopmental abnormalities appear to be involved (Galaburda, 1994; Galaburda & Kemper, 1978). It has been reported that there are a wide range of structural brain
CHAPTER 48

differences between people with dyslexia and controls (Eckert, 2004) and an “anatomical risk index” comprising measurements taken from the brain regions implicated in dyslexia has been reported to distinguish between people with specific decoding difficulties and those with poor reading comprehension (Leonard, Eckert, Lombardino et al., 2001, Leonard, Eckert, Given et al., 2006).

Functional brain imaging studies have contributed to understanding of the brain bases of dyslexia (see chapter 11). Findings indicate that children and adults with dyslexia typically show less activity than controls in left hemisphere temporo-parietal cortex when reading (Price & McCrory, 2005; Shaywitz, Shaywitz, Blachman et al., 2004), and preliminary evidence suggests that intervention may reduce this underactivation (Simos, Fletcher, Bergman et al., 2002). The causal status of brain differences in dyslexia is debatable because brain development shows considerable plasticity and both its structure and function are shaped by use (Johnson, 2005). A reasonable conclusion is that the brain differences between dyslexic and normal readers reflect the interplay of genetic influences and environmental experiences on brain development.

Social and Environmental Influences on Reading Development and Disorder

Home and School Background

It is important not to overlook the critical role of the environment in shaping a child’s reading development (Phillips & Lonigan, 2003). Evidence indicates that reading disorders show a strong social gradient that is not entirely attributable to differences in phonological skills or general intellectual abilities (Hecht, Burgess, Togesen, Wagner, & Rashotte, 2000), and poor readers often come from large families, where later-born children may face delays in language development (see chapter 47). One aspect of delayed language development is poor vocabulary, a mediator of deficits in phoneme awareness (Carroll, Snowling, Hulme, & Stevenson, 2003). Direct literacy-related activities in the home are also important (Whitehurst & Lonigan, 1998), although these primarily affect reading comprehension, via vocabulary growth (Stevenson & Fredman, 1990).

Traditional definitions of dyslexia excluded children whose reading failure was caused by “inadequate opportunity to learn,” but how to interpret this is unclear. Comparisons of children from the same catchment area attending different schools have emphasized that schooling can make a substantial difference to reading achievement (Rutter & Maughan, 2002). Equally, school experience can differ markedly between good and poor readers.

Cross-linguistic Manifestations of Reading Disorders

Aside from the home and school environment, an important macro-environmental influence on reading development is the language in which a child learns (Harris & Hatano, 2000). The reading and spelling symptoms of dyslexia vary across orthographies; in languages such as German or Italian, reading difficulties are identified by slow rates of reading (few reading errors occur), whereas in English poor reading accuracy is the primary behavioral marker (Landerl, Wimmer, & Frith, 1997). However, reading universally is a process involving the mapping of visual characters on to phonological forms; it follows that children with phonological impairments are at risk of reading difficulties in all languages.

Gene–Environment Correlation and Reading Practice

Aside from the above, being a poor reader affects the motivation to read. From very early in development, children differ in their interest in books, and children at risk of dyslexia may well be among those who are more difficult to engage. Where parents themselves have literacy problems, this might also set the stage for less than optimal reading-related experiences in the home (cf. Petrill, Deater-Deckard, Schatsneider, & Davis, 2005).

One variable that can have a significant impact on the behavioral manifestation of a reading disorder is reading practice. Measures of “print exposure” (assessed by questionnaires that require participants to differentiate real book titles or real authors’ names from distracter items, and which document reading habits) account for variance in reading skills when other critical variables such as IQ and phonological awareness have been controlled (Cunningham & Stanovich, 1990). Print exposure measures are simply a proxy for the amount of reading done and it is likely that the effects of low exposure are cumulative, causing reader-differences in reading competence to become magnified over time.

In summary, as might be expected for a complex trait such as reading, the etiology of reading disorders is varied and depends on both genetic and environmental factors. It is critical to distinguish between problems with decoding and problems of reading comprehension. Some children carry a genetic risk of dyslexia but whether or not they are classified as dyslexic depends upon the particular language and school context in which they learn and the other skills (or deficits) they bring to the task of reading. In keeping with this, there is currently a move away from single-deficit toward multifactorial models that explain the nature and causes of dyslexia (Pennington, 2006).

Language-Learning Impairments

In recent years, there has been a growing tendency to collapse together disorders of reading (primarily dyslexia) with disorders of speech and language development, reflecting the clinical impression of considerable behavioral overlap between these disorders and their effects on academic performance. However, this is a retrograde step. Children with speech and language impairments are at high risk of reading problems because they children at family risk of dyslexia (Lyytinen, Erskine, Tolvonen et al., 2006; Pennington & LeFley, 2001; Scarborough, 1990; Snowling, Gallagher, & Frith, 2003), children with specific language impairment (Bishop & Adams, 1990; Catts, Adlof, Hogan, & Weism, 2005; Snowling, Bishop, & Stothard, 2000) or children with speech sound disorders (see chapter 47; Bird, Bishop, & Freeman, 1995; Nathan,
Stackhouse, Goulandris, & Snowling, 2004; Raitano, Pennington, Tunick, & Broada, 2004). The nature of the risk depends on a number of factors including the pervasiveness and persistence of the speech-language impairment.

In order to understand the relationship between the different disorders, Bishop and Snowling (2004) proposed a two-dimensional model (Fig. 48.2). Within this model, the risk of word-level decoding deficits is related to phonological skills (that vary from good to poor) and the risk of reading comprehension deficits is related to language skills beyond phonology (grammar and vocabulary, again varying from good to poor). This two-dimensional model has direct implications for the assessment and management of children’s reading difficulties and suggests that concerns over whether a particular child fulfills the diagnostic criteria for a specific reading disorder may be of little importance – there are continuous variations in reading skills in the general population and children with either decoding or reading comprehension problems will benefit from appropriate educational interventions which need to be tailored to individual children’s needs.

Problems of Numeracy

Definition, Classification and Incidence

Children experience different kinds of difficulty with numeracy skills. Some affect arithmetic (computation) whereas others affect more conceptual aspects of mathematics that require problem-solving. However, these are not well differentiated either in diagnostic manuals or in practice; tests of number skills differ in the extent to which they assess basic arithmetic as opposed to mathematical concepts (e.g., numerosity, magnitude, commutativity or geometry) and this leads to an unhelpful tendency to categorize all mathematical difficulties together. It is also important to note that mathematical learning is a cumulative process and therefore a basic deficit in computation will have downstream effects: addition, subtraction and multiplication processes are involved in higher-level mathematics, such as geometry, algebra and calculus. In addition, high levels of anxiety are often associated with mathematics and these can pose obstacles to learning for children who find basic arithmetical tasks difficult (Ashcraft & Kirk, 2001).

Individual differences in the manifestation of number problems have been reported in the cognitive–neuropsychological literature using a framework developed by McCloskey, Caramazza, and Basili (1985). Within this framework, the calculation system can be dissociated from the number processing system. Temple (1994) has reported single-case evidence for the existence in childhood of “digit dyslexia,” in which there is a specific difficulty in the acquisition of lexical processes within the number processing system. Geary (1990) suggested that mathematically disabled children use the same strategies as age-matched controls but differ in the speed and skill of strategy execution, they can retrieve fewer number facts, they are poor at monitoring their counting and they are poor at detecting computational errors (Geary, Bow-Thomas, & Yao, 1992).

The incidence of mathematics difficulties is less well documented than for reading difficulties. In the UK, Lewis, Hitch, and Walker (1994) used a simple cut-off approach to defining difficulties among 9- to 10-year-old children and reported that only 1.3% of children showed a specific difficulty in maths
(standard score less than 85) in the presence of normal non-verbal ability and reading (at or above a standard score of 90 on both). However, another 2.3% had both reading and maths problems defined in an analogous way. This study reported an equal incidence of maths difficulties in boys and girls, in contrast to the higher incidence of reading difficulties among boys that they (and other studies) reported. Other large-scale studies have reported incidence rates of 6–7% for mathematics difficulties (Baker & Cantwell 1983; Gross-Tsur, Manor, & Shalev, 1996) while Share, Moffit, and Silva, (1988) using laxer criteria (a standard score of 92, the bottom 30% of the population) found combined rates of mathematics difficulties (with and without reading problems) of 11.2%. Given the different populations studied, and the different criteria for classification adopted, it is difficult to compare the rates reported. Nonetheless, it is clear that mathematical learning difficulties occur quite frequently and are often associated with reading difficulties. They also commonly co-occur with attention problems; Gross-Tsur, Manor, & Shalev, (1996) reported that 26% of children with mathematics disorder also had ADHD.

Cognitive Explanations of Arithmetic Difficulties

There is a relatively small literature investigating the cognitive impairments associated with mathematical difficulty in children who do not have comorbid reading impairments. Most of the evidence comes from arithmetic tasks (rather than mathematical problem-solving) and is therefore limited.

Deficits in Number Processing

Dehaene (1997) has argued that the basis of numerical cognition is a “number sense” – a preverbal system involving the ability to understand physical magnitudes and numerical quantities. It is possible that many of the problems observed in children with mathematics difficulties stem from a basic impairment in a number sense system that develops early and forms the foundation for later acquired verbally mediated mathematical skills (such as addition; Geary, 1993).

In line with this, Geary, Hoard, and Hamson (1999) found that children with arithmetic problems were less accurate than controls at comparing the magnitudes of Arabic digits. Landerl, Bevan, & Butterworth, (2004) found that children with arithmetic difficulties, either alone or comorbid with reading difficulties, were slower than controls at number naming, number reading, number comparisons and verbal counting. Thus, basic number processing has been shown to be impaired in children with specific arithmetic difficulties, and is to some degree independent of other abilities (Dehaene, 1997; Gelman & Butterworth, 2005). In children with intact number sense, other cognitive resources that are used in mathematics seem to be deficient.

Working Memory and Speed of Processing Impairments

During calculation, subcomponents of an arithmetic problem must be held in temporary storage while processing proceeds. With multidigit problems, it is necessary to monitor the calculation process, to inhibit numbers from the initial calculation and to hold in mind the products of different steps in the calculation. Thus, arithmetic skills carry both simple and complex working memory demands and also tap executive function. It is therefore not surprising that working memory deficits are associated with arithmetic difficulties.

Children with arithmetic difficulties perform poorly on complex working memory tasks, such as backward digit span (which has an executive component) and counting span (Geary, Hoard, & Hamson, 1999; Hitch & McAuley, 1991; Passolunghi & Siegal, 2001) but not typically on simple tests of verbal short-term or phonological memory unless the task has a numerical component (Geary, Brown, & Samaranayake, 1991; Hitch & McAuley, 1991).

According to Kail (1991), the amount of information that can be retained in memory depends on speed of processing, which in turn is related to the amount of attentional resources that can be directed to different tasks (Case, 1985). Bull and Johnston (1997) found that processing speed accounted for unique variance in arithmetic ability among 7-year-old children after controlling for differences in reading ability; children with lower arithmetic ability were slower than controls at number naming and sequencing, number matching, pegboard speed, one-syllable speech rate and reciting the alphabet. However, no IQ data were provided, and therefore processing speed may have been a proxy for general ability. Durand, Hulme, Larkin, and Snowling (2005) found that speed of information processing (as assessed by speed of visual search) was not a unique predictor of arithmetic skill after the effects of IQ and the speed of number comparison had been accounted for. This suggests that the speed of processing numerical information (rather than general information processing speed) may be critical for the development of arithmetic skills.

Executive Deficits

A body of evidence implicates executive deficits in arithmetic disability. McLean and Hitch (1999) found that 9-year-old children with specific arithmetic difficulties were impaired on the “Trail-Making” task where they were required to connect alternating sequences of numbers and letters (e.g., 1-A, 2-B) or numbers and colors (e.g., 1-yellow, 1-pink, 2-yellow, 2-pink). In a similar vein, Bull, Johnston, and Roy (1999) reported that children with high and low arithmetic ability differed on several aspects of the Wisconsin Card Sorting Test, notably perseveration (see also Bull & Scerif, 2001). The authors proposed that children with specific arithmetic difficulties have executive impairments that impair their ability to shift psychological set, plan action and judge the reasonableness of answers – all skills that are involved in mathematics. However, such difficulties may be attributable to comorbidities with other disorders (e.g., ADHD) that have not been controlled for in these studies.

Spatial Deficits

There is good evidence for associations between mathematical and spatial abilities (Dehaene, 1997; Hermelin & O’Connor,
It is also common for children with non-verbal learning difficulties (typically associated with deficits on tests of spatial ability and performance IQ) to show mathematical difficulties (but not necessarily problems with number facts that are verbal). Such associations may reflect the anatomical proximity of brain systems subserving number sense and spatial processing. Alternatively, they may reflect a more fundamental association; the number sense system is itself a spatial system involving a spatially arranged “number line” (Dehaene, 1997). More basically, dealing with place values in arithmetic requires that we keep track of the spatial arrangements of numbers.

**Verbal Impairments**

Some aspects of arithmetic involve verbal skills. Learning to count is a verbal skill and problems with learning the count sequence are common in children with mathematics disorder. Similarly, arithmetic problems may place heavy demands on verbal working memory systems and these in turn place heavy demands on phonological (speech-based) coding. The frequent co-occurrence of reading and mathematics difficulties indicates that many children with mathematics difficulties will have phonological problems, and such problems might well be expected to compromise learning to count and the manipulation of numerical information in verbal working memory tasks.

To summarize, the nature of mathematics difficulties is much less well understood than reading difficulties, and this reflects the fact that much less is understood about the mechanisms of mathematical skills and their development than for reading skills and their development. Mathematical skills depend upon a complex interplay between non-verbal and verbal cognitive systems, and mathematical skills are arguably more diverse and more complex than reading skills. It seems likely from a cognitive perspective that mathematical difficulties may result from a number of underlying deficits, including deficits in a non-verbal “number sense” system located in parietal brain areas as well as verbal systems that interact with this system. Further progress in this area is likely to depend upon longitudinal studies that attempt to focus on more well-defined arithmetical skills.

**Etiology**

**Genetic Effects**

There is evidence indicating substantial genetic and environmental influences on the development of mathematical skills generally, and more specifically on the development of mathematics difficulties. There is good evidence that mathematical difficulties tend to run in families but this may reflect either shared environment or genetic effects. In a large-scale UK twin study, Kovas, Harlaar, Petrill, and Plomin (2005) found evidence for substantial heritability for normal variations in mathematical skills. There were substantial overlaps between the genes responsible for arithmetic and general intelligence, and arithmetic and reading, although the degree of overlap was far from perfect, suggesting that there are specific genetic effects on the development of arithmetical skills.

There are very few studies that have directly assessed possible genetic influences on mathematical difficulties (as opposed to normal variations in mathematical skills). In a study with a large sample size (Oliver, Harlaar, Hayiou-Thomas et al., 2004), the heritability of mathematical difficulties was assessed by selecting children in the bottom 15% of the population on teacher ratings of children’s mathematical abilities. This study yielded a high group heritability estimate for mathematical difficulties of 0.65 (compared to the estimate of 0.38 reported by Alarcón, DeFries, Light, & Pennington, 1997, based on a smaller sample). These results are compatible with the same genetic influences operating to produce the group deficits in mathematics as well as the range of individual differences in mathematical skills observed within the population as a whole (Plomin & Kovas, 2005).

In summary, current evidence suggests that there are substantial genetic influences on mathematical difficulties and that these same genetic influences may also operate to influence individual differences among people in the normal range of mathematical ability. It has also been reported that the comorbidity between mathematical and reading difficulties is in part brought about by common genetic influences operating on both disorders (Knopik, Alarcón, & DeFries, 1997).

**Brain Bases of Arithmetic Disorders**

Neuroscientific studies suggest that the neural substrate of the number sense system depends critically upon bilateral areas of the horizontal intraparietal sulcus (HIPS) (Dehaene & Cohen, 1997). Dehaene, Piazza, Pinel, and Cohen (2003) have proposed that there are three parietal circuits for numerical processing. Problems in the development of such brain systems may be fundamental to the problems observed in children with mathematical difficulties, although as yet direct evidence for this is lacking (Wilson & Dehaene, 2006). Consistent with the idea of mathematical difficulties being associated with parietal dysfunction, Isaacs, Edmonds, Lucas, and Gadian (2001) reported a specific reduction in gray matter in the left HIPS in a group of adolescents with mathematical difficulties (without reading problems) who had been born prematurely, compared with a control group without mathematical difficulties who had been born equally prematurely. This difference in the left HIPS was only found for children with problems with calculation, and not for another group of children who had problems with mathematical reasoning. Also, several studies have shown parietal deficits in Turner’s syndrome, a syndrome associated with arithmetic deficits (Reiss, Mazzocco, Greenlaw, Freund, & Ross, 1995).

**Developmental Co-ordination Disorder**

**Nature, Classification and Incidence**

Developmental co-ordination disorder (sometimes referred to as “dyspraxia”) is a disorder of motor skills and is included here because problems with motor skills can adversely affect children’s educational achievements and self-esteem. Formally,
CHAPTER 48

the diagnosis of developmental co-ordination disorder (DCD) is used to describe problems of motor co-ordination that occur in otherwise normal children and significantly affect the activities of daily living. In practice, such problems often signify risk factors for other disorders, and DCD is commonly found in association with developmental disorders such as language impairment (Hill, 2001) or autism, and the overlap with attention problems is high (Gillberg, 1999).

Population estimates of the incidence of DCD vary widely (5–18%) and these estimates depend both on the tests and the cut-offs used for diagnosis (Geuze, Jongmans, Schoemaker, & Sit-Englesman, 2001). Arguably, tests for the assessment of motor difficulties are less thoroughly developed and less well standardized than tests of reading, arithmetic and IQ but teacher and parent ratings are useful screening tools (Chambers & Sugden, 2006; Green, Bishop, Wilson et al., 2005). It has been reported that there is a ratio of at least two boys to each girl with DCD (Wright & Sugden, 1996), although data on sex ratios may be hard to interpret because some of the tasks used to assess motor skills are gender-biased (e.g., throwing a ball) and there is little agreement among professionals about how to diagnose DCD (Sugden & Chambers, 2005). The symptoms of DCD can vary considerably and may include gross motor difficulties, such as problems running, hopping, jumping, catching a ball and balancing, and fine motor difficulties including a lack of manual dexterity, difficulty in doing up buttons and laces, in dressing and in using eating utensils. Speech-motor skills can be affected and problems of pencil control are widespread. When DCD occurs in pure form, such children have been reported to have normal reading skills and only minor spelling problems (Lord & Hulme, 1987a) even though their handwriting is usually very poor.

A mistaken view is that children with DCD grow out of their clumsiness; follow-up studies are rare but evidence suggests that such children remain less physically competent throughout adolescence (Gillberg, Gillberg, & Groth, 1989) and the difficulties they have at secondary school include problems with handwriting and the presentation of work, and difficulties in science, art, design and technology (Losse, Henderson, Elliman et al., 1991). However, the coupling between motor impairments and academic achievement may not be causal and is likely mediated by comorbidities and/or psychosocial problems.

Explanations of Developmental Co-ordination Disorder

A dominant approach to explaining the motor deficits found in children with DCD has been in terms of perceptual impairments, particularly in terms of problems with kinesthetic or visual perception. (An earlier term used to refer to this group of children was developmental apraxia and agnosia which captures the central role of perceptual disorders in the clinical profile of these children.)

Problems of Kinesthetic Perception

Kinesthesia refers to an awareness of the position, location and velocity of movement of the limbs and the forces exerted by the muscles. Poor kinesthetic sensitivity has been reported among children with DCD (Laszlo, Bairstow, & Bartripp, 1988) but this finding has not been widely replicated (Lord & Hulme, 1987b) and a meta-analysis found only a weak association between kinesthetic sensitivity and poor motor skills (Wilson & McKenzie, 1998).

Visual Perceptual Deficits

Stronger evidence exists for an association between visual perceptual problems and motor disorders (in the absence of problems with visual acuity; Henderson, Barnett, & Henderson, 1994; Lord & Hulme, 1987a), with the greatest deficiency being observed in visuospatial tasks, regardless of whether they have a motor component. It has been proposed that guidance of our movements in space depends upon a sensorimotor map that serves to translate visually perceived locations to spatially appropriate action patterns (Held & Hein, 1963). It could be argued that a deficit in the visual perception of spatial information will inevitably lead to problems in the guidance of movements and problems in “calibrating” and “recalibrating” the sensorimotor map during development. Clinically, occupational therapists often use visual perceptual training programs with these children (Germak & Larkin, 2002).

Balance and Postural Control

More proximal causes of DCD have been proposed in balance and postural control, movement planning and preparation, and execution and feedback processes (Geuze, 2005). In addition, limitations of memory and attention and reduced muscle strength may have a role to play. It should be noted that in principle some of these difficulties might arise as a consequence of the perceptual impairments discussed above.

Etiology

There is evidence that low birth weight or prematurity increases the risk of developing the disorder (Jongmans, Demetre, Dubowitz, & Henderson, 1996; Marlow, Roberts, & Cooke, 1989), suggesting links with neurodevelopmental immaturity. Furthermore, as noted in ICD-10 (WHO, 1996), a careful clinical examination may reveal neurological symptoms such as choreiform movements of unsupported limbs in such children. More generally, the comorbidity of DCD with impairments of reading and language, as well as with ADHD and autism spectrum disorder suggests shared genetic risk with these other developmental disorders (see chapter 3; Chambers & Sugden, 2006). A recent behavioral genetic study using questionnaire-based measures of DCD and ADHD with a large sample of twins (Martin, Pick, & Hay, 2006) indicates a substantial heritable influence on each disorder, as well as a substantial shared genetic influence.

Non-verbal Learning Disabilities

Definition

A diagnosis of non-verbal learning disabilities (NLD) is sometimes given to a child who displays difficulties with
visual-perceptual-organizational abilities, motor skills, tactile perception, and non-verbal problem-solving in the absence of basic decoding or spelling impairments (Rourke, 1989, 1995). However, non-verbal learning difficulty syndrome is not a disorder with validated clinical criteria and therefore the diagnosis is controversial; rather it cuts across taxonomies such as reading and mathematical disorders that classify children according to patterns of impairment in the academic arena. Although described as a non-verbal difficulty, many children with NLD experience speech-language difficulties including pragmatic deficits (Semrud-Clikeman & Hynd, 1990). Worrill, Humphries, and Tannock (1999) reported that children with NLD had difficulties making inferences despite apparently good verbal skills, and Klin, Volkmar, Sparrow, Cicchetti, and Rourke (1995) found a strikingly high degree of concordance between Asperger’s syndrome and NLD but not between NLD and high-functioning autism.

Cognitive Deficits in Non-verbal Learning Disabilities

Most studies of NLD involve clinical samples and epidemiological data are not available. Moreover, few research studies have included adequate control groups and findings regarding the cognitive deficits in NLD are often tautological in that they reflect diagnostic or recruitment criteria. For example, although it is possible that deficits in spatial cognition are at the core of the syndrome, it must be remembered that the diagnosis may have been given to children who in particular gain lower performance than verbal IQs. Similar criticisms can be leveled at studies that test Rourke’s (1995) hypothesis that the primary deficits are in visual and tactile perception, dealing with novel stimuli, and analogical reasoning (e.g., Chow & Skuy, 1999; Cornoldi, Dalla Vecchia, & Tressoldi, 1995).

It seems likely that, as theoretical understanding of the different components of NLD and their cognitive causes improves, the syndrome will be reconceptualized. At the present time, positing an overarching syndrome of NLD has little value and it is more productive clinically to assess and treat the diverse problems that are brought together under this heading.

Emotional and Behavioral Adjustment in Learning Difficulties

Reading Difficulties

There is evidence of a link between reading difficulties and both disruptive behavior (Hinshaw, 1992; Maughan, Pickles, Hagell, Rutter, & Yule, 1996) and emotional disorders (Maughan, Rowe, Loebel, & Southamer-Loebel, 2003; Willcutt & Pennington, 2000). However, the processes responsible for these outcomes are not understood. An influential hypothesis has been that behavior problems associated with reading difficulties may result from progressive school failure and lowered self-esteem (Chapman & Tunmer, 1997). An alternative causal model of the relationship is that disruptive behavior at school is the result of attention problems which are common with poor reading and may interfere with the acquisition of reading skills. However, the causal relationships between reading, behavior and emotion are complex, and may differ between boys and girls and depend upon the stage of development that is considered (Williams & McGee, 1994).

In a study of 289 9- to 15-year-olds identified as having specific literacy difficulties from a representative sample of some 5000 UK children, Carroll, Maughan, Goodman, and Meltzer (2005) reported that children with reading difficulties are at increased risk of attention problems, conduct disorder, anxiety disorders and depressed mood. However, they argued that the mediating mechanisms differ. The association between literacy difficulties and behavior problems was mediated by inattention (rather than hyperactivity), whereas the link with heightened levels of anxiety was direct. A similar conclusion was reached from a twin study of literacy difficulties by Willcutt and Pennington (2000). These investigators reported an increased risk of attention and conduct difficulties in probands as well as cotwins; however, anxiety was reported only in those with reading difficulties, suggesting that such difficulties may arise as the result of stresses associated with educational difficulties. Regarding the link between poor reading and low mood, Willcutt and Pennington (2000) reported heightened levels of depression in girls mediated by ADHD, whereas Carroll, Snowling, Hulme et al. (2003) found that self-reported low mood was more common in boys than girls, and primarily in the 11- to 12-year-old age group.

Longitudinal data are required to test hypotheses regarding the psychosocial sequelae of reading difficulties. Snowling, Muter, & Carroll, (2007) assessed the outcomes of children at family risk of dyslexia at 12 years. There was an elevated risk of attentional and emotional problems in those who had reading problems (according to parental report); however, the children rated themselves as positively as did normal readers, except in the academic arena. Maughan, Pickles, Hagell et al. (1996) followed 127 poor readers from the age of 10 years into early adulthood. There was a tendency for reading difficulties to be associated with poor attention and overactivity, which in turn placed poor readers at risk of behavioral problems (see also Fergusson & Lynskey, 1997). However, behavior problems at 14 years reflected earlier behavior problems rather than reading difficulties, and social adversity was found to increase the risk of antisocial behavior among girls but not among boys (for whom increased rates of offending were associated with poor school attendance).

As young adults, about 25% of this sample remained severely impaired in reading (Maughan & Hagell, 1996). Nonetheless, relatively positive self-reports suggested that many had gained employment in which there were restricted literacy demands and their reading problems were no longer of functional significance. In the majority of areas, those with a history of specific reading difficulties were functioning comparably to peers. However, young women with a history of specific reading retardation were at increased risk of psychiatric disorder, possibly related to a high rate of relationship breakdown. Male poor readers, in contrast, had more difficulty
CHAPTER 48

in gaining independence. However, these difficulties were the consequence of comorbid difficulties with peer relationships rather than reading problems.

Other Learning Difficulties
Relatively little attention has been paid to the outcomes of specific learning difficulties other than reading although there is evidence that anxiety specific to the subject at school increases with time among poor mathematicians and in turn affects maths attainments.

A little evidence suggests that the psychosocial outcomes of children with developmental co-ordination disorder can be reasonably good with low self-esteem restricted to the motor domain (Losse, Henderson, Elliman et al., 1991), although poor social competence has also been reported. A frequent observation has been that rates of depression and suicidal behavior or ideation in adolescents and young adults with NLD are relatively high. However, studies suffer from the lack of representative samples and appropriate control groups (Little, 1993), and mediating mechanisms are unclear. In particular, the role of comorbid disorders in determining outcomes has not been addressed.

In summary, although it is generally believed that specific learning difficulties can cause psychosocial problems, the evidence for this view is sparse. The literature suggests that the majority of children with specific difficulties in literacy, numeracy or motor skills are relatively free of mental health problems. The heightened susceptibility to psychiatric disorder reported for children with NLD may reflect its comorbid nature.

Clinical Implications
Assessment
Children with specific learning difficulties will rarely be referred to child psychiatrists unless such difficulties have contributed to emotional or behavioral difficulties. However, it may be easy to miss a specific learning difficulty in a child with a mental health problem (particularly in a child referred for ADHD).

Children's Reading Difficulties
If a referred child reports a failure to learn to read, has dyspraxic tendencies or is seriously underachieving, the most appropriate strategy is to refer this child to an agency within the school system for assessment. A comprehensive assessment should include assessment of general cognitive ability (IQ), single word reading and spelling, reading comprehension, expressive writing and number skills (the Wechsler scales provide tools for comprehensive assessment of these skills; WISC-IV, Wechsler, 2004; WIAT-II, Wechsler, 2005). The assessment will have more value if it proceeds to assess phonological skills and the reading strategies the child is currently using with a view to prescribing appropriate intervention. In addition, tests of speed of processing and working memory, and in-depth investigation of oral language skills may be appropriate (Snowling & Stackhouse, 2006). In the past such assessments were the domain of educational psychologists; however, now it is often a teacher with specialist qualifications who would undertake such assessments, replacing IQ testing with assessment of language and/or non-verbal reasoning.

Other Learning Difficulties
Given the substantial overlap between reading difficulties and difficulties with mathematics, an assessment of mathematical performance using standardized tests should ideally be part of a comprehensive literacy assessment. However, time constraints often preclude this and a regrettable fact is that most referrals are from parents or teachers who are more concerned with planning literacy rather than numeracy support.

It can be difficult for clinicians to provide parents with the answer to the question foremost in their mind, “Is my child dyslexic?” Current diagnostic practice varies considerably, and although the term “dyslexia” is more widely accepted in educational circles than in the past, it may be used in a general sense to convey “reading difficulties with a phonological basis,” irrespective of IQ. It is also important for clinicians to be aware that the label dyslexia may be used differently by different agencies. As with all developmental disorders, clinicians need to emphasize to families the dimensional nature of dyslexia; it can vary from mild to severe, there may be individuals who show some but not all of the symptoms (likely in families with dyslexia) and the problems that the child experiences may change through development with compensation possible in favorable circumstances (Snowling & Maughan, 2006).

A number of different practitioners, including physiotherapists, occupational therapists, specialist teachers and pediatricians, have a role in the assessment of DCD. It is generally agreed that such assessments should incorporate the evaluation of a range of movements as well as the impact of motor difficulties on everyday skills and psychosocial functioning. Individually administered tests of gross and fine motor skills, incorporating ball skills, manipulative skills and balance, are commonly used (Henderson & Sugden, 1992) and parent and teacher completed checklists and self-report questionnaires can be useful (Chambers & Sugden, 2006; Green, Bishop, Wilson et al., 2005). It is also recommended that prior to an intervention program, physical fitness should be assessed.

Interventions
At the time of writing, there are few randomized controlled trials evaluating educational interventions; however, calls have been made that these should become the “gold-standard” methodology for informing educational policy and practice (Torgerson & Torgerson, 2001).

Children who have a family history of dyslexia or a history of speech-language difficulties are at high risk of reading difficulties, and motor delays appear to be part of an inherited form of dyslexia. If speech production deficits persist to school age, the likelihood of literacy problems is high. It is therefore important that such children receive appropriate
support during the preschool period, including speech and language therapy, and, more generally, parental support with literacy can be helpful (Hewison, 1988). However, it is important to be mindful that many children with preschool speech and language impairments may make a good start in learning to read but fail later as the demands of reading increase. Careful monitoring of high-risk children is therefore advisable throughout the primary school years to ensure the effects of early interventions do not wash out.

Reading Intervention

Theoretical knowledge of the relationship between phonological skills and learning to read, and phonological deficits in dyslexia has led to the development of effective reading intervention programs that promote phonological skills in the context of reading (Brooks, 2002; National Reading Panel, 2000; Troia, 1999). For children with reading difficulties, such programs are best delivered by trained personnel who understand how to tune a program to a child’s specific needs. The main elements of such approaches (e.g., Hatcher, Hulme, & Ellis, 1994) include:

- Training in letter knowledge;
- Teaching concepts of print;
- Training to manipulate the phonemes in words;
- Applying letter and sound knowledge to word reading and writing (phonics);
- Reading text;
- Writing activities.

Recently, the approach has been adapted for delivery by mainstream teachers to whole classes, and by teaching assistants to small groups (Hatcher, 2006). In a randomized controlled trial, the approach has been shown to be effective with reading gains of on average 0.23 standard score points per hour of intervention, an educationally significant improvement (Hatcher, Hulme, Miles et al., 2006). These findings converge with those of other research groups and have direct policy implications for the treatment of children with dyslexia in the school system (Torgesen, 2005).

However, it is important to emphasize that children with dyslexia can respond very slowly even to the most effective of teaching approaches (Hindson, Byrne, Fielding-Barnsley et al., 2005). An important issue therefore is the problem of “treatment resistors” — those children who, despite high-quality intervention, do not respond to teaching and continue to have persistent reading impairments (Torgesen, 2000). These “difficult to remediate” children tend to have the most severe phonological deficits (Vellutino, Scanlon, Sipay et al., 1996), are often socially disadvantaged and many experience emotional and behavioral difficulties. Because of the intractable nature of the disorder in some cases, some families turn to alternative or complementary therapies. The evidence base for the efficacy of such therapies is almost totally lacking (Muter, 2003). For children who do not respond to conventional treatments, the best advice at the present time is to consider more intensive therapies, including placement in

special units. In addition, information technologies have a lot to offer. Ideally, students with dyslexia should be taught to become fluent keyboard users, with special instruction in the use of a spell-checker. In addition, some children with dyslexia can use voice-recognition technology as an aid to written work. In formal assessments and examinations, people with dyslexia should normally be eligible for concessions. The most common arrangement is extra time in written examinations, and dispensation for spelling errors. If the student has particularly poor reading and writing skills, then they may be allowed someone to read the questions to them or an amanuensis.

In contrast to what is known about how to teach word-level reading skills, far less is known about how to promote reading comprehension effectively (for review see Westby, 2004). A meta-analysis of reading comprehension interventions designed for typically developing children reported that the eight most effective methods for improving text comprehension were comprehension monitoring, co-operative learning, graphic/semantic organizers for learning new vocabulary, story structure training, question answering, question generation, summarization and multiple strategy teaching (National Reading Panel, 2000). Also, the collaborative practice of speech and language therapists with teachers is likely to provide useful strategies for these children to learn.

Maths Intervention

Evidence regarding effective interventions for children’s mathematical difficulties is sparse. In the USA, there has been some limited evaluation of preschool programs for the prevention of mathematical difficulties (Starkey & Klein, 2000) and in the UK, evaluations of individualized programs of instruction for children with poor mathematical skills are in progress (Dowker, 2004). So far, to our knowledge, there are no studies that have investigated the effectiveness of interventions for older children who have developed mathematical difficulties. This is clearly an important area for further research. To date, the received view is that interventions are best targeted at specific arithmetic processes that are weak or impaired; however, there is as yet no evidence regarding specifically what works for which children.

Interventions for Developmental Co-ordination Disorder

Evidence regarding effective interventions for DCD is sparse (Mandich, Polatajko, Macnab, & Miller, 2001). Broadly speaking, there are two approaches to intervention for such children: process-oriented and task-oriented approaches (Sugden & Chambers, 2005; Wilson, 2005). Process-oriented approaches begin with an analysis of the underlying components of the task to be achieved and aim to train these processes. Examples include sensory integration methods and kinesthetic approaches but neither has met with much success when compared with control interventions. Task-oriented approaches are more functional and aim to teach skills that are deficient, for example, eating, dressing, ball catching or writing. Most practitioners aim to harness the support of parents and teachers
when implementing such programs. This is one way of circumventing a possible disadvantage of such approaches which is lack of transfer to related activities.

**Conclusions and Future Directions**

Understanding of the nature and causes of children’s reading difficulties is well advanced as is knowledge about appropriate interventions for word-level decoding difficulties. In this domain, cognitive models of reading acquisition have had a positive effect on progress. Although less is known about children’s arithmetic difficulties, the influence of cognitive models is beginning to bear fruit on methods of assessment and intervention. An advantage of the cognitive approach to learning difficulties is that it makes contact with what is known about normal development; furthermore, an understanding of the cognitive phenotype of disorders can foster understanding of links between genes, brain and behavior. Future research is needed to understand the causes and treatments of motor impairments and to better understand how comorbidity changes the nature, developmental course and outcomes of specific learning difficulties.

CHAPTER 48

CHAPTER 48

Terminology and Definitions

The terms used to refer to intellectual disability have undergone numerous changes over the last century. As terms used to describe socially devalued groups enter the common vocabulary, they quickly acquire disparaging connotations. Today’s scientific terminology quickly becomes tomorrow’s terms of abuse. “Idiots,” “imbeciles,” “morons,” “subnormals” and “retards” are nowadays nothing more than terms of denigration.

In this chapter we use the term intellectual disability in preference to the synonymous terms “mental retardation” (used in the ICD-10 and DSM-IV-TR classificatory systems) and “learning disability” (often used in the UK). Our choice reflects intellectual disability having become the preferred terminology within the international scientific community. It also has the value of avoiding confusion arising from the use of terms that have very different meanings in different countries (e.g., learning disability).

The definition of intellectual disability involves two core components: a general deficit in cognitive functioning, which emerges during childhood (American Psychiatric Association, 2000; World Health Organization, 1996). A “general deficit in cognitive functioning” is usually operationalized as a score of less than 2 standard deviations (SD) below the mean on a standardized IQ test. (Given that most IQ tests are constructed to have a mean of 100 and standard deviation of 15, this is ordinarily equivalent to a score below 70.) However, intelligence is not a unitary construct. As such, individuals whose test performance places them within this range may have markedly different profiles across the wide range of cognitive skills and abilities that are assessed by IQ tests. The definition is important in discriminating between people with significant deficits in multiple areas of cognitive functioning and people with very specific cognitive deficits (or specific learning difficulties).

The second component of the definition (emergence during childhood, typically before the age of 18) is important in distinguishing people with intellectual disability from people with cognitive deficits acquired in later life; in particular, deficits associated with dementia.

A third component, deficit in adaptive behavior, is sometimes added to the definition although this is more controversial. First, classificatory systems differ in the extent to which such deficits are seen as an inherent characteristic of the deficit in cognitive functioning or as an independent characteristic whose presence needs to be determined for the classification to apply. For example, ICD-10 guidance suggests that “adaptive behavior is always impaired, but in protected social environments where support is available this impairment may not be at all obvious in subjects with mild mental retardation” (World Health Organization, 1996, p. 1, italics added). In contrast, adaptive behavior is considered as an independent criterion in the commonly used definition advocated by the American Association on Intellectual and Developmental Disabilities (AAIDD, formerly the American Association on Mental Retardation; AAMR). Second, at present there is no consensus on how such “impairments” or “deficits” in social functioning and/or adaptive behavior should be operationalized.

Finally, a strong scientific case can be made for considering social functioning and adaptive behavior in terms of the conjunction between impairments in cognitive ability and prevailing social arrangements (rather than as a defining characteristic of intellectual disability). Such an approach is consistent with the World Health Organization’s International Classification of Functioning, Disability and Health (ICF; World Health Organization, 2001). The ICF represents an attempt to integrate medical and social models of disability by describing the interplay between changes or impairments in body functions or structures (e.g., intellectual ability) and the person’s potential capacity and actual performance in a range of activities in specific environmental, cultural and personal contexts. Domains of activity/participation considered under the ICF include: learning and applying knowledge; general tasks and demands; communication; movement; self-care; domestic life; interpersonal interactions; major life areas such as participation in education and employment; community, social and civic life.

Typology of Intellectual Disability

Intellectual disability (ID) can be considered to comprise two distinct groups. The first represents the lower end of the normal distribution of intelligence in the population. As a consequence, this group predominantly comprises individuals
with mild ID with little evidence of identifiable brain disorder. ID is presumed to result from both genetic and environmental influences. There is a strong correlation between the intellectual function of the child and that of first-degree relatives (Bunney, Thake, & Todd, 1989). The heritability of ID in this group is about 0.5 (Spinath, Harlaar, Ronald, & Plomin, 2004). Genetic influences are presumed to be polygenic, although some specific gene loci have recently been identified as influential (Butcher, Meaburn, Knight et al., 2005). Fertility in this group is normal or near-normal (Maughan, Collishaw, & Pickles, 1999), as is life expectancy (Patja, Iivanainen, Vesala, Oksanen, & Ruoppila, 2000). There is a strong association with lower socioeconomic status (see p. 822; Birch, Richardson, Baird, Horobin, & Illsley, 1970). That this association is at least partly mediated by environmental effects is apparent from the results of adoptee studies (Capron & Duyme, 1989). General health is usually unimpaired. Adaptive function and adult capacity to work and live independently are relatively mildly impaired.

The second group comprises ID as a consequence of identifiable or apparent brain disorders, of genetic or environmental origin (see p. 823). In this group, ID is typically more severe. There are more comorbid neurological problems such as epilepsy, and sensory or motor deficits, evidence of the greater degree of brain impairment. In this group, overt brain pathology is evident postmortem in most cases (Crome & Stern, 1972). Given that the majority of individuals in this group have a sporadic cause for ID, there is little or no correlation between the intellectual level of the affected child and their siblings or parents (Simonoff, Bolton, & Rutter, 1996). Stereotypic behaviors including self-injury and autistic symptoms are common (Einfeld, Piccinin, Mackinnon et al., 2006). In the developed world, there is also little or no correlation with socioeconomic status (Roeleveld, Zielhuis, & Gabreels, 1997). Fertility is regarded as substantially reduced and life expectancy is significantly lower than that of the community (Lavin, McGuire, & Hogan, 2006). Given the more severe intellectual impairment, eventual adaptive capacity to fill normal adult roles is substantially more impaired.

However, there are several important caveats to this typology. First, a minority of individuals with mild ID have identifiable causes. These may include acquired brain injuries, (e.g., from infection or trauma) or genetic disorders such as Prader–Willi or velocardiofacial syndromes (see p. 825). Second, a minor proportion of more severe ID will represent the group more than 3 SD below the mean on the normal distribution for intelligence. Third, it is important to recognize that there is substantial variation in level of function within each of these broad groupings.

**Functional Levels of Intellectual Disability**

Four levels of severity of ID, defined by ranges on standardized IQ tests, are described by both the ICD-10 and the DSM-IV. These are mild (approximate IQ 50–70), moderate (35–50), severe (20–35) and profound (below 20). However, it is important to note that individuals can vary considerably in their attainments across different developmental domains, often reflecting varied degrees of brain impairment to different cortical areas.

The following descriptions are derived from the ICD-10 Guide for Mental Retardation (World Health Organization, 1996) and Harris (2006) and describe functional abilities at the end of adolescence. More detailed descriptions of attainments at different functional levels are provided by standardized measures of adaptive behavior, such as the Vinelad Adaptive Behavior Scales (Sparrow, Balla, & Cicchetti, 1984). Individuals with mild ID typically have impaired literacy but normal language. There may be some emotional and social immaturity. Some young people with mild ID will develop a capacity for open or partially supported employment, albeit with unsophisticated task roles. They may marry and have children. However, as adults, rates of employment and independent living away from the family are lower in those with mild ID than in the general community (Hall, Strydom, Richards et al., 2005; Maughan, Collishaw, & Pickles, 1999).

Those with moderate ID typically have impaired language. For example, Carr (2000) found that a cohort of adults with Down syndrome, with a mean IQ in the moderate range, had on average language development at the 5-year level. Basic self-care skills are achieved. Social relationships such as friendships can be well developed. As adults, such individuals can eventually work productively in a special workplace setting with structured tasks and supervision. Fully independent living, marriage and parenting are very unusual.

In severe ID, language may be absent or limited to individual words or phrases, or a limited range of signs may be used in communication. Elementary self-care may be achieved but assistance is usually needed with most basic living activities. Mobility may be normal. Daytime recreational activity programs are usual rather than work placement (Tesio, Valsecchi, Sala, Guzzon, & Battaglia, 2002). Profound ID is often a consequence of catastrophic brain damage, with multisensory and major motor impairments accompanying limited cortical cerebral function. Some comprehension of basic commands is attainable. Assistance, often through nursing care, may be required for nearly all activities.

**Incidence and Prevalence of Intellectual Disability**

Most epidemiological studies of ID have sought to estimate prevalence rates – the total number of cases existing in a population at a given point in time (Roeleveld, Zielhuis, & Gabreels, 1997). These studies typically use IQ assessments (see chapter 21) to classify a person as having either mild (IQ 50 or 55–70) or severe (IQ <50 or 55) ID, rather than a combination of IQ and adaptive behavior.

In high-income countries in North America, Europe and Australia, studies have produced broadly consistent overall
prevalence rates for severe ID of 3–4 per 1000 of the general population, although studies that have screened entire populations tend to yield slightly higher prevalence rates (approximately 6 people with severe ID per 1000; Roeleveld, Zielhuis, & Gabreels, 1997).

Studies that have sought to ascertain the prevalence of mild ID have reported much more diverse prevalence rates. This is likely to reflect at least two factors. First, most adults with mild ID do not use specialist services for people with ID. As a result, prevalence studies based on administratively defined adult populations will significantly underestimate prevalence rates of mild ID. Second, given that there is a strong association between socioeconomic deprivation and the prevalence of mild ID (see below), the level of socioeconomic deprivation in the communities sampled would be expected to have an impact on ascertained prevalence rates for mild ID. Studies that have screened entire populations have yielded prevalence rates of 25–80 people with mild ID per 1000 general population (Roeleveld, Zielhuis, & Gabreels, 1997; Simonoff, Pickles, Chadwick et al., 2006).

Few studies have sought to ascertain the incidence of ID (the number of new cases arising in a population in a given period of time). A US study reported a cumulative incidence at age 8 years of 4.9 children with severe learning disabilities per 1000 births and 4.3 children with mild ID per 1000 births (Katusic, Colligan, Beard et al., 1996). Similar rates have been reported in Northern European research (Rantakallio & von Wendt, 1986). The low incidence of mild ID reported in these studies is likely to reflect the reliance on biased, administratively defined (rather than “true” population-based) samples of people with ID.

There is no reliable information available on the global distribution of ID (Institute of Medicine, 2001). There is reason to believe that the incidence of severe ID in low-income countries is at least double that in high-income countries (Durkin, 2002). It has been estimated that the impact of undernutrition (as evidenced by severe to moderate stunting) alone may be responsible for a 31–43% elevation in the incidence of ID during childhood in low-income countries (Emerson, Fujiura, & Hatton, 2007). The prevalence and incidence of ID vary according to gender, age, ethnicity and socioeconomic circumstances.

**Gender**

Most studies report that males are more likely than females to have both severe ID (average male : female ratio 1.2:1) and mild ID (average male : female ratio 1.6:1), although gender ratios vary widely across studies (Roeleveld, Zielhuis, & Gabreels, 1997). It has been suggested that sex-linked genetic factors (Partington, Mowat, Einfeld, Tonge, & Turner, 2000), male vulnerability to insult and social processes in labeling and classification partly account for the majority of males with ID (Roeleveld, Zielhuis, & Gabreels, 1997). The latter are likely to be particularly relevant in studies that have relied on administratively defined populations of people with ID.

**Age**

Estimates of age-specific prevalence rates are highly influenced by methods of case identification (e.g., population screening versus the use of administrative samples). Most studies have reported an increase in the prevalence of both severe and mild ID throughout childhood, with prevalence peaking at 10–20 years of age (Roeleveld, Zielhuis, & Gabreels, 1997). While this may be because of the increasing “visibility” of ID in later school years, there is also evidence of IQ decline in some disorders. For example, Fisch, Simensen, and Schroer (2002) found evidence of declining IQ scores in children with fragile X syndrome, and this decline was greater than in children with autism.

**Ethnicity**

Estimating the impact of ethnicity on the prevalence and incidence of ID is difficult as other important factors also vary among ethnic groups. These include poverty, access to health care, lifestyles, communication barriers and uptake of specialist services (Modood, Berthoud, Lakey et al., 1997). However, research in the USA, UK and Australia has found tentative evidence to suggest higher prevalence rates of mild ID amongst some minority ethnic groups, such as African-American groups in the USA (Fujiura & Yamaki, 1997) and Aboriginal groups in Australia (Leonard, Petterson, De Klerk et al., 2005). In the UK, higher prevalence rates in South Asian communities have been reported for children and young adults with severe ID (Hatton & Emerson, 2004). However, it is unclear whether these higher rates are biologically or genetically linked with ethnicity (e.g., as a result of consanguinity), or are the result of other factors that have an impact upon minority ethnic groups, such as socioeconomic status or classification practices (e.g., through the use of culturally biased assessment methods).

**Socioeconomic Circumstances**

There is a strong association between lower socioeconomic position and higher prevalence rates of mild, but probably not severe, ID (Hatton & Emerson, 2004; Leonard, Petterson, De Klerk et al., 2005; Roeleveld, Zielhuis, & Gabreels, 1997). For example, children in the most socioeconomically disadvantaged 10% of Western Australian families had more than five times the risk of mild and moderate ID when compared with those in the least disadvantaged 10% (Leonard, Petterson, De Klerk et al., 2005). In Britain, children in the most socioeconomically disadvantaged 20% of families had more than four times the risk of ID when compared with those in the least disadvantaged 20% (Emerson, Graham, & Hatton, 2006). These associations have also been reported in middle- and low-income countries (Durkin, 2002).

**Possible changes in Prevalence**

The prevalence and incidence of ID are likely to change over time as a result of complex changes in society and the provision of education, health and social care. In high-income countries, factors that are likely to lead to an increase in the incidence of ID include: increases in maternal age (associated with higher risk factors for some conditions associated with
ID, such as Down syndrome; increased survival of “at risk” infants, such as very low birth weight infants or very preterm deliveries; increasing levels of HIV and AIDS in children; and increased rates of assisted conception. Factors that are likely to lead to a decrease in incidence include: increasing availability of prenatal screening for Down syndrome; improving health care and support resulting in fewer “at risk” infants developing ID. The net effect of these competing pressures on the overall incidence of ID is not known. However, there is a perception among practitioners that the rate of profound ID may have increased significantly over the past decade.

Social and Health Impact of Intellectual Disability

The social impact of ID can be considered at the level of the individual, their relatives and the wider society. As children, and later as adults, people with both mild and more severe ID are at significantly increased risk of facing discrimination, social exclusion and abuse (Department of Health, 2001; Grant, Goward, Richardson, & Ramcharan, 2005). In England, only 44% of the 95,000 children with a Statement of Special Educational Need for ID are educated in mainstream schools, a percentage that drops to just 20% for children with severe ID (Department for Education and Skills, 2005). As adults, people with both mild and severe ID are significantly less likely than their non-disabled peers to move out of their family home, have long-term intimate relationships, be employed, have friends and participate in the life of their communities (Emerson, Malam, Davies, & Spencer, 2005; Maughan, Collishaw, & Pickles, 1999). These trends toward extensive social exclusion appear to transcend national boundaries (Emerson, Fujiura, & Hatton, 2007) and be particularly exacerbated in people with more severe ID (Emerson, Malam, Davies et al., 2005).

There is also extensive evidence that mothers (and to a much lesser extent fathers) of children with ID are more likely to show signs of psychological distress and have lower well-being than parents of “typically developing” children (Baker, Blacher, Kopp, & Kraemer, 1997; Blacher & Baker, 2002; Blacher & Mink, 2004; Emerson, 2003). In addition to the health burden imposed on a vulnerable subgroup of parents, these findings are of concern as distress among mothers has been linked to a wide range of adverse outcomes for children, including less than optimal parenting, failure to engage with services, decisions to seek out-of-home care for their disabled child, impeded child development, and higher rates of child psychopathology and antisocial behavior (Llewellyn, McConnell, Thompson, & Whybrow, 2005; Zahn-Waxler, Duggal, & Gruber, 2002). Marriages in families with children with ID are only a little more likely to end in divorce (Risdal & Singer, 2004).

It is perhaps surprising that severity of ID per se is not the major determinant of family stress (Baker, McIntyre, Blacher et al., 2003). The response of families to the presence of a chronically ill or disabled child is partly determined by parents’ ways of thinking about the child. There is evidence that mothers with a high sense of locus of control and a belief in chance feel less burdened by caregiving than those with the opposite cognitive set (Green, 2004).

Other factors predicting high levels of stress for parents are increased rate of psychopathology among children with ID (Baker, McIntyre, Blacher et al., 2003; Eisenhower, Baker, & Blacher, 2005; Emerson, 2003; Hastings & Beck, 2004; Tonge & Einfeld, 2003) and the poorer socioeconomic circumstances of families supporting children with ID (Emerson, 2003; Emerson, Hatton, Blacher, Llewellyn, & Graham, 2006). Problematic or “challenging” behaviors are one of the main predictors of whether parents will seek a residential placement for their son or daughter (Llewellyn, Dunn, Fante, Turnbull, & Grace, 1999; Llewellyn, McConnell, Thompson et al., 2005). Daily care requirements on account of lack of mobility and incontinence of children with ID are also burdensome for parents, but do not cause as much stress in parents as behavior problems (Tonge & Einfeld, 2003). Siblings of children with ID in general do not show increased levels of distress or other psychopathology. There is some evidence that such siblings have more secure attachment styles and higher levels of emotional maturity (Levy-Wasser & Katz, 2004).

At the clinical level, there is wide variation in the way families respond to the experience of having a child or sibling with ID. One approach that is helpful in counseling such families is to support effective grieving for the loss of the wished-for healthy child. Families who are not unduly burdened by anger, guilt, shame or sadness are best able to have a realistic appreciation of their disabled child. In such families, the child with the disability is given the same value as other family members. Where this is not achieved, scapegoating of the affected child at one extreme, or overenmeshment with the disabled child at the other extreme is sometimes seen. In such families, “survivor guilt” may be apparent in siblings.

There is evidence that parental stress can be ameliorated by group interventions. Tonge, Brereton, Kiomall et al. (2006) used a randomized control design in demonstrating that parent education and behavior management training, or parental counseling alone were effective in reducing parental distress in parents of children with autism. Hastings and Beck (2004) reviewed a range of controlled parent intervention studies and found most support for the effectiveness of cognitive-behavioral techniques in reducing parental stress, although effects were of small to medium size.

The primary impact of ID on the wider society is financial. Current expenditure in England on health and social care services for people with ID is approximately £4 billion per annum (Association of Directors of Social Services, 2005). Increased rates of psychopathology among people with ID (see p. 827) also add major costs to care. Adolescents with ID who could gain vocational training through supported employment programs are unable to do so (Hupalo, 1997). Injuries to care workers are a major source of expense from compensation and occupational health and safety claims (Lowe, 1999) and the costs of supported accommodation
CHAPTER 49

services are significantly influenced by the extent of psychopathology exhibited by residents (Hallam & Emerson, 1999).

Causes of Intellectual Disability

Any pathogenic process that significantly impairs cognitive processing during childhood can cause ID. The most widely used classification of such causes is that of the AAIDD (Luckasson, Coulter, Polloway et al., 1992, Luckasson, Borthwick-Duffy, Buntinx et al., 2002). This groups causes into prenatal, perinatal and postnatal in origin. Prenatal causes include chromosomal disorders, various dysmorphic syndrome disorders, inborn errors of metabolism and developmental disorders of brain formation, such as hydrocephalus or spina bifida, toxic and teratogenic influences such as fetal alcohol exposure and malnutrition. The second group, perinatal causes, includes placental insufficiency and neonatal disorders such as septicemia. Postnatal causes include head injuries, infections such as meningitis, and degenerative disorders such as the leukodystrophies, ID associated with seizures, toxic disorders such as lead poisoning, malnutrition and chronic social and sensory deprivation.

In surveys of individuals with more severe ID (Curry, Stevenson, Aughton et al., 1997; Farthing, Mowat, Einfeld et al., 2000), chromosomal abnormalities are identifiable in 20%, about three-quarters of whom have Down syndrome. Monogenic disorders, either autosomal or X-linked, account for about 3–4% each. Recognizable or provisional genetic syndromes are found in about a further 5%. Environmental causes have been estimated as responsible for about 8% of cases. The causal link in some of these cases is clearly apparent (e.g., herpes encephalitis in childhood). However, it is important to appreciate that some conditions apparent perinatally or postnatally have uncertain prenatal origins (Nelson, 2003). These include structural abnormalities of the central nervous system (5%) and complications of prematurity (5%). No cause is currently identifiable in 45–50%.

There is reason to believe that the prevalence of severe ID in low-income countries is at least double that in high-income countries and that the distribution of causes is different (Durkin, 2002). Because of the lack of epidemiological studies it is not easy to distinguish cognitive impairments leading to specific learning disorders from those leading to ID. In low-income countries, undernutrition accounts for a larger proportion of at least mild ID (Olness, 2003). The most critical impact on brain development for undernutrition appears to be between the second trimester of pregnancy and age 2 years.

Endemic iodine deficiency occurs in up to 10% of the population in some areas of the world, particularly parts of China, the Congo, South America and mountainous areas of South-East Asia (Olness, 2003). Deficiency in thyroid hormone during pregnancy or in the newborn period impairs development of cortical neurons and retards myelinationization (Pharoah, Butfield, & Hetzel, 1971). Infectious diseases continue to be prominent causes of ID in low-income countries. Important infections include tuberculous meningitis, hemophilias, influenza and type B meningitis. Given the failure to achieve widespread immunization, insect-borne viruses such as Western Nile virus, cerebral malaria and congenital human immunodeficiency virus infection are increasingly prevalent in low-income countries and the brain impairment as a consequence has been documented (Drotar, Olness, Wiznitzer, et al., 1997). The wider use of antiviral agents to treat AIDS may result in large numbers of survivors with ID. Many conditions leading to cognitive impairment occur concurrently, increasing the risk for ID (Olness, 2003). For example, low-birth-weight babies may also have malnutrition and malaria.

There is also some evidence to suggest that some genetic causes of developmental disabilities may also be unequally distributed (Institute of Medicine, 2001). For example, thalassemia, which is prevalent in 2–3% of all children in West Africa, has been linked to high rates of mild ID (Steen, Xiong, Mulhern, Langston, & Wang, 1999). In low-income countries, a higher proportion of births are to mothers aged over 35, possibly increasing the incidence of Down syndrome (Steen, Xiong, Mulhern et al., 1999). Finally, high rates of cosanguineous marriage have been associated with increased rates of child disabilities (Institute of Medicine, 2001; Teebi & El-Shanty, 2006). The causes of ID vary with the severity of intellectual impairment (see chapter 30).

Down syndrome

The genetic basis of Down syndrome is discussed in chapter 24; here we focus on the clinical characteristics. Down syndrome is the most common genetic cause of ID, occurring in approximately 1 in 800 live births. The risk for Down syndrome increases with increasing maternal age. Down syndrome is characterized by upturned outward slanting eyes, a wide nasal bridge, a large posterior fontanelle, a single transverse palmar crease and hypotonia. Congenital heart disease and duodenal atresia are common (Harris, 2006). Hearing impairments, hypothyroidism and atlantoaxial instability and an increased vulnerability to leukemia are also characteristic. Guidelines for the management of the general health of children with Down syndrome have been formulated by the Committee on Genetics (American Academy of Pediatrics Committee on Genetics, 2001). Severity of ID covers a broad range, but is most commonly moderate or severe. It is also associated with earlier onset of menopause in Down syndrome women (Schupf, Pang, Patel et al., 2003). Down syndrome is striking among genetic disorders causing ID in that it is associated with relatively low levels of psychopathology (Carr, 2002). There is some evidence to support the notion that children with Down syndrome have a stubborn temperament, but this is not problematic for most parents (Carr, 1994). Alzheimer-type dementia occurs at an increased rate and at an earlier age (mean of around 50 years) in Down syndrome. Early signs of dementia are a sustained increase in behavioral problems and a decline in independence and adaptive behavior skills (Carr,
studies (Shapira, Lessig, He et al., 2005). However, early dementia is occasionally apparent in young adulthood.

**Fragile X syndrome**

Fragile X syndrome (FXS) is caused by an expansion of the CGG trinucleotide sequence at Xq27.3 on the X chromosome (see chapter 24). Approximately one-third of boys with FXS have mild to moderate ID. One-third of carrier females have mild ID and the other two-thirds an IQ in the average range. The physical phenotype is characterized by a long face with protruding ears, a large jaw, hyperextensible joints and enlarged testes in postpubertal males (Hagerman, 1999).

ID is usually mild to moderate and the degree correlates inversely to the level of fragile X mental retardation protein (FMRP) (Loesch, Huggins, & Hagerman, 2004). Verbal intelligence often exceeds performance abilities in both affected males and non-learning disabled female carriers. The IQ may decline in childhood and adolescence, with an average adult IQ in males at the low end of the moderate range. Approximately 70% of females with the full mutation have an IQ of less than 85. Verbal dyspraxia is common (Spinelli, Rocha, Giacheti, & Richieri-Costa, 1995).

Children with FXS typically have initial social anxiety with aversion to eye contact, hand flapping and stereotypic behavior, but usually are socially responsive and affectionate with an interest in social interactions (Turk & Cornish, 1998). Self-injury, notably hand biting and scratching provoked by frustration, anxiety and excitement is common. Some children with FXS have autistic behaviors in childhood.

**Prader–Willi syndrome**

Prader–Willi syndrome has a prevalence of about 1 in 10,000–15,000 live births. It results from the failure of the paternally imprinted genes in the region 15q11–q13 (see chapter 24). Physical characteristics of Prader–Willi syndrome include hypotonia and poor feeding in infancy followed by hyperphagia and consequent obesity and its cardiopulmonary complications from early childhood, hypogonadism and small hands and feet and short stature. There is a characteristic, although subtle, facial appearance. Most individuals with Prader–Willi syndrome function in the mild ID range, although a few have more severe ID impairment and some have average intelligence.

Behavioral characteristics include marked hyperphagia, pica, gorging and stealing food. In addition, there are severe temper tantrums or episodes of rage. Insensitivity to pain, skin-picking or rectal gouging and impaired temperature regulation, hypersomnolence and reduced motor activity are also features (Einfeld, Smith, Durvasula, Florio, & Tonge, 1999b). Obsessional symptoms have also been noted (Dykens, 2004). There appears to be an increased vulnerability to psychosis in Prader–Willi syndrome. Although psychosis has been noted in both the deletion and uniparental disomy (UPD) forms, it is about six times more common in the UPD derived cases. There is evidence of hypothalamic disturbance from both post-mortem and functional magnetic resonance imaging (fMRI) studies (Shapira, Lessig, He et al., 2005).

Neither surgery nor medications have been found effective in managing the hyperphagia. Instead, strict control of food intake is necessary. Sometimes this requires locking cupboards or refrigerators to prevent access to food (Holland, Whittington, & Butler, 2002). Medical management of the complications of obesity is required. Behavioral difficulties continue into young adulthood, but there is evidence that they decline in the 4th and 5th decades (Dykens, 2004).

**Williams syndrome**

Williams syndrome is caused by a chromosome deletion at 7q11.23 (see chapter 24). Around 95% of children with the condition have the same deletion, but a few individuals have partial deletions. Williams syndrome is characterized by short stature; hypercalcemia in infancy and subsequent abnormal dentition; vascular abnormalities, particularly supravalvular aortic stenosis; a stellate pattern in the iris; atypical face, sometimes described as “elfin-like”; and ID, generally in the low/mild or upper moderate range. Psychometric testing usually identifies language function significantly better than visuospatial function (Howlin, Davies, & Udwin, 1998).

Children with Williams syndrome show more noise sensitivity, sleep disturbance and anxiety than other children with ID (Einfeld, Tonge, & Rees, 2001). The anxiety pattern is quite distinct. Children with Williams syndrome have a high phobic anxiety but not social anxiety. Indeed, they have an absence of social anxiety. This has led to a substantial rate of sexual abuse of girls with Williams syndrome (Davies, Udwin, & Howlin, 1998; Dykens, 2003). Although the behavioral difficulties remain evident in young adulthood, they are less prominent (Tonge & Einfeld, 2003).

**Angelman syndrome**

Angelman syndrome involves a deficit in the same region on chromosome 15 as Prader–Willi syndrome. However, Angelman syndrome is caused by a deficit in the region inherited from the mother, whereas Prader–Willi syndrome is a consequence of a deficit in the same region inherited from the father (see chapter 24). Individuals with Angelman syndrome have a characteristic face with a wide mouth, a thin upper lip and a prominent tongue. The head is small. Most are fair with blue eyes. Feeding problems are common in the neonatal period. Children with Angelman syndrome have a characteristic ataxic gait with arms upheld and flexed. They have frequent laughing, which is mainly in response to social stimuli (Horsler & Oliver, 2006). Fascination for water, hand flapping, abnormal food-related behaviors and sleep disturbance occur more commonly than in IQ-matched controls (Barry, Leitner, Clarke, & Einfeld, 2005). Epilepsy is usual and often severe. ID is in the severe or profound range with little speech, although some affected children use a limited range of signs to communicate (Holland, Whittington, & Butler, 2002).

**Velocardiofacial Syndrome**

Velocardiofacial syndrome (VCFS) is a consequence of a deletion at 22q11.2 (see chapter 24). The physical phenotype
includes congenital heart disease, cleft palate or other palatal anomalies, and a characteristic facial appearance including a long narrow face and a prominent nasal tip. Abnormalities of calcium metabolism and immune function are common. Individuals with VCFS often have mild ID but may have intelligence in the normal range. Particular difficulties with mathematics are common. As children, they are commonly shy and withdrawn with a bland affect. In adolescence or young adulthood, psychosis emerges in a high proportion of cases. In a large series, Murphy, Jones and Owen (1999) found a prevalence of psychosis of 30%, the majority of which was schizophrenia. At present, there is no known way of preventing the onset of psychosis. One series reported a poor response to antipsychotics (Gothelf & Lombroso, 2001), but another series suggested outcomes similar to schizophrenia in general (Murphy, 2005).

Prevention of Intellectual Disability

The prevention of ID raises a complex set of ethical issues (Louhila, 2004). Least contentious among approaches to prevention are those that seek to avoid exposure to social and environmental risk factors for ID such as poverty, undernutrition, environmental toxins, infections, poor obstetric care, understimulating home environments, intrafamilial marriage, child abuse or low maternal education. It has been estimated, for example, that reducing the proportion of children living in poverty who are exposed to environmental deprivation could decrease the prevalence of ID in the USA by approximately 10% (McDermot & Altekruse, 1994).

Recently, the International Child Development Steering Group have reviewed the evidence relating to risk factors for adverse developmental outcomes for children in low and middle income economies (Engle, Black, Behrman et al., 2007; Walker, Wachs, Gardner et al., 2007). While not specifically related to ID, there is a clear overlap between risk factors for not attaining general developmental potential and risk factors for ID. They identified four key risk factors where existing evidence suggested that the need for intervention was “urgent” (stunting as a result of inadequate nutrition, inadequate cognitive stimulation, iodine deficiency and iron deficiency anemia) and five areas where sufficient evidence existed to “warrant intervention” (malaria, intrauterine growth restriction, maternal depression, exposure to violence, and exposure to heavy metals; Walker, Wachs, Gardner et al., 2007). They suggested that the most effective early child development programs “provide direct learning experiences to children and families, are targeted toward younger and disadvantaged children, are of longer duration, high quality, and high intensity, and are integrated with family support, health, nutrition, or educational systems and services” (Engle, Black, Behrman et al., 2007).

Although there has been progress towards reduction of iodine deficiency in many countries, the WHO still estimates that in 2003, 36.5% of school-age children had insufficient iodine intake. Iodine deficiency actually increased in Europe between 1993 and 2003. Salt iodization continues to be an effective strategy (Andersson, Takkouche, Egli, Allen, & de Benoist, 2005). Folate supplementation reduces the rate of neural tube defects (Stoll, Alembik, & Dott, 2006). Lead poisoning can be prevented through screening children living near lead industries, the elimination of lead in petrol, old paint removal and replacement of lead water pipes. Some programs to reduce antenatal exposure to alcohol have been successful but others have been disappointing (Hankin, 2002). Reduction of head injuries through improved road safety and compulsory wearing of bicycle helmets and reductions in near-drowning morbidity are feasible. A number of studies have reported effective primary prevention programs to reduce injuries through child abuse, but secondary prevention to reduce repeat abuse has been less successful (Vandeven & Newton, 2006).

Concerning genetic causes of ID, genetic counseling provides information to guide reproductive choice (see chapter 73). Reducing the rate of consanguineous marriages can be a target of public health education (Alwan & Modell, 2003). The best candidates for prenatal gene therapy have been studied for glycogen, lipid and mucopolysaccharide storage diseases. However, successful prenatal gene therapy has not yet been demonstrated successfully in animals and there are a number of bioethical concerns about developing technology that can potentially manipulate the human genome (Ye, Mitchell, Newman, & Batshaw, 2001).

The contemporary rarity of once common causes such as congenital rubella and kjernciterus demonstrate what can be achieved. Reduction of the prevalence of ID remains a viable goal.

Health Complications of Intellectual Disability

General Health

People with ID are more likely to experience poor general health and have a decreased life expectancy (Ouellette-Kuntz, 2005). While much remains to be learned about the causes of these disparities in health outcomes, existing research has drawn attention to the potential importance of a number of factors including the impact on health of the genetic and biological bases of ID, for example, thyroid impairment and atlantoaxial instability in Down syndrome (Cohen, 2006; Dykens, 1999, 2000; Hodapp & Dykens, 2004); increased risk of exposure to socioeconomic disadvantage (Emerson & Hatton, 2007a,b), behavioral or lifestyle factors (Emerson, 2005b; Robertson, Emerson, Gregory et al., 2000); and the quality of existing health care support provided to people with ID (Webb & Rogers, 1999; Whitfield, Langan, & Russell, 1996).

The evidence pertaining to the potential importance of socioeconomic, behavioral or lifestyle factors and the quality of health care support suggests that the health status of people with ID could be improved and that the disparity in health outcomes between people with ID and their non-disabled peers may be reduced (Department of Health, 2001; Disability Rights Commission, 2004; Einfeld, Smith, Durvasula et al., 1999b; Meijer, Carpenter, & Scholte, 2004; US Department of Health...
and Human Services, 2005). To the extent that the poorer health status of people with ID is avoidable and unjust, it can be considered to constitute an example of health inequity or inequality (Whitehead, 1992).

Guidelines have been developed to guide health care practitioners in addressing the particular health needs of individuals with ID (e.g., monitoring thyroid status in individuals with Down syndrome; Beange, Lennox, & Parmenter, 1999). These have been developed in response to research showing high rates of undiagnosed common health problems in persons with ID. It is important to consider intercurrent or chronic physical ill health as potential causes of behavioral disturbances in those with ID. For example, esophageal reflux is a common covert cause of agitation and distress in children and adolescents with severe and profound ID.

**Epilepsy**

Around 30% of children with ID have epilepsy. The prevalence varies substantially between causes of ID. For example, those with Down syndrome have low levels of seizures, whereas for those with tuberous sclerosis or cerebral palsy, epilepsy is common. In some disorders (e.g., autism and FXS), epilepsy often begins for the first time in adolescence. Epilepsy can be associated with psychopathology in young people with ID in a number of ways. Complex partial seizure disorder (previously known as temporal lobe epilepsy) may manifest only with behavioral manifestations, such as un directed aggression or olfactory or dissociative phenomena. Second, anticonvulsants can have an impact on the behavior of children with ID (see chapter 30). In general, children with ID and seizures do not have higher rates of psychopathology than children with ID but without seizures (Lewis, Tonge, Mowat et al., 2000).

**Sensorimotor impairments**

Abnormalities of vision, hearing and motor function are common accompaniments of ID, but are often overlooked (Beckung, Steffenburg, & Uvebrant, 1997). Around 25% of children with idiopathic ID had visual impairments in one large study (Ghose & Chandra Sekhar, 1986). The prevalence of hearing impairment in children with ID is twice that found in typically developing children (Karlajainen, Kaariainen, & Vohlonen, 1983). Some conditions such as congenital rubella or severe anoxic brain injury can cause impairment of multiple senses.

**Psychopathology**

Psychopathology is a common and important feature of ID. Whereas methodological differences produce differing rates (for a review see Dykens, 2004), most studies find an increased rate two to four times that in the general population. The Isle of Wight studies of Rutter, Tizard, Yule, Graham, and Whitmore (1976) found that 7% of 10- to 12-year-old children in the community had psychiatric disorders, but for children with ID, the rate was 30%. Einfeld & Tonge (1996a,b) assessed psychopathology in an epidemiologically derived cohort of children and adolescents with more severe ID and identified 40% of the children aged between 4 and 18 years as meeting criteria as a psychiatric case. In comparison, 14% of Australian children without ID in a random community sample were found to have a psychiatric disorder (Sawyer, Arney, Baghurst et al., 2001). In Britain, it has been estimated that 39% of 5- to 15-year-old children with ID had a diagnosable psychiatric disorder, compared to 8% among children without ID (Emerson, 2003).

Major psychopathology affects over 40% of young people with ID (Einfeld & Tonge, 1996b), therefore the number of persons affected by ID and severe psychopathology is approximately equal to the number with schizophrenia.

**Factors Contributing to the High Prevalence of Psychopathology**

These may be grouped as biological, psychological and social risk factors. Biological factors include particular genetic causes of ID that lend vulnerability to particular syndromes of psychopathology. Einfeld, Tonge, Turner, Parmenter, and Smith (1999a) found that children with Prader–Willi and Williams syndromes had considerably higher levels of psychopathology than did children with FXS or an epidemiological control group. Those with Down syndrome had significantly lower levels than controls. Various concomitant brain impairments that may accompany ID may increase the risk of behavior disturbance, such as complex partial seizures, or frontal lobe damage causing impulsivity. Sensory impairments are frequent in children with ID, and these are known to increase the risk of psychopathology (Sisson, Van Hasselt, & Hersen, 1993).

Psychological factors include the reduction in capacity for finding creative and adaptive solutions to life challenges. This is the corollary of the observation that children and adolescents of high intelligence have greater resilience to psychopathology (Goodman, 1995; Tiet, Bird, Davies et al., 1998). Family dysfunction and parental mental health problems are associated with increased psychopathology in children with ID (Wallander, Koot, & Dekker, 2006), but the direction of causality is unclear.

Social disadvantage and poverty are an increased risk for children and adolescents with ID; social conditions that have been linked to risk of psychopathology (BMA Board of Science, 2006; Hatton & Emerson, 2004). They also experience higher rates of stressful life events, such as abuse, school failure and peer rejection, than children without ID (Ammerman, Hersen, van Hasselt, Lubetsky, & Sieck, 1994; Hatton & Emerson, 2004). It has been estimated that 20–33% of the increased risk of psychopathology among children with mild ID can be attributed to the impact of social disadvantage mediated by an increased risk of exposure to a range of adverse life events (Emerson & Hatton, 2007b).

**Conceptual Issues and Classification of Psychopathology**

Historically, the concepts of ID and mental illness have had
CHAPTER 49

a confused relationship. Mental health professionals have tended to view emotional and behavioral disturbances in the presence of ID as a “behavioral” manifestation of ID, rather than evidence of mental illness. At the same time, disability advocates have been keen to distance ID from the perceived stigma and overly medicalized concept of mental illness (Einfeld, 1992). More recently, there has been an increasing awareness that psychopathology is distinct from, but can co-occur with ID. An exception to this would occur, for example, where a 14-year-old boy with a mental age of 2 years may have tantrums which are appropriate for his mental age, which nevertheless, because of the boy’s physical size, constitute a serious behavioral problem.

Taxonometric or “bottom-up” models of psychopathology were examined by Aman (1991). He identified seven syndromes common to the factor analyses of several symptom-based inventories of psychopathology used in individuals with ID: aggressive/antisocial, social withdrawal, stereotypic behavior, hyperactivity, repetitive verbalization, anxious/tense/fearful and self-injurious.

Standard DSM and ICD classifications are of limited value in individuals with the more severe levels of ID (Cooper, Melville, & Einfeld, 2003; Einfeld & Aman, 1995). Most specific diagnoses have not been subject to studies of intrarater agreement. However, Einfeld, Tonge, Chapman et al. (2007) found the intrarater agreement for the diagnoses of psychosis (any psychotic disorder) and depression (of any type) in a group of young people with ID to be high among clinicians who were trained in both psychiatry and ID. With the exception of autism, few diagnoses have had demonstrated concurrent, predictive or postdictive validity in individuals with more severe ID.

Case reports and epidemiological studies suggest that the range of psychiatric syndromes seen in the general population also occur in the presence of ID (Emerson, 2003; Menolascino, Levitas, & Greiner, 1986). Some writers have identified a “pathoplastic” effect of cognitive impairment on symptoms (e.g., depression presenting with agitation or increase in stereotypic behavior; Smiley & Cooper, 2003).

Children and adolescents with mild ID display psychopathology similar to that seen in others of the same mental age (Menolascino, 1971). The moderately and severely intellectually disabled are also subject to the psychiatric disorders seen in normal populations, albeit with modified symptoms, but also have a range of symptoms that are uncommon or rare in those without ID (Quine, 1986). Of those psychiatric problems that are closely associated with moderate and severe ID, and are unusual in the general population, the best studied syndrome is that of autism (see chapter 46). A further syndrome is that of stereotypic repetitive movements, such as rocking, head banging, or face slapping. These are most prevalent in those with severe ID, especially when accompanied by sensory deficits (Oliver, Murphy, & Corbett, 1987). These repetitive movements can cause tissue damage, when they are often termed “self-injurious behaviors.”

Influences on and Course of Psychopathology

High rates of significant psychopathology are present in children with ID by the age of 4 (Baker, Blacher, & Olsson, 2005; Chadwick, Kusel, Cuddy, & Taylor, 2005; Einfeld & Tonge, 1996b; Quine & Pahl, 1989). Two longitudinal cohort studies of mainly untreated young people with ID, the Aberdeen Study (Richardson & Koller, 1996) and the Australian Child to Adult Development (ACAD) Study (Einfeld, Piccinin, Mackinnon et al., 2006; Tonge & Einfeld, 2003) have shown that the severity of overall behavioral and emotional problems declines slowly through to young adulthood but still remains higher than for normally developing young people. The ACAD study found that all psychopathology syndromes declined over 14 years apart from social relating problems, which increased in severity. While the overall severity of psychopathology was similar across the mild to severe range of ID, the type of psychopathology that was most prominent varied. Those with mild ID were more likely to have antisocial and disruptive behaviors, while those with moderate or severe ID had more self-absorbed and social relating problems. Those with profound ID had lower overall levels of disturbed behavior. The genetic cause of ID had the most influence on severity of psychopathology, and this is largely consistent over time.

Assessment of Behavioral and Emotional Disturbance

Given that adolescent emotional development continues through the third decade for many young people with ID, child and adolescent mental health professionals are often consulted about young adults with ID. Therefore, the following discussion includes issues pertinent to that age group. The care of children and adolescents with ID often takes place within a matrix of environments, such as home, school, respite care facility, and vocational training placements. It is best to obtain information from as many of these sources as possible. This compensates for the often poor verbal skills of the patient, and enables one to determine if disordered behaviors are limited to one or pervasive through many contexts.

As a general guide, the interviewer may use language that would be understood by a child of equivalent mental age. Guided assessment techniques especially with visual cues are also useful, such as a mood thermometer or “COOP” pictograms (Nelson, Wasson, Kirk et al., 1987), and drawing a picture of the family, or the people in his or her group home, if one suspects that these are areas of concern to the patient. This general guide requires several caveats, which derive from the discrepancy that can be present between expressive language, comprehension and emotional maturity. For example, individuals whose ID is a consequence of Williams syndrome may have relatively sophisticated verbal skills that belie a significantly lower level of comprehension and performance skill (Bennett, La Veck, & Sells, 1978). Adolescents with Prader-Willi syndrome often have a more immature level of
empathy with others’ needs than would be suggested by their level of verbal expression. On the other hand, many young adults or older adolescents with ID reach a level of emotional maturity, perhaps through life experience, which is greater than that suggested by a mental age derived from IQ tests. Such a person might regard an invitation to play with toys as devaluing or demeaning.

The interviewer should be aware of a general tendency on the part of some patients to answer “yes” to any question about symptoms. There is some evidence to suggest that this “yea-saying” phenomenon occurs with a higher prevalence in individuals with ID than in the general population (Finlay & Lyons, 2002; Sigelman, Budd, Spankel, & Schoenrock, 1981). Some, although fewer, have the opposite response bias, the “nay-saying” response (Sigelman, Schoenrock, Wiver et al., 1979). Given the limitations in applying DSM or ICD diagnoses, formulation is often limited to an assessment of problems operating at the level of symptoms rather than at the level of disorders.

A number of questionnaires have been developed with the goal of supporting clinical assessment of children and adolescents with ID. Two in common use are the Aberrant Behavior Checklist (ABC; Aman, Singh, Stewart, & Field, 1985) and the Developmental Behavior Checklist (DBC; Einfeld & Tonge, 2002).

The ABC is an informant-based 58-item questionnaire suitable for people with moderate to profound levels of intellectual disability aged 5 and over. The checklist was designed to measure the effects of interventions and levels of maladaptive behavior. The checklist consists of five subscales.

The DBC-Parent/Primary Carer and DBC-Teacher versions are 96-item inventories used with young people aged 4–18 years, and measure the Total Behavior Problem Score as well as scores on five subscales: disruptive/antisocial, self-absorbed, communication disturbance, anxiety and social relating. Cases of disorder can be determined by a score of 46 or more on the Total Behavior Problem Score. The instrument is designed to supplement clinician assessment for use in treatment studies. It has been used in epidemiological studies because of the availability of norms from Australia, the UK and the Netherlands. A short form has recently been developed (Taffe, Gray, Einfeld et al., 2007).

**Issues in the Assessment of Some Particular Psychopathology Syndromes**

Psychotic disorders are estimated to occur with increased frequency among adults with ID, with a prevalence of about 3–6% (Shedlack, Hennen, Magee, & Cheron, 2005), but the prevalence in children and adolescents is unknown. Despite this, there is evidence that psychosis is overdiagnosed (Aman, 1985). This may derive from the misdiagnosis of hallucinations. For example, care providers often describe a patient as conducting conversations while no-one else is present, or admitting to hearing voices of absent persons. However, if sufficient time is spent questioning and observing the young person, they may explain that they are remembering conversations or just thinking about them. These memories often center on troubling relationships or events and the patient has no difficulty in distinguishing between the remembered conversations and current reality. Such conversations with absent persons may be a behavioral habit, albeit a socially inappropriate one, but they do not constitute hallucinations. Similar caution needs to be exercised in the assessment of possible delusions. A common report is that a young person with ID is unjustifiably complaining that staff or peers are threatening him or her. It should be remembered that young people with ID actually do experience a good deal of devaluation, mockery, rejection and are victims of assaults, so it is not surprising that some individuals develop a sensitivity to communications from others that could be interpreted as critical. A patient interview will often reveal that the individual has not understood what was said and that the “persecutory” ideas resolve with explanation. Where delusions or hallucinations are truly present, the sophistication of their content is appropriate for the mental age. The consequence of uncritical diagnosis of psychotic illness is the overprescription of antipsychotics with serious consequences of impairment of adaptive function, akathisia and long-term risk of tardive dyskinesia.

Epilepsy syndromes are frequently associated with behavior disturbances in children and adolescents with ID, especially complex partial seizures and cyclical aggression and epilepsy (see chapter 30). Disinhibition and irritability with clonazepam are common. Given the presence of brain pathology, children and adolescents with ID are susceptible to delirium, and a search should be made for intercurrent physical illness as a cause for a recent onset of behavioral disturbance.

Various manifestations of inflexibility in cognitive processing are commonly associated with ID, manifesting as autistic rituals, preoccupations with particular topics, and anxiety with changes in routine or arrangement of objects in the environment. Preoccupations usually are not related to ideas of contamination or harm and lack the “magical” quality of true obsessions.

Ascertaining the cause of ID where possible is an important part of assessment, as psychological symptoms can be a consequence of localized or generalized brain pathology. For example, in tuberous sclerosis focal space-occupying lesions or “tubers” are present or develop, often in the limbic system, with consequent production of a wide range of psychiatric symptoms (Roach, 1988).

**Developmental Issues**

Key issues presenting to clinicians vary with the mental age of the young person. The birth of a disabled child presents a major crisis for parents. The psychiatrist may be consulted to assist with various aspects of the bereavement process (e.g., parental rejection of the handicapped child, or sudden marital separation). In infancy and childhood, the psychiatrist may be consulted to assist families with manifestations of unresolved grief, such as excessive denial of handicap, as the extent of disability becomes more apparent in the moderately
CHAPTER 49

to severely handicapped. As schooling progresses, the academic handicap of the child with mild ID becomes apparent. Parents of these children must face a grief, which is sometimes more difficult to accept as the cause of handicap is less often identified. Family relationship issues, such as sibling anger consequent to disturbances of family roles, often present in this phase. Autistic and hyperactive symptoms may also lead to psychiatric consultation at this stage. In adolescence, increased size adds to the stress of care of the physically dependent child. Handicapped teenagers with aggressive behaviors may become frightening to mothers or other carers. The emerging sexual drive of teenagers may lead to psychiatric referral for assistance with inappropriate sexual behaviors in both boys and girls. In general, those issues facing the normal adolescent continue through the twenties or thirties for many young people with ID. Psychotic disorders mainly present in early adulthood, but may be earlier in velocardiofacial syndrome and Prader–Willi syndrome. Adaptive decline may appear in this period in individuals with Down syndrome, but manifest dementia is unusual before age 30.

Pharmacological Treatment

There have been many reports documenting high levels of prescription of psychotropic medications to adults with ID (for a review see Sprent, Conroy, & Fullerton, 2004) but no contemporary surveys for children and adolescents. The surveys of adults with ID have commonly found poor prescribing practice. For example, Holden and Gitelson (2004) found that 37% of people with ID in one Norwegian county were using psychotropics, and that prescriptions frequently violated current guidelines, especially when given by general practitioners. For example, many prescriptions had not been indicated by a diagnosis, alternatives to medications had rarely been explored, and evaluations of effects and side effects were exceptions. Clinical experience suggests that these problems may also apply to children and adolescents with ID. Consequently, it is important for prescribers to consider the use of drugs in children and adolescents with ID. Pharmacological treatment needs to be an integrated part of other concurrent treatments, and this frequently requires good communication with colleagues providing the other treatments. The precise target symptoms for which the psychotropic medication is being prescribed should be stated. It is very difficult to gain valid information from global impressions, such as “child will be less disruptive” or “more compliant.” It is better to use specific descriptions such as “frequency of child hitting others will be less.” In order to assess this, a method for reliably and validly documenting changes in the target symptoms during the course of treatment is needed. One such method is the Developmental Behavior Checklist-Monitoring module (Einfeld & Tonge, 2002). The use of structured records of behavior is particularly important for children and adolescents with ID, because their care often takes place in a variety of settings (e.g., home, school and respite care). Conflicting information may be received from various carers who attend consultations, each of whom will have a different experience of the patient and different interpretations of behaviors manifested. It is also useful to have two independent carers in a setting (e.g., both parents, or teacher and teacher’s aide) completing such charts independently to provide a basic measure of inter-rater reliability.

This record should note whether target symptoms have had a positive response to the medication before the psychotropic medication is continued. It is common for adult patients to be seen who have been receiving large doses of antipsychotics since adolescence without any evidence of benefit. When target symptoms have been reduced or absent for a reasonable period then an attempt should be made to reduce the dosage being prescribed, and structured measures of the effect of this dosage change should be used. Similarly, children and adolescents are frequently maintained on medication long after symptoms have resolved, out of fear that the behaviors will recur, despite developmental or environmental changes.

When a psychotropic medication is withdrawn, a proper withdrawal regime should be designed. Withdrawal symptoms appear commonly in individuals with ID if long-standing treatments are terminated suddenly. Because of the presence of organic brain dysfunction, the response to psychotropic drugs is often idiosyncratic. Therefore, the minimum dosage should be used initially with close attention paid to the emergence of side effects. Adverse effects may be more common in individuals with ID, partly because communication difficulties may impede reporting of symptoms (Aman, Paxton, Field, & Foote, 1986). Issues of compliance, pharmacokinetics and drug interactions need consideration also (see chapter 16).
Antipsychotics

The “typical” antipsychotics (see chapter 16) are the most researched medications in the ID field, but few studies have been rigorous enough to allow conclusions as to their value for the treatment of psychosis or disruptive behavior. The few exceptions have failed to identify any specific impact of antipsychotic medication on the treatment of challenging or problematic behaviors (Brylewski & Duggan, 2004). Aman, De Smedt, Derivan et al. (2002) and Snyder, Turgay, Aman et al. (2002) have reported double-blind placebo controlled trials of risperidone in children and adolescents with ID, using regimens of 0.02–0.06 mg·kg⁻¹·day⁻¹. These studies demonstrated an approximately 50% reduction in conduct disorder symptoms, significantly greater than placebo. Somnolence was transient and there was no impairment of cognition. However, weight gain was common, and prolactin levels were persistently elevated. While these agents cause lower levels of short-term extrapyramidal side effects, there is only limited evidence that the risk of tardive dyskinesia is lessened (Beasley, Dellva, Tamura et al., 1999).

There is now substantial evidence that atypical antipsychotics are associated with an increased risk of metabolic syndrome and diabetes (De Hert, van Eyck, & De Nayer, 2006). There is no substantive evidence that the newer antipsychotics have greater efficacy than the traditional ones in individuals with ID. Buzan, Dubovsky, Firestone, and Dal Pozzo (1998) have reviewed 84 published cases of clozapine use in adults with ID. They concluded that clozapine was both efficacious and well tolerated. However, the occasional serious hematological side effects of clozapine warrant caution in using this medication. Antipsychotic medications frequently cause sedation and compromise cognitive functions and self-help skills. In addition, extrapyramidal side effects are common. Tremors and other movement disorders are common in individuals with ID who have taken antipsychotic medication (Sachdev, 1991). Campbell, Armenteros, Malone et al. (1997) found that 34% of autistic children who were receiving haloperidol over a prolonged period developed dyskinesias, mostly associated with withdrawal. Akathisia is an important side effect of antipsychotics to consider in persons with ID. Persons with limited verbal skills frequently are unable to describe the sense of restlessness and irritability, which can be very distressing. This can lead to increased agitation, which may mistakenly be seen as an indication for increased doses of antipsychotics, making the problem worse. Carers are sometimes very surprised to see a decline in agitation or aggression when antipsychotic dose is reduced.

Another rare but important complication of antipsychotic medication is neuroleptic malignant syndrome. Boyd (1993; as cited in Reiss & Aman, 1998) found the fatality rate (21%) to be double that occurring in persons without ID.

Antidepressants

Depression can be difficult to diagnose with confidence in people with limited verbal skills. However, given the relative safety of selective serotonin reuptake inhibitors (SSRIs), a low threshold for instigation of an antidepressant trial is reasonable. SSRIs (see chapter 16) have largely supplanted the tricyclic antidepressants in the treatment of depression in this population, given the lesser impact of side effects. Agitation and nausea are the most common. The evidence that one SSRI has any greater efficacy than another is inconclusive. It is important to start with small doses and for this reason SSRIs that are available in liquid form present advantages in that titration of small doses is possible.

SSRIs have also been widely used in the field to treat perseverative and repetitive behaviors including rituals of autism, preoccupations in Asperger’s disorder and self-injurious behavior. Singh, Kleynhans, and Hersen (1998) found marked reductions in self-injurious behavior in 10 out of 12 individuals treated with fluoxetine or fluvoxamine. Janowsky, Shetty, Barnhill, Elamir, and Davis (2005) found statistically significant decreases in the ratings of aggression, self-injurious behavior, destruction/disruption and depression/dysphoria in institutionalized adults. Controlled studies in children and adolescents have not been reported.

Anxiolytics

There have been no specific studies of the treatment of anxiety in persons with ID. Clinicians have reported improvements in phobic or generalized anxiety disorders as well as obsessive-compulsive disorder with treatment with SSRIs similar to that seen in the general population. Moclobemide is an alternative, but, in the authors’ experience, has less efficacy than the SSRIs. Buspirone has been described in case reports as of assistance. There is little or no indication for the use of benzodiazepines for the treatment of behavioral and emotional disturbance, although they are commonly used in the treatment of epilepsy. Benzodiazepines, particularly clonazepam, frequently cause disinhibition and irritability in persons with organic brain impairments (Kalachnik, Hanzel, Sevenich, & Harder, 2002). When a patient with ID taking benzodiazepines presents with these symptoms, it is always worth asking the patient’s neurologist to consider an alternative anticonvulsant if possible.

Mood Stabilizers

Typical bipolar illness is occasionally seen, but more frequently people with ID present with instability of mood, that is to say rapid fluctuations between excitement, irritability and high levels of activity alternating with withdrawal and loss of interest. Langee’s (1990) retrospective file study found 42% of individuals treated with lithium for a range of behavioral disorders improved significantly. Lithium has also been widely used particularly for impulsive aggressive behavior although evidence for a particular efficacy for this presentation is equivocal.

It should be noted that hypothyroidism is common in Down syndrome, so particular care is needed to monitor for the side effects of lithium. Carbamazepine and valproate have been widely used as mood stabilizers in children and adolescents with ID and have lower toxicity risks than lithium. Despite their wide use there are surprisingly few studies of their use, predominantly case reports. Carbamazepine has the
disadvantage of requiring more frequent monitoring of serum level.

Stimulants
The principal indication is for the same purpose as in children without ID, for the treatment of ADHD. There is some evidence to suggest that those with moderate and severe ID do not respond as well to stimulants as those with mild ID (Aman, Marks, Turbott, Wilsher, & Merry, 1991). ICD-10 includes overactive disorder associated with intellectual disability and stereotyped movements, a category of uncertain validity. Stimulants may worsen epilepsy, anxiety and tics, all of which are more common in children with ID. Curiously, there have been no systematic studies of which this author is aware studying stimulants in Prader–Willi syndrome, despite their appetite suppressant properties.

Atomoxetine, a noradrenergic reuptake inhibitor, has been shown in randomized controlled trials to be effective in the treatment of ADHD in children with autism (Arnold, Aman, Cook et al., 2006). Clonidine has been shown in a randomized controlled trial to reduce symptoms in children with ADHD and ID (Agarwal, Sitholey, Kumar, & Prasad, 2001) but at the cost of sedation, tolerance development and requirements to monitor blood pressure.

Anticonvulsants
Anticonvulsants are frequently prescribed for persons with ID, given the high prevalence of epilepsy. They are also prescribed as mood stabilizers as above.

Antiliodinal agents
Inappropriate sexual behaviors of some adolescents with ID can cause considerable concern to others and restriction for the individual. Consequently, there has been a growth in the use of testosterone antagonists to reduce libido. Cyproterone is now widely favored as it is active orally, but causes weight gain. Luteinizing hormone-releasing hormone (LHRH) analogs (e.g., leuprorelin) are the most effective and safest method for reducing testosterone levels over prolonged periods but are expensive and of limited availability. The pharmacology of these medications and protocols for their use in paraphilias are described by Reilly, Delva, and Hudson (2000). The pharmacological reduction of libido is potentially of some ethical concern. Prescription to this end should only follow efforts to redirect inappropriate sexual behavior through behavioral and educative means. It may then be that the best interest of the adolescent with ID is served by suppression of a natural aspect of human function. These issues are discussed in greater detail by Clarke (1989).

Psychological Treatment
There is extensive evidence to support the efficacy of applied behavior analytic approaches in the treatment of problematic or challenging behaviors shown by both children and adults with ID (Ball, Bush, & Emerson, 2004; Emerson, 2001; Lucyshyn, Dunlap, & Albin, 2002; O’Reilly, Sigafoos, Lancioni et al., 2007). While there is significantly less direct evidence, it is likely that some “talking therapies” (e.g., cognitive–behavior therapy) may be efficacious for some children with ID who have acquired more complex language skills (Dagnan, Joahoda, & Kroese, 2007). Detailed guidelines are available with regard to the implementation of behavioral approaches (Ball, Bush, & Emerson, 2004; Bush & Emerson, in press; Luiselli, 2006).

Contemporary behavioral approaches (often referred to as positive behavior support) tend to share three key underlying characteristics in that they strive to be functional, constructional and socially valid (Emerson, 2001). A functional approach assumes that it is necessary to identify the specific psychological processes that maintain a person’s challenging behavior in order to maximize the efficacy of interventions. Constructional approaches seek to build competencies, rather than eliminate behaviors. Thus, the key question asked by any constructional intervention is “What should this person be doing in this context (instead of showing challenging behavior)" rather than “How can we prevent the person engaging in challenging behavior in this context?” Socially valid approaches employ methods that are acceptable to the main constituencies involved to generate socially significant change in the person’s behavior and life opportunities.

Behavioral approaches view challenging behavior as an example of operant behavior. That is, challenging behavior is seen as functional and (in a general sense) adaptive. It can be thought of as a way through which the person exercises some degree of control or power over key aspects of their world (see chapter 62).

One important aspect of the application of behavioral analytic methods in relation to children with ID is the attention given to the analysis and modification of antecedent and contextual factors. Contextual factors operate in two ways. First, and most importantly, they may establish the motivational base that underlies behavior. Second, they may provide information or cues to the individual concerning the probability of particular behaviors being reinforced.

Behavioral Assessment
Behavioral assessment has four distinct aims (Emerson, 2005a). These are to:
• Identify what it is that the person does that is challenging;
• Describe the impact of challenging behavior upon the person’s quality of life;
• Attempt to understand the processes underlying the person’s challenging behavior;
• Identify possible alternatives to replace challenging behavior.

Challenging behaviors are often described by carers and care staff in very general terms. The first step in any process of assessment therefore is to clarify the “How, what, where and when” of challenging behavior. Usually, the information needed to answer these questions will come from interviews with people who are in close contact with the person (e.g., family members, care staff). It may also be useful, both as a
The results of a behavioral assessment should identify:
1. Contexts or settings in which challenging behavior is significantly more likely to occur.
2. Establishing operations that may either activate or abolish the contingencies maintaining the person’s challenging behavior.

This knowledge opens up possibilities for either preventing or reducing the occurrence of challenging behaviors by the manipulation of antecedent variables. Examples of such approaches include:

- Modification of biobehavioral states (e.g., alertness, fatigue, sleep–wake patterns, hormonal changes, drug effects, seizure disorders, mood, and illness or pain) that are correlated with the occurrence of challenging behavior.
- Changing the nature of activities that precede situations in which challenging behavior is more common (e.g., the use of behavioral momentum to increasing compliance and reduce challenging behaviors associated with non-compliance; increasing opportunities for choice making; increasing task variety and physical exercise).
- Changing the nature of activities that are concurrent with situations in which challenging behavior is more common through, for example, redesigning curricula to increase preferred activities, generally enriching the person’s environment and providing non-contingent reinforcement and by embedding requests that may elicit challenging behaviors in a more positive prosocial context.

Behavioral theory suggests that decreases in challenging behavior may be brought about indirectly through processes of behavioral competition or response covariation. Two sets of procedures that share this common aim are the use of functional displacement and procedures involving the differential reinforcement of other alternative or incompatible behaviors.

Intervention through functional displacement (typically referred to as functional communication training) seeks to introduce a new behavior (or increase the rate of a pre-existing behavior) that serves exactly the same function as the person’s challenging behavior. If this alternative is more efficient than the challenging behavior, it should displace the challenging behavior in the person’s behavioral repertoire (Carr, Levin, McConnachie et al., 1994). For example, if a child’s aggression in the classroom serves the function of enabling them to escape from non-preferred activities, teaching the child an alternative method of escape (e.g., verbally requesting a change of activities) will displace aggression as long as it is a more efficient option (i.e., takes less effort and is just as or is more “successful” than aggression in delivering the desired consequences). A number of studies have demonstrated the viability of the procedure across a number of settings, participants and challenging behaviors and have indicated that treatment gains may generalize across settings and therapists and may be maintained over time (Emerson, 2001).

A more general set of approaches based on the notion of differential reinforcement also seek to intervene indirectly in challenging behavior by increasing the rate of other behaviors: the differential reinforcement of other behavior (DRO); and...
the differential reinforcement of alternative (DRA) or incompatible (DRI) behavior. The available evidence suggests that such procedures may not be particularly effective in reducing severely challenging behaviors (Didden, Duker, & Korzilius, 1997).

A third set of procedures seek to intervene by directly changing the contingencies of reinforcement that maintain the person’s challenging behavior. These are primarily based upon variants of extinction (preventing the maintaining contingency from occurring). Whereas extinction may constitute a useful component of an intervention package (e.g., in combination with functional communication training), evidence and consensus suggests it should never form the primary mode of intervention (Ball, Bush, & Emerson, 2004; Emerson, 2001).

Finally, there exist a number of “default” or “last resort” approaches based on variations of punishment (including time out), which may be given consideration when more functional and constructional approaches have failed. While they can be effective in temporarily suppressing severe challenging behaviors, their use raises a number of significant ethical issues (Ball, Bush, & Emerson, 2004).

In addition to specific treatments, there is also evidence to suggest that programs of family-focused early intervention may have a significant and lasting impact on the cognitive and social development of children with ID (Anderson, Lakin, Hill, & Chen, 1992; Baker & Feinfield, 2007; Guralnick, 2005). This evidence has raised the possibility for the design and delivery of approaches to the prevention of or early intervention for psychopathology among children with ID (Powell, Dunlap, & Fox, 2005). As yet, the effectiveness of such approaches has still to be demonstrated.

**Mental Health Services for Children and Adolescents with Intellectual Disability**

Whereas child and adolescent mental health professionals may be well-equipped by training to provide help for children and adolescents with ID, the service settings in which they work have not always welcomed requests to assist such patients. At the same time, carers of those with ID have not always readily sought mental health assistance. In Australia, the USA and other countries, the uncritical application of the normalization principle interpreted mental health interventions as “restrictive” and expressive of the “medical model,” which was seen as devaluing. On the mental health side, the fear grew that, as institutions for people with ID were closed, those with behavioral problems could be “dumped” on the mental health system (Bradley, Summers, Breereton et al., 2007).

While this was more apparent in services for adults, child and adolescent mental health services sometimes also reflected this reluctance. As a consequence, families were sometimes told by disability services that their child’s problems were “psychiatric” and needed mental health services, while mental health services told families that the problems were “behavioral” and therefore not the province of mental health.

One key dilemma in service design is the extent to which mental health services for children and adolescents with ID should be “mainstreamed” within general child and adolescent mental health systems, or should exist as separate specialized teams. One approach is for generic child and adolescent mental health services to provide initial care, with support available from a specialized resource.

In the UK there exist explicit policy objectives to provide comprehensive child and adolescent mental health services in all localities (Department of Health, 2004b) and supposedly to ensure that such services are also responsive to the needs of children and adolescents with ID (BMA Board of Science, 2006; Department of Health, 2004a). Thus, for example, the recent National Service Framework for Children, Young People and Maternity Services states that “All children and young people with both a learning disability and a mental health disorder have access to appropriate child and adolescent mental health services” (Department of Health, 2004b).

These policy initiatives reflect a growing understanding of the importance of addressing the mental health needs of children and adolescents more generally (BMA Board of Science, 2006; Department of Health, 2004b), and an appreciation that mental health services for children and adolescents with ID were often of poor quality and highly variable in their availability (Foundation for People with Learning Difficulties, 2003; McCarthy & Boyd, 2002; YoungMinds, 2006). Since the publication of the National Service Framework, the percentage of specialist child and adolescent mental health services that also provide support to children and adolescents with ID has risen from 33% to 45% (Barnes, Wistow, Dean et al., 2005). No data are available on the effectiveness or efficiency of these services for children and adolescents with ID. In some service contexts, mental health practitioners may find themselves responsible for ensuring that children and adolescents with ID receive appropriate service for the physical as well as mental health of their patients.

**Service Issues Across Developmental Phases**

In the antenatal period, parents may need mental health support in the face of prenatal detection in the fetus of conditions causing ID. The birth of a newborn with obvious congenital abnormalities, especially affecting the brain, precipitates a profound crisis for parents. Child and adolescent mental health professionals are needed either to assist parents with severe difficulty in coping with this crisis, or to support other health professionals who are working with families. The same crisis will be manifest at whatever age ID is first diagnosed. To resolve this crisis, families need to achieve a healthy bereavement in the face of the loss of the wished-for child. Typically, such bereavement recurs as each delayed major developmental milestone is experienced as a loss. During infancy and childhood, the parental focus is often on the acquisition of basic developmental tasks such as mobility, toileting and speech. Despite the evidence described above that behavioral and emotional problems are already apparent in early childhood, parents see these as containable as the child is
still physically small. This can make it difficult to ensure parental interest in early intervention programs to prevent psychopathology.

The relationships between the child with ID and their siblings are important for mental health professionals to consider. If the child with ID is older, he or she may become aware over time that his or her younger siblings are granted more independence than he or she is. This reversal of the norm can lead to considerable sibling tension. The normal siblings will often have to contend with the stigma engendered by the presence of their disabled brother or sister. Groups aiming to support siblings of children with ID have been used to address this need (Evans, Jones, & Mansell, 2001).

Adolescence is often accompanied by new requests for mental health assistance, frequently on account of the increased size of the child. For example, a large 14-year-old with severe ID whose tantrums are precipitated by the same circumstances as earlier may be difficult to prevent from injuring themselves or others. In young adulthood, individuals with mild ID may still be struggling with adolescent independence and identity issues left behind by their normally developing peers. It is thus appropriate for child and adolescent mental health professionals to continue care for some years into the adult chronological age period.

Mental health practitioners will need to interact effectively with a range of other services and these will change with the patient’s development. As the young person with ID grows, the focus of inter-agency collaboration may shift from maternal and infant services, through stages of the preschool and education system, to transitional vocational or day activity programs to degrees of independent living. The state of the young person’s mental health will have a substantial impact on the success of this development.

**Future Directions**

Future research and practice hold out the possibility of advances on three fronts: furthering our understanding of the biological bases of ID; strengthening the evidence-base for specific interventions; and developing a more preventative approach to addressing psychopathology in children and adolescents with ID.

Prospects for substantial advances in understanding the biology of ID are likely to arise from advances in human genetics. In particular, microarray techniques promise to identify new small aneuploidies underlying ID. Lewis (2005) provides a useful review of these technologies in ID research. We also anticipate continuing advances in mapping gene–behavior pathways in the behavior phenotypes of genetic disorders causing ID (see chapter 24). These advances offer the prospect of prevention through prenatal molecular karyotyping (Larrabee, Johnson, Pestova et al., 2004).

The evidence-base relating to interventions for reducing psychopathology primarily addresses issues of efficacy. There is a dearth of evidence relating to effectiveness or the factors associated in successfully scaling up existing interventions, and no evidence relating to efficiency (see chapter 18; Emerson, 2006). Such evidence is a prerequisite for evidence-based policy and practice.

The high prevalence and persistence of psychopathology among children and adolescents with ID, when combined with existing knowledge regarding risk factors and possible underlying mechanisms, open up the possibility of developing more preventative approaches. These are likely to encompass a range of possibilities including primary prevention through reducing exposure to risk factors associated with the development of psychopathology (e.g., poverty reduction, enhanced child protection, reduced exposure to unresponsive communicative environments) and developing resilience in the face of exposure to these risk factors, through to increased investment in targeted early intervention.

CHAPTER 49

INTELLECTUAL DISABILITY
CHAPTER 49

Disorders of Personality

Jonathan Hill

The concept of personality disorder in adult life is important and elusive. It is important because the problems it encompasses are a major cause of burden to patients, to the adults and children with whom they have relationships, and to society. It is elusive because there is relatively little agreement on basic issues such as whether there is one overarching disorder or many, and what the core defining features of a personality disorder are. Nevertheless, there is broad agreement that the concept must include stability of behaviors over substantial periods of time, and extensive or pervasive dysfunction encompassing a range of psychological, behavioral and interpersonal capacities. Prima facie it seems likely that such stable and severe problems will have started before adult life, and there is evidence that in many instances analogous disorders or their antecedents start in childhood, and that childhood experiences may affect risk for subsequent personality disorder. Accordingly, it seems crucial to consider what is known about personality disorders, with special reference to two key questions for child psychiatrists and child mental health practitioners more widely: the extent to which there is continuity in personality disturbance between childhood and adult life, and on whether it is useful to apply the diagnosis in childhood and adolescence.

Concepts of Personality Disorder

Attempts to classify personality types and dimensions go back to antiquity but concepts of personality disorder are of much more recent origin (Frances & Widiger, 1986; Rutter, 1987; Tyrer, Casey, & Ferguson, 1991). Although there are numerous variations on the specifics, the unifying notion is the idea that there are pervasive and persistent abnormalities of overall personality functioning that cause social impairment and/or subjective distress, which are not caused by episodic disorders of mental state. The basic assumption is that, in some way, personality disorders are different from other psychiatric conditions, such as schizophrenia, depression or anxiety states.

Most personality disorder research has made use of the American Psychiatric Association (2000) DSM classification which put forward four diagnostic criteria. There were first enduring patterns of inner experience and behaviours that deviated markedly from cultural expectations (specifying that they should be manifest in at least two of cognition affectivity, interpersonal functioning or impulse control). Second, this enduring pattern had to be inflexible and pervasive across a broad range of personal and social situations. Third, it had to lead to clinically significant distress or impairment. Fourth, the pattern must be stable over time with an onset by adolescence or early adult life.

Several attempts to provide a unified concept have been made, notably using the idea that personality disorder represents an extreme of normal personality. One approach, based on the proposal that there are five major domains of personality – the Five Factor Model – (Widiger & Costa, 1994), argues that “Personality disorders are not qualitatively distinct from normal personality functioning. They are maladaptive, extreme variants of common personality traits” (see chapter 14). In discussions of models such as these, two issues are commonly conflated: whether categorical or dimensional approaches to personality disorder are more useful, and what is “normal personality functioning?” The categorical versus dimensional dilemma is discussed later in the chapter. The identity of the key elements of personality remains a matter of debate. In the Five Factor Model, the higher-order traits extraversion/positive emotionality, neuroticism/negative emotionality, conscientiousness/constraint, agreeableness and openness-to-experience are proposed as providing a succinct yet comprehensive summary of personality dimensions. However, from the perspective of personality development several questions require attention. How coherent or homogenous are the hypothesized traits? Although the big five are characterized as “higher-order,” each includes “lower-order” traits, some of which differ substantially. This issue is reviewed by Caspi, Roberts, and Shiner (2005) (see chapter 14). For example, the higher-order trait neuroticism is well validated and highly predictive in childhood and adult life, but includes both proneness to anxious distress and to anger. These different emotions motivate different behaviors, they are mediated via different neurological substrates, and they have different implications for development and psychopathology (Frick & Morris, 2004; Lemerise & Arsenio, 2000). Some of the personality traits also resemble temperamental characteristics. Thus, proneness to fearfulness and to anger are two aspects of temperament commonly assessed in infancy (Robinson & Acevedo, 2001). More generally, the overlap between temperament and
personality traits requires further attention (Caspi, Roberts, & Shiner, 2005). Big five personality traits are determined by the frequency of behaviors across context and time; however, traits can be conceptualized in other ways. In particular, coherence across context and time may occur at the level of the organization of behaviors (e.g., from the interplay between social information processing and context; Mischel, 2004). Personality development entails the development of the person as a social organism. Personality traits such as neuroticism undoubtedly influence social relationships (Robins, Caspi, & Moffitt, 2002), but there are also aspects of personality functioning such as social cognitive processes that are inherently social and entail dedicated neuronal networks (Johnson, Griffin, Csibra et al., 2005). The capacity to regulate behaviors and emotions according to the demands of different kinds of social domain (e.g., contrasting teachers and parents) is key to effective personality development. Personality develops in interaction with the environment so that its features are likely to reflect more or less successful adaptations than any simple manifestation of stable traits.

An alternative view of personality disorders proposes that the key features entail limitations of social role performance. Studies of adult personality disorders consistently find that they are associated with social dysfunction (Hill, Fudge, Harrington, Pickles, & Rutter, 2000; Seivewright, Tyrer, & Johnson, 2004; Skodol, Pagano, Bender et al., 2005) and “the characteristic that seems to define them all is a pervasive persistent abnormality in maintaining social relationships” (Rutter, 1987). Causes of social dysfunction may include extremes of personality traits, such as those identified in the big five, and also deficits or biases in social processes including mentalization, attachment and the capacity for social domain management (Hill, Pilkonis, Morse et al., 2008).

While these frameworks are promising, it should be borne in mind that the concept of personality disorder did not originate from a model of normal personality, and indeed descriptions of different personality disorder types have come about through several contrasting routes. First, there are those that derive from the clinical observation that there are individuals who show enduring patterns of inflexible and seriously maladaptive behavior that seem to fall outside the traditional criteria for mental illness or psychiatric syndrome. The need to have a term to describe these patterns of abnormal behavior led to the concepts of psychopathy put forward by writers such as Hare (1970), Henderson (1939) and Cleckley (1941) (see chapter 51). Second, there are the categories of personality disorder that identify individuals who are thought to be most prone to episodic mental disorders. Schneider’s (1923, 1950) notion of psychopathic personality (defined quite differently from the psychopathy formulations of Hare, of Henderson and of Cleckley) provides the main historic notion of this approach. Many of the ICD-10 specific personality disorder categories (e.g., paranoid, anankastic and anxious) represent this tradition (World Health Organization, 1996). Third, some categories have their origins in empirical observations of the continuities between psychopathological disorders in childhood, and pervasive social malfunction in adult lifestyle. The DSM-IV (American Psychiatric Association, 2000) diagnosis of antisocial personality disorder is the obvious example of this type, with its starting point in the findings of the long-term longitudinal studies pioneered by Robins (1966, 1978). Fourth, some categories stem fairly directly from theoretical, especially psychoanalytic, notions. The concept of borderline personality organization (Kernberg, 1967, 1975) underlies specification of the DSM-IV diagnosis of borderline personality disorder (Gunderson, Kolb, & Austin, 1981). Finally, a few categories have come, at least in part, from genetic findings. Meehl (1962) coined the term schizotypy to describe the postulated characteristics of schizophrenia-prone individuals. The Danish adoption study showed that the biological families of adopted schizophrenic probands included a raised rate of personality disorders that seemed to exhibit some features reminiscent of schizophrenia (Kety, Rosenthal, & Wender, 1971). Spitzer, Endicott, and Gibbon (1979) developed more explicit criteria for this type of personality syndrome, which has come to be termed “schizotypal personality disorder.”

The differences in the origins of personality disorder have contributed to substantial heterogeneity in the balance between behaviors and psychological states that are included in the subtypes of personality disorder. For instance, DSM-IV antisocial personality disorder is based primarily on antisocial behaviors and interpersonal difficulties, and includes only one state of mind item “lack of remorse” which is closely tied to behavior. By contrast, the borderline personality disorder category includes three items “identity disturbance,” “chronic feelings of emptiness” and “transient paranoid ideation” referring solely to states of mind.

Validation

Stability and Separation from Episodic Disorders

It is assumed that the personality disorders should show substantial stability over time. However, there is surprisingly little evidence that this is the case. Several studies of referred adults have found low to moderate stability (Ferro, Klein, Schwartz, Casch, & Leader, 1998). There is increasing evidence that some personality disorders may remit over relatively short periods of time. In a follow-up every 2 years of 290 patients meeting DSM-IV criteria for borderline personality disorder, 74% had remitted after 6 years, and only 6% had remitted and then relapsed (Zanarini, Frankenburg, Hennen, Reich, & Silk, 2005).

The distinction between episodic disorders and personality disorder is enshrined in the DSM distinction between Axis I and Axis II. Axis II disorders should show persistence over a period in which there is either recovery from, or onset of, Axis I disorder. It is important to note that this distinction is not made for childhood disorders. Thus, DSM oppositional defiant disorder and conduct disorder are classified on Axis I even though they show strong continuities, and probably share causal mechanisms, with both Axis I and Axis II disorders in
adult life. Remarkably few studies have been carried out to test the stability of personality disorder after accounting for episodic disorders in adults. Loranger, Lenzenweger, Gartner et al. (1991) examined changes in the diagnosis of personality disorder (on a standardized interview) in a series of 84 psychiatric patients over 1–6 weeks and found no effect of change in mental state on the diagnosis of personality disorder, supporting the personality disorder/episodic disorder distinction. Nevertheless, remission was associated with some fall in personality disorder symptoms and the diagnosis of personality disorder showed only moderate temporal stability (K = 0.55). Studies over greater time periods have used social dysfunction as the index of personality disorder at baseline and follow-up (Quinton, Gulliver, & Rutter, 1995; Rutter & Quinton, 1984) or a trait-based assessment of personality disorder at baseline and social dysfunction at follow-up (Seewerwright, Tyrer, & Johnson, 2004). All reported substantial stability of personality dysfunction after accounting for duration or severity of symptoms of episodic disorders.

While these findings support the distinction between episodic and personality disorders, the two are strongly associated. There are very high rates of personality disorder in patients with episodic disorders – nearly half in in-patient samples and 20–40% in out-patient groups (Docherty, Fister, & Shea, 1986; Tyrer, Casey, & Ferguson, 1991). These figures are much higher than the rates of 6–13% that are typical of general population samples (Casey & Tyrer, 1986; Merikangas & Weissman, 1986). The meaning of these associations is not clear. It is likely that to a certain extent they are artifacts arising from difficulties in distinguishing Axis I and Axis II items. In clinical and research practice it is often difficult to disentangle symptoms associated with episodes and those that reflect personality disorder.

However, this is unlikely to be the whole explanation. There are three main ways in which the associations may arise. First, personality disorder may constitute a risk factor for episodic conditions. This could occur through direct mechanisms whereby a feature of the disorder, such as poor coping (Vollrath, Alnaes, & Torgersen, 1994), leads to helplessness and hence depression or indirect mechanisms in which the personality disorder increases the likelihood of psychosocial stressors that in turn are associated with a disorder such as depression (Daley, Hamman, Davila, & Burge, 1998). Second, episodic conditions may create the conditions in which personality disorders develop because a chain of maladaptive behaviors and adverse environmental responses is set in motion that fosters more persistent psychopathology (Casen, Cohen, Skodol, Johnson, & Brook, 1999). Third, both the personality disorder and the episodic disorder could reflect one underlying liability. Malone, Taylor, Marmorstein, McGue, and Iacono (2004) assessed antisocial personality disorder and alcohol dependence in 289 twin pairs at ages 17, 20 and 24. There were moderate genetic influences on each disorder at each age, and a substantial proportion of these influences was common to the two disorders.

It might be expected that whatever the relationship between episodic disorders and personality disorder, the combination should in some sense reflect a more severe variant, with implications for treatment outcome. However, the evidence has been mixed. One recent review concluded there was no effect of personality disorder on treatment outcomes for depression (Mulder, 2002). Newton-Howes, Tyrer, and Johnson (2006) conducted a meta-analysis of all depression treatment studies in which personality disorder had been assessed and concluded that personality disorder was associated with a doubling of the risk of a poor outcome for depression (Newton-Howes, Tyrer, & Johnson, 2006). The authors point out that even the largest studies reviewed had inadequate statistical power to detect a difference of this size. Very little is known about the ways in which personality disorder may be associated with a poor outcome. Possibilities include that it may be associated with poor treatment compliance, with greater severity of overall psychopathology or with more psychosocial adversities and fewer interpersonal resources.

**Differentiations Among Personality Disorders**

The World Health Organization (1996) classification, ICD-10, makes a basic differentiation between organic personality disorders (meaning those resulting from severe head injury, encephalitis and other forms of overt brain damage); enduring personality changes deriving from some catastrophic experience (see chapter 42); personality abnormalities that reflect the residue of some mental illness (e.g., residual schizophrenia); and what they term personality disorders. The American Psychiatric Association (2000) scheme makes broadly comparable distinctions. This chapter is concerned with this last group of specific personality disorders, because the others have only an extremely limited application in childhood and adolescence.

The ICD classification specifies nine personality disorder types, and the DSM system eleven. To a certain extent the different categories reflect the different origins referred to earlier. The DSM classification has received a lot of attention and, in spite of the operational definitions of each of the categories, the evidence for the discriminant validity of the majority is not strong. Consistently, studies have shown that individuals who receive one DSM Axis II diagnosis often receive several (Morey, 1988; Oldham, Skodol, Kellman et al., 1992; Pfohl, Coryell, Zimmerman, & Tsangl, 1986). Although there is evidence that the DSM categories cluster into three broad bands of the odd/ eccentric, the dramatic/emotional/erratic and the anxious/fearful (Kass, Skodol, Charles, Spitzer, & Williams, 1985), combinations of personality disorders that cross these bands are common (Oldham, Skodol, Kellman et al., 1992).

Support for the discriminant validity of particular personality disorders would be provided if it were possible to show differential association with other psychiatric conditions, family clustering, or associations with genetic or environmental influences. Studies of the association of borderline personality disorder with other episodic and personality disorders have provided some support for its discriminant validity. Zanarini, Frankenburg, Dubo et al. (1998) compared patients with borderline personality disorder with patients with other personality disorders. Those with borderline disorder had higher rates of
CHAPTER 50

associated paranoid, avoidant and dependent personality disorders, and higher rates of mood, anxiety and eating disorders.

The most clear-cut finding from family studies is the association between schizophrenia and a loading of schizotypal personality disorders in the biological relatives (Kendler, Gruenberg, & Strauss, 1981; Kendler, Gruenberg, & Strauss, 1984). The evidence for a link between schizotypal personality disorder and schizophrenia is further supported by findings that there are similarities in magnetic resonance imaging appearances (Dickey, Shenton, Hirayasu et al., 2000) and in deficits of attention and information processing (Cadenhead, Light, Geyer, & Braff, 2000). A significant but weaker association with schizophrenia has been found with paranoid personality disorders (Kendler & Gruenberg, 1982; Kendler, Masterson, & Davis, 1985).

There are very few family and genetic data on other personality disorders (Maier, Franke, & Hawalke, 1998; McGuffin & Thapar, 1992). There is some evidence that borderline personality disorders cluster in families and also are associated with affective disorders in other family members, but it remains quite uncertain whether the family loading has a genetic basis. Joyce, McHugh, McKenzie et al. (2006) reported a significant association between a 9-repeat allele of a dopamine transporter gene variant and borderline personality disorder in depressed patients entered into two treatment trials. This requires replication. There is consistent evidence for genetic influences on adult antisocial behaviors (Langbehn, Caderet, Yates, Troughton, & Stewart, 1998), but not adult violence (Carey & Goldman, 1997).

Most studies of the association between adverse childhood experiences and personality disorders have reported associations with a wide range of episodic and personality disorders (Johnson, Cohen, Brown, Smailes, & Bernstein, 1999). It should be borne in mind that such associations can reflect genetic as well as environmental influences; nevertheless, specificity with particular disorders would support their validity. Bezirganian, Cohen, and Brook (1993) found that the combination of maternal inconsistency and high maternal over-involvement assessed in adolescence was associated with the persistence or emergence of borderline personality disorder, and no other episodic or personality disorders. Parker, Roy, Wilhelm et al. (1999) reported that dysfunctional parenting in childhood was associated with the dramatic and anxious DSM clusters, but not the odd/eccentric cluster.

Categorical versus Dimensional Characterizations of Personality Disorders

Diagnostic systems treat psychopathology as a categorical entity; however, it is evident that in most, and perhaps all, instances there are no natural cut-offs demarcating disorder from absence of disorder (see chapter 2; Pickles & Angold, 2003). The majority of early studies treated personality disorders as categories; however, the advantages of considering personality disorders dimensionally are becoming increasingly apparent. Simply from a measurement perspective, better interreliability is achieved using symptom counts. Evidence for validity tends to be stronger for dimensional methods. Personality disorder symptoms scores show greater stability than diagnoses (Skodol, Gunderson, Shea et al., 2005b) and there is a greater elevation of borderline symptoms than borderline personality disorder diagnoses in the first-degree relatives of borderline probands (Zanarini, Frankenburg, Yong et al., 2004). Furthermore, there is no evidence that there is a natural diagnostic cut-off (Daley, Burge, & Hammen, 2000). Diagnoses may also lump together symptoms that reflect different processes. Zanarini, Frankenburg, Hennen et al. (2005) have suggested that borderline personality disorder comprises acute symptoms that wax and wane and may be affected by life events, and others are chronic or "temperamental." Such a proposal requires further investigation. However, it illustrates the advantages of a dimensional framework in relation to the personality disorders. In community studies, increasing personality disorder symptoms below a diagnostic threshold are associated with increasing social dysfunction (Daley, Burge, & Hammen, 2000; Hill, Hope, Lorenz et al., unpublished data). This is of great clinical importance because it suggests that even among patients who do not meet criteria for a diagnosis, personality disorder symptoms may be associated with processes that influence course and treatment responsiveness in common presentations such as adolescent deliberate self-harm. It is also possible that in the same individual, symptoms below the diagnostic threshold from more than one disorder may each have prognostic significance.

Specific Personality Disorders

In view of the lack of good discriminant validity among the many specific personality disorders, only those particularly relevant in childhood and adolescence are covered in this chapter. Antisocial personality disorder (ASPD) is well validated and important because of its association with conduct disorders in childhood, particularly those with early onset, and because of its implications for the next generation via parenting difficulties and domestic violence (Moffitt, 2006). Psychopathic disorder is identified in a smaller group of antisocial adults, most of whom have ASPD, and is associated with distinctive patterns of offending and neurobiological correlates. In childhood, there appears to be a subset of antisocial children with "callous unemotional" traits with distinctive genetic and neurobiological contributions that may be the precursors of adult psychopathic disorder (Blair, Peschardt, Budhani et al., 2006). Childhood conduct disorders and callous unemotional traits, and ASPD and psychopathic disorder are described in chapter 51. In this chapter we review borderline, schizotypal and schizoid disorders.

Borderline Personality Disorder

The overall concept of borderline personality disorder (BPD) is of a pervasive pattern of instability of interpersonal relationships, self-image, affects and control over impulses. The operationalization of this concept has varied somewhat over the years but the criteria have usually included a pattern of unstable and intense interpersonal relationships with alternating idealization...
and devaluation, frantic efforts to avoid real or imagined abandonment, an unstable or distorted self-image, impulsiveness, recurrent suicidal behavior, affective instability with intense episodic dysphoria, chronic feelings of emptiness and a lack of control over anger. In contrast to ASPD, BPD is more commonly diagnosed in females.

Very little is known about the childhood antecedents of BPD. Many individuals have both antisocial and borderline features, and some traits such as impulsivity are core to both disorders (Paris, 2005). It is possible that there is a common origin in early-onset disruptive behavior problems, with a gender-based divergence in adolescence or early adult life. Equally, borderline personality difficulties may emerge during early adolescence without a history of overt antisocial behavior problems. Retrospective studies suggest that, as children, adults with BPD may have had difficulties in separating from emotionally important people and show high mood reactivity (Reich & Zanarini, 2001) and that many started to self-harm before the age of 12 (Zanarini, Frankenburg, Ridolfi et al., 2006).

Many theories of the origins of BPD have proposed a central role for adverse, and in particular traumatic, experiences in childhood. If this were the case there would be a particularly important preventative role for child care and mental health professionals. It is important to re-emphasize that both genetic and environmental mechanisms may be implicated in associations with childhood adversities, and genetic designs are usually required to tease them out. Moreover, in their meta-analysis covering 21 studies into possible associations between child sexual abuse and BPD, Fossati, Madeddu, and Maffei (1999) found there was only a moderate pooled effect size. It is difficult to disentangle the effects of child maltreatment from other family environmental and genetic risk factors, to identify which aspects of maltreatment may be relevant to BPD, and to determine the specific association with borderline as opposed to other conditions commonly comorbid with BPD. For example, it may be that particular kinds of child maltreatment are specific to BPD (see chapter 28). In a comparison of borderline patients and those with other personality disorders, those in the borderline group were more likely to have been abused by a male non-caretaker, to have experienced denial of their thoughts and feelings by a male caretaker and to have experienced inconsistent behavior by a female caretaker (Zanarini, Ruser, Frankenburg, Hennen, & Gunderson, 2000). We referred earlier to the particular patterns of mother-child interactions found in a general population study of adolescent predictors of borderline personality disorder (Bezirganian, Cohen, & Brook, 1993). There may also be specificities between type of maltreatment and features of BPD. For example, individuals with BPD also report more dissociative experiences (Jones, Heard, Startup et al., 1999). Zanarini, Ruser, Frankenburg et al. (2000) found that dissociative experiences among BPD patients were associated with particular experiences that included inconsistent behavior by a caretaker and sexual abuse by a caretaker. Finally, some effects of childhood maltreatment on BPD may be evident only in subgroups with genetically influenced susceptibilities to experiences (see chapter 23).

Theories regarding mechanisms in BPD have focused on impulsivity (Paris, 2005), emotion dysregulation (Putnam & Silk, 2005), unresolved or insecure attachment (Levy, 2005) and failure of mentalization (Bateman & Fonagy, 2004). Some of the features of BPD, including suicide attempts, self-mutilation, substance misuse and sexual promiscuity, may reflect a more general trait of impulsivity. Impulsive spectrum disorders, such as ASPD and substance misuse, are elevated in the first-degree relatives of borderline patients (White, Gunderson, Zanarini, & Hudson, 2002), and levels of impulsivity predict clinical outcomes in BPD (Links, Heslegrave, & van Reekum, 1999). However, disorders other than BPD are also characterized by impulsivity, notably ASPD, and although there is substantial overlap between the disorders, there are important differences.

Emotion dysregulation is likely to be one of the keys to the difference between BPD and ASPD. “The inability to sustain positive affect coupled with the pervasive and unremitting distress as experienced by patients with BPD can become a veritable prison to those with the disorder and often as well to those who attempt to treat the individual with BPD” (Putnam & Silk, 2005, p. 900). Borderline individuals commonly have a low threshold for reacting to events, or to anticipated events (such as abandonment), with intense negative emotion. According to Linehan (1993), BPD arises from an interaction between temperament emotional reactivity and an “invalidating” environment in which the child’s communication about inner emotional experience is regarded as reflecting an inaccurate perception of themselves and others. One of the major consequences of this response is thought to be that children raised in these environments do not learn to identify emotional states accurately, nor do they learn to regulate affect, as it is more often than not denied. In addition, invalidating environments also intermittently reinforce escalations of emotional displays. This results in two opposing responses to affect being shaped. The first is the inhibition or denial of emotional states, and the second is an extreme response, which often appears to be inappropriate to the level of the stimulus that elicited it.

Instability of family and romantic relationships characterized by highly intense interactions, fear of abandonment and emotionally charged breakdown, are also common in individuals with BPD. Several studies have linked this to disturbances of attachment (Levy, 2005), although very few have tested whether attachment difficulties are associated specifically with BPD, as opposed to other personality disorders. Bateman and Fonagy (2004) argued that individuals with BPD have an impoverished model of their own and others’ mental function (mentalization). “Their schematic, rigid and at times extreme ideas about their own and others’ states of mind make them vulnerable to powerful emotional storms and apparently impulsive actions, and create profound problems of behavioral and affect regulation” (Fonagy & Bateman, 2004, p. 2). They also argue that these limitations in mentalization are seen particularly in relation to attachment relationships, thus leading to particular difficulties in close relationships.
CHAPTER 50

The clinical picture of BPD may arise from interacting processes. For example, the combination of intrusive and inconsistent mother–child interactions associated specifically with BPD (Bezirganian, Cohen, & Brook, 1993) may contribute to affect dysregulation and a failure of mentalization. Intrusive parenting is likely to lead to intense negative affect from which the child takes evasive action, hence leading to extremes of high and low emotional intensity, and also to a reduced capacity to monitor mental states when highly aroused. Inconsistent mother–child interactions may inhibit the child’s capacity to read the intentions or states of mind of the parent, and hence limit his or her ability to think of others’ behaviors in mental state terms.

Repeated self-injury, cutting, burning or hitting, is frequently observed in individuals with severe personality disorders, and is one of the diagnostic items for BPD. It is a serious and puzzling phenomenon. There is a wide range of theories concerning the motivation for self-injury, and themes that are common to most of them are of regulation of emotions, communication and social reinforcement (Kemperman, Russ, & Shearin, 1997). Linehan (1993) has proposed that self-injury directly relieves painful emotions, and is reinforced by the attention and care given by others. Several studies have supported the role of self-injury in reducing painful affect, although most have used retrospective measures with samples that in different ways were unrepresentative. Proposals have been made that the mechanisms may entail effects on endogenous opioids or serotonin regulation, but results from a small number of investigations have been inconsistent (see chapter 40; Kemperman, Russ, & Shearin, 1997).

Dissociative Identity Disorder

The category multiple personality disorder (MPD), renamed dissociative identity disorder (DID) in DSM-IV, has provoked considerable controversy. The diagnosis is rarely made outside of the USA and Canada (Merskey, 1995), and in the USA only a minority of psychiatrists believe that DID is supported by strong evidence of scientific validity (Pope, Oliva, Hudson, Bodkin, & Gruber, 1999). Nevertheless, the phenomenon has been described in a range of scientific and clinical publications, and the case has been made that the symptoms can be corroborated, and that in offenders there is a strong association with documented severe abuse in childhood (Lewis, Yeager, Swica, Pincus, & Lewis, 1997). It is likely that this specific manifestation of personality disorder is culturally determined and to a certain extent iatrogenic, but it is possible that disorders of similar severity and with the same risk factors are seen more widely.

Schizotypal Personality Disorder

The general concept of schizotypal personality disorder is that of a pervasive pattern of social and interpersonal deficits marked by acute discomfort with, and reduced capacity for, close relationships, as well as by cognitive or perceptual distortions and eccentricities of behavior, beginning by early adulthood. It is likely that the concept of a spectrum of schizophrenic disorders, including schizotypal personality disorder, applies in the pre-adult years, as well as later. However, there have been only a small number of attempts to apply the criteria in childhood. One study suggested an overlap with pervasive developmental disorders, although not autism as such (Nagy & Szatmari, 1986); another suggested a course similar to that of schizophrenia arising in childhood (Asarnow & Ben-Meir, 1988); and a third suggested that there was a pattern of communication deficits similar to, but milder than, those found in schizophrenia (Caplin & Guthrie, 1992). Olin, Raine, Cannon et al. (1997) gathered prospective questionnaire data from teachers on 15-year-olds who subsequently developed schizotypal personality disorder. Compared with a range of other groups at varying levels of risk for psychiatric disorder other than schizophrenia, the schizotypal individuals as adolescents had been more passive and unengaged and more hypersensitive to criticism.

Schizoid Personality Disorder

The usual concept of schizoid personality disorder is of a pervasive pattern of detachment from social relationships and a restricted range of expression of emotions in interpersonal settings (American Psychiatric Association, DSM-IV, 2000). Thus, ICD-10 criteria (World Health Organization, 1996) include a lack of pleasure in activities, emotional coldness, apparent indifference to praise or criticism, a limited capacity to express either positive or negative emotions, a lack of close friends, a preference for solitary activities, a marked insensitivity to prevailing social norms and an excessive preoccupation with fantasy and introspection. The literature on the syndrome is almost confined to adults. However, since the 1970s, Wolff has pressed the case for the application of the diagnosis in childhood (Wolff & Barlow, 1979). Unfortunately for comparative purposes, her criteria differ in several key respects from those generally applied with adults. Thus, she has specified increased sensitivity and paranoid ideas, whereas ICD-10 and DSM-IV indicate marked insensitivity, and she has included an unusually odd style of communicating which would ordinarily be part of schizotypal, not schizoid, personality disorders (Wolff, 1991a,b; Wolff & Chick, 1980). The initial findings in childhood suggested some similarities with autism (Wolff & Barlow, 1979) and the follow-up showed substantial continuity with schizotypal personality disorder in adult life (Wolff, Townshend, McGuire et al., 1991). However, a study of psychophysiological responses of adults who in childhood met Wolff’s criteria for schizoid disorder failed to find abnormalities previously documented in the relatives of schizophrenic patients and adults with schizotypal personality disorder (Blackwood, Muir, Roxborough et al., 1994).

Utility of Personality Disorder Diagnosis in Childhood and Adolescence

In the light of these considerations, is there an argument for applying the concept of personality disorder in adolescence or even in childhood? Clearly, given the probable heterogeneity
of the personality disorders, it is unlikely that there will be one answer to this question.

There would be a strong case if it could be shown that the category unified diverse symptoms with a common cause, prognosis or response to treatment. It is for example clearly the case that the diagnosis of autism, which meets most of the requirements for personality disorder, provides an effective unifying diagnosis for diverse social and behavioral abnormalities. Might this be true also for childhood conditions such as oppositional defiant disorder or conduct disorder? Angold and Costello (2001) reviewed the DSM criteria for personality disorder outlined earlier and concluded that early-onset antisocial behaviors in children satisfy all the DSM requirements. Childhood oppositional and conduct disorders associated with poor peer relationships are more likely to persist (Vitaro, Brendgen, & Tremblay, 2000), and adult antisocial outcomes are most common in children with multiple and diverse oppositional, social and educational difficulties (Stattin & Magnusson, 1996).

However, the use of the personality disorder designation could introduce the limitations of the adult categories into childhood. Crucially, it might reduce our scope for investigating the links between different types of dysfunction. Vitaro, Brendgen, & Tremblay, (2000) found that, in boys, although having a best friend who was deviant at age 10 predicted delinquency at age 14, this was much less the case among those with warm relationships with their parents. Such a specific mechanism could not be investigated within a personality disorder framework if poor peer relationships was simply one of a number of items within a childhood ASPD. Similarly, notwithstanding the strong association of conduct disorder and ADHD and evidence that ADHD in the presence of conduct disorder increases the likelihood of persistence (Loeber, Green, Keenan, & Lahey, 1995), important genetic and neuropsychological differences would not have been identified if they had been included in a hyperactivity–conduct personality disorder. Whatever the pros and cons of creating childhood personality disorders, or of other kinds of solution such as dissolving the Axis I–Axis II demarcation, the placement of disruptive disorders of childhood on DSM Axis I, and antisocial personality disorder on Axis II, is an anomaly and does not reflect a fundamental distinction between them.

Is there a case for applying adult personality disorder criteria in adolescence? Studies of hospital patients, mainly with BPD, have suggested that adolescent personality disorders may be less distinct and less stable than adult disorders, but the profile of symptoms is largely similar (Becker, Grilo, Edell, & McGlashan, 2004). There is a case for using a dimensional approach to personality disorders in adult life, and this is likely to be the case also in adolescence. The stability of personality disorder symptoms is no less during adolescence, and from adolescence to adult life, than it is in adult life (Cohen, Crawford, Johnson et al., 2005). Correlation coefficients of 0.5–0.7 are commonly reported between adolescent and adult measures and over periods of up to 10 years. Equally, there can be informative developmental sequences involving personality disorder symptoms. Hamigami, McArdle, and Cohen (2000) showed that there were reciprocal effects of narcissistic and borderline symptoms on each other from early adolescence into the mid-twenties. Borderline symptoms predicted increasing narcissistic symptoms over time, but narcissistic symptoms predicted lower borderline symptoms! This may indicate that the appearance of borderline symptoms in early adolescence reflects substantial underlying pathology, whereas early narcissistic symptoms may be more developmentally benign. Later narcissistic symptoms, by contrast, may also reflect more problematic functioning, perhaps particularly when associated with borderline features.

**Borderline Personality Disorder in Adolescence**

Many of the studies of personality disorder in adolescence have focused on BPD. A substantial proportion of adolescent psychiatric in-patients in the USA and the UK can be diagnosed with the disorder using adult criteria. It resembles the adult diagnosis in that there is a strong association with episodic disorders, particularly depression, and its stability is low. In adolescents, the BPD diagnosis picks out a group who, compared with other adolescent psychiatric patients, have experienced high levels of maternal neglect and rejection, grossly inappropriate parental behavior and a number of parental surrogates, sexual abuse (Ludolph, Westen, Misle et al., 1990) and higher levels of angry irritable interactions in the family (James, Berelowitz, & Verker, 1996). Associations of inconsistent and intrusive parenting with the emergence of BPD were found in the longitudinal study of a general population sample referred to earlier (Bezirganian, Cohen, & Brook, 1993).

**Clinical Implications**

In the light of the varied, and in many respects limited, body of research, should we make use of personality diagnoses in adolescence in clinical practice? The answer is, as is often the case, it depends on the purpose. It can serve the purpose of ensuring that attention is drawn to types of persistent dysfunction that are not reflected in the episodic diagnoses such as depression. For example, among adolescents assessed for suicidal behaviors, a substantial minority is depressed and a smaller group has borderline personality disorder. There are implications for treatment depending on the presence both of depression and of BPD. However, current evidence and clinical experience would suggest that the key issue is not whether the threshold for BPD is crossed but how many features of BPD are present. Similarly, the extent to which these are accompanied by symptoms of other disorders, notably ASPD, is equally important.

It should be emphasized that the evidence linking different personality disorders to treatment needs is limited in both adults and adolescents. In relation to ASPD, while there is some evidence for the efficacy of treatments such as multi-systemic therapy (MST) for juvenile offending, the studies have not assessed ASPD nor have they examined outcomes in relation to symptoms of other personality disorders such as BPD (see chapters 35 and 62).
Dialectical behaviour therapy (DBT) is increasingly being used as an approach with suicidal adolescents, many of whom are likely to have BPD symptoms (Katz, Cox, Gunasekara, & Miller, 2004). The “dialectic” refers to helping the adolescent to change what needs to be changed, while accepting what is a valid response to circumstances (Hill, Swales, & Byatt, 2006). Treatment is delivered by a team, and has several elements. Capability enhancement aims to increase the adolescent's basic capabilities of affect regulation, distress tolerance and interpersonal skills. This function is most often delivered by a skills training group. Motivational enhancement involves assisting adolescents to apply their new-found skills to their own life problems, in particular attending to cognitions, emotions or reinforcement contingencies that interfere with the implementation of skillful behavior. This function is most commonly delivered via individual psychotherapy. Explicit coaching in the application of problem-solutions to the adolescent’s real world situations is designed to increase generalization of skills learned in the program. This may be delivered by between-session skills coaching, by telephone, by case management or by training family members in the same skills that the adolescents are learning. Considerable attention is also paid to supervision by and support of therapists and to the family and wider environment of the adolescent, including social services and education.

Studies of adult populations in relation to BPD and chronic self-harm may provide some pointers to provide support for the effectiveness of DBT and other psychosocial treatments in BPD in adolescents. Perry, Bannon, and Ianni (1999) reviewed the results of 15 studies, and Bateman and Fonagy (2000) reviewed 25 reports of a range of psychotherapeutic approaches in adult personality disorders. Both reviews concluded that there was evidence for short- to medium-term effectiveness in a number of indices of disorder including depression and interpersonal problems, as well as personality disorder diagnosis. However, there have been very few randomized controlled studies. By 2004 there had been seven randomized controlled trials of DBT, but only two had sample sizes of greater than 60 (Lieb, Zanarini, Yen et al., 2004). These suggest a major effect on suicidal behaviors sustained for up to 1 year. Bateman and Fonagy (2001) conducted a randomized controlled trial of psychoanalytically oriented partial hospitalization with 38 borderline patients, based on their theory of impaired mentalization in BPD. The treated group had a lower frequency of self-harm, suicide attempts, hospital admissions, use of medication and depression, and better social adjustment over an 18-month treatment period. Generally, studies of effectiveness of treatment of personality disorders have used outcomes such as service utilization or depression levels as proxies for measures of changes in personality functioning. Tackling the difficulties associated with the current conceptualization and measurement of personality disorder should lead to improved treatment and more refined measurement of outcomes.

Bateman and Fonagy have summarized the principal features of treatments for which there is some evidence of effectiveness. The approach is active and structured with clear focus, in the context of a strong relationship between therapist and patient over a substantial period of time. The treatment is well integrated with other services available to the patient. Effective treatments for adolescents who have extensive dysfunction, paralleling that of the adult personality disorders, may well require an approach with these features, coupled with active involvement of the family and attention to educational or vocational needs.

Studies have been conducted of tricyclic antidepressants, selective serotonin reuptake inhibitors, neuroleptics and mood stabilizers in BPD (Lieb, Zanarini, Yen et al., 2004). Most have shown some evidence of efficacy but with small sample sizes. Of the 16 studies reviewed by Lieb, Zanarini, Yen et al., only two had a sample size of greater than 60, and in most cases they were substantially smaller. Soler, Pascual, Campins et al. (2005) randomized 60 patients with BPD to placebo or to olanzapine together with DBT. In assessments after 4 months, the combined DBT plus drug group had lower affective symptoms and impulsivity/aggression than the DBT only group.

Conclusions

Much remains to be discovered regarding the forms of dysfunction that best characterize the personality disorders. This will inform, and be informed by, increasing knowledge of childhood antecedents, developmental pathways, the interaction between individual and environmental processes, and basic psychopathological processes in the personality disorders. For all its shortcomings, the concept of personality has endured because it adds to our understanding of risk and psychopathology and, increasingly, research in this area highlights individuals with distinctive treatment needs. Patterns of symptomatology resembling adult personality disorders are seen during adolescence and also indicate distinctive and generally intensive treatment needs.

Psychopathy as a Clinical Entity

Classification of Psychopathy

The origins of the current description of the psychopathy syndrome can be traced back to the work of Cleckley (1941) and his book, The Mask of Sanity. Some of the key features of psychopathy recorded by Cleckley (1941) included: absence of nervousness, interpersonal charm, lack of shame, impoverished affect and poorly motivated antisocial behavior. From the criteria delineated by Cleckley, and his own clinical impressions, Hare (1980) developed the original Psychopathy Checklist (PCL), a formalized tool for the assessment of psychopathy in incarcerated adults. On the basis of considerable empirical work, this has been revised: first in 1991, the Psychopathy Checklist-Revised (PCL-R; Hare, 1991), and then again in 2003 (Hare, 2003). The first extension of the psychopathy concept to children was Bowlby’s (1946) description of “affectionless psychopathy.” It mirrored some of the key features introduced by Cleckley (such as lack of responsiveness to the suffering of others), but lay forgotten for a long time until the extension of the psychopathy construct to children was proposed again by Frick, O’Brien, Wootton, and McDermott (1994). This chapter considers how far neuropsychological formulations about psychopathy in adult life may be useful for understanding related characteristic in childhood.

The current definitions of psychopathy comprise both ratings of emotional dysfunction and ratings of overt antisocial behavior. The emotional dysfunction definition involves reduced guilt and empathy as well as reduced attachment to significant others. The antisocial behavior definition involves a predisposition to antisocial behavior from an early age and comprises overt behavioral problems also manifest in those individuals with antisocial behavior who do not have psychopathy (e.g., adults with antisocial personality disorder [ASPD] and children with conduct disorder [CD]). This two-component structure was identified through factor analysis and the identification of a number of individuals with psychopathy.

Psychopathy is not part of the DSM-IV diagnostic system (see chapter 2). Given the current definition of psychopathy syndrome that comprises both the emotional dysfunction and antisocial behavior, most individuals with psychopathy would receive a childhood diagnosis of CD or adulthood diagnosis of ASPD (see chapters 33 and 50, respectively). The diagnosis of CD groups individuals together because they engage in antisocial behavior. Thus, children with CD can be found whose antisocial behavior is associated with the specific form of reduced emotional responsiveness characteristic of psychopathy as well as children whose antisocial behavior is associated with heightened emotional responsiveness or dysregulated emotional responding (Blair, Mitchell, & Blair, 2005). In short, the DSM-IV CD diagnosis identifies a heterogeneous population who do not appear to share a common etiology and have some distinct clinical features (with resulting troubling implications for successful treatment). In contrast, the available evidence points towards a core neurocognitive profile shared by a number of individuals with psychopathy.

Assessment of Psychopathy

Following the development of the adult PCL-R, tools for the assessment of psychopathy in childhood and adolescence have also been developed. Here we briefly highlight those measures that directly stem from the PCL-R. These include the Psychopathy Checklist: Youth Version (PCL-YV; Forth, Kosson, & Hare, 2003; Kosson, Cyterski, Steuerwald, Neumann, & Walker-Matthews, 2002) and the Antisocial Process Screening Device (APSD; Frick & Hare, 2001). There is evidence of substantial convergence among these measures (Salekin, Leistico, Trobst, Schrum, & Lochman, 2005).

The assessment techniques (PCL-R, PCL-YV and APSD) all involve 20 behavioral items. Both the PCL-R and PCL-YV are...
scored on the basis of an extensive file review and a semi-structured interview. The APSD takes the format of a parent or teacher-rated questionnaire. For each behavioral item, an individual can score between 0 and 2 points. The individual’s total score can therefore vary from 0 to 40 points. Adults scoring 30 or above on the PCL-R are generally considered as having psychopathy, at least in the USA, while those scoring less than 20 are considered as not having psychopathy. There are less-well-established criteria for considering whether a child has psychopathy. Typically, in empirical studies, cut-offs of 20+ scores have been used. Given that emotional dysfunction is what sets psychopaths apart, any APSD scoring criteria should ensure a high score on the emotional dysfunction index (i.e., the callous-unemotional scale of the APSD). The inter-rater reliability for the PCL-R (Hare, 1991) and APSD is comparable with other instruments assessing psychopathology (Frick & Hare, 2003; Frick, Kimonis, Dandreaux, & Farell, 2003).

At the present, callous-unemotional traits are not routinely assessed when making a clinical diagnosis of CD. The assessment of callous-unemotional traits in research settings has generally relied on parent and teacher ratings. Such assessments could be easily adapted for clinical use to supplement standard diagnostic interviews.

Utility and Validity of the Classification
Evidence for the validity of the psychopathy construct is extensive for clinic and criminal populations. Much research has been devoted to relating psychopathy construct to other instruments and scales, collecting data on recidivism and violence as well as laboratory measures involving behavioral, psychophysiological and functional magnetic resonance imaging (fMRI) indices (see Patrick, 2006). One of the major strengths of the construct has been its utility in risk assessment. Considerable work has shown the predictive power of scores on the PCL-R with respect to recidivism (for a review of this literature see Douglas, Vincent, & Edens, 2006). Moreover, this work has shown that the correlation between recidivism and psychopathy is significantly higher than that of the DSM diagnoses (Hare, 2006). The evidence of the success of the psychopathy construct in risk assessment has been almost exclusively conducted in adult samples (for data with adolescent samples see Frick & Marsee, 2006; Frick, Stickle, Dandreaux, Farell, & Kimonis, 2005). The available data indicate that children with psychopathy show more conduct problems, more severe aggression, poorer prognosis and more instrumental aggression than other children with conduct problems (see chapter 35; Frick & Marsee, 2006).

For children, considerable stability ($r > 0.70$ across all time points) of the core emotional dysfunction has been demonstrated over a 4-year period (Frick et al., 2003). A long-term follow-up study measuring psychopathy at age 13 years demonstrated that the construct showed moderate stability to age 24 years ($r = 0.32$), despite different informants and assessment instruments used across the two age periods (Lynam, Caspi, Moffitt, Loeber, & Stouthamer-Loeber, 2007). This 11-year correlation is equivalent to that typically seen when different informants use the same instrument at the same time-point to rate an individual’s behavior on a construct.

Importantly, recent data have shown that differentiating children who receive the DSM diagnoses of CD or oppositional defiant disorder (ODD) on the basis of the callous-unemotional (the emotional dysfunction component of psychopathy) traits has clear implications for treatment prognosis (Hawes & Dadds, 2005). Boys with high callous-unemotional traits were less responsive to treatment, and callous-unemotional traits uniquely predicted clinical outcomes when analyzed in relation to CD/ODD severity, other predictors of antisocial behavior, and parents’ implementation of treatment (Hawes & Dadds, 2005). Moreover, children with psychopathy appear more difficult to socialize through standard socialization techniques (Oxford, Cavell, & Hughes, 2003; Wootton, Frick, Shelton, & Silverthorn, 1997).

As most of the research on psychopathy has concentrated on clinic or incarcerated populations, or has focused on the impact of psychopathy on antisocial outcomes, much less is known about the utility and validity of psychopathy construct in predicting other outcomes aside from antisocial behavior.

Co-occurrence With Other Syndromes
Attention Deficit/Hyperactivity Disorder
Considerable work has demonstrated that CD and attention deficit/hyperactivity disorder (ADHD) often co-occur (Hinshaw, 1987; Taylor, Schachar, Thorley, & Wieselberg, 1986). More recent work has suggested that psychopathy and ADHD also frequently co-occur (Barry, Frick, DeShazo et al., 2000; Colledge & Blair, 2001; Lynam, 1996). However, it remains unclear whether the ADHD seen in the context of psychopathy can be considered equivalent to that seen in the absence of psychopathy symptoms or whether it should be considered as a behavioral phenocopy with a divergent neurocognitive signature (Blair, Mitchell, & Blair, 2005).

Autism and Asperger’s Syndrome
Both autism and Asperger’s syndrome are, like psychopathy, associated with problems in “empathy” (see chapter 46). However, the nature of the empathy impairment appears very different between the two populations (Blair, 2003a). Individuals with autism and Asperger’s syndrome, as a group, tend to show impairment in Theory of Mind, the ability to represent the mental states of others (Baron-Cohen, Leslie, & Frith, 1985; Frith & Happé, 2005). Individuals with psychopathy do not (Blair, Sellars, Strickland et al., 1996; Richell, Mitchell, Newman et al., 2003). Individuals with psychopathy show impairment in processing the fearful and sad expressions of others and are poor at feeling for others, while capable of representing mental states (Blair, 2005; Blair, Colledge, Murray, & Mitchell, 2001). Individuals with autism or Asperger’s syndrome, while potentially showing a global impairment in processing emotions, do not show indications of specific impairment for fear and sadness and appear to find others’ distress aversive (Adolphs, Sears, & Piven, 2001;
CHAPTER 51

Blair, 1999; Rogers, Viding, Blair, Frith, & Happé, 2006). To date there have been no reports of comorbid psychopathy and either autism or Asperger’s syndrome although there have been isolated reports of individuals showing some of the emotion dysfunction associated with psychopathy (Fine, Lumsden, & Blair, 2001; Rogers, Viding, Blair, et al., 2006). As pointed out by Rutter (2005), unlike for psychopathy, the impaired socioemotional responsiveness found in autism spectrum disorders does not seem to be generally linked to increased risk for antisocial behavior. In support of this, Hippler & Klicpera (2003), in their study of 177 cases originally diagnosed by Asperger, found no raised incidence of criminal offences compared with general population rates. In contrast, Frick, Stickle, Dandreaux et al. (2005) have demonstrated that elevated levels of psychopathy predict increased antisocial behavior at a later time-point, even in children who do not start off as being antisocial. It thus appears that although both psychopaths and individuals with autism spectrum disorders can appear emotionally blunted, there are likely to be different roots to their emotional problems, which also explains the lack of increased risk for antisocial behavior in people with autism spectrum disorders. However, more research is needed that provides direct comparison of individuals with psychopathy and individuals with autism spectrum disorders.

Anxiety and Mood Disorders

Individuals presenting with anxiety and mood disorders (e.g., post-traumatic stress disorder and depression; see chapters 42 and 37, respectively) are at elevated risk for aggression at the time of this presentation (Silva, Derecho, Leong, Weinstock, & Ferrari, 2001; Zoccolillo, 1992). For example, in a recent community sample of almost 6000 individuals, over half (54.33%) of the 3.3% of adults with ASPD had a comorbid anxiety disorder (lifetime; Goodwin & Hamilton, 2003). Similarly, 42.31% of adults with a history of CD (9.4%) but who did not meet criteria for ASPD had a lifetime anxiety disorder.

In contrast to ASPD, psychopathy has been traditionally considered to be marked by reduced anxiety levels (Cleckley, 1941; Hare, 1970; Lykken, 1957). Moreover, studies have shown that anxiety level is inversely associated with the callous and unemotional/emotional dysfunction dimension of psychopathy (Frick, Lilienfeld, Ellis, Loney, & Silverthorn, 1999; Patrick, 1994; Verona, Patrick, & Joiner, 2001). In short, increases in anxiety are associated with increases in antisocial behavior but decreases in the emotional dysfunction component of psychopathy (for further discussion of this issue see Blair, Mitchell, & Blair, 2005).

Epidemiology of Psychopathy

The prevalence rates of CD are very high (6–16% for males and 2–9% for females, according to DSM-IV). The prevalence rate of psychopathy is far lower although full epidemiological studies have not been conducted. However, preliminary work conducted by Frick using the APSD, and using a cutoff for psychopathy commonly used in the literature, results in a prevalence rate of psychopathy of 1–3.5% (Frick & Hare, 2001). Using what we know about prevalence rates of ASPD from epidemiological studies and the proportion of psychopaths in the prison ASPD group, we can conservatively estimate the incidence of adult psychopathy at 0.75% (Blair, Mitchell, & Blair, 2005).

There is very little known with respect to prevalence and gender. Work on psychopathy has been conducted largely on males and relatively little is known about psychopathy in females (for a review see Verona & Vitale, 2006).

Development of the Behavioral Manifestation

There are few longitudinal data on the development of psychopathy, making it impossible to effectively describe how its behavioral manifestation varies with age. However, a recent study does suggest that cruelty to animals may be a potent indicator of early callous/unemotional predisposition (Dadds, Whiting, & Hawes, 2006). There is also some suggestion that fearlessness in early childhood may be one index of risk for callous-unemotional traits and conduct problems (Frick & Marsee, 2006; Kochanska, Gross, Lin, & Nichols, 2002). The importance of assessing age-appropriate behavioral features was recognized during the development of assessment instruments such as the APSD and PCL-YV. For example, attention is given to whether a child keeps the same friends rather than whether they have multiple marital partners (Frick & Hare, 2001). However, the extent to which individual components of the psychopathy are associated with the syndrome across time points remains unknown. The few existent data indicate reasonable stability of callous-unemotional traits from middle childhood to early adolescence (see Frick & Marsee, 2006 p. 853). Also, it is worth noting the literature on fearlessness. While it is not an explicit measure of psychopathy, it has long been associated with the disorder (Cleckley, 1941; Patrick, 1994). This is interesting because fearlessness also shows moderate stability in early childhood, as well as a clear relationship with empathic and moral development (Kochanska, Gross, Lin et al., 2002).

Does Psychopathy Extend into the Normal Distribution?

There has been some debate as to whether psychopathy is best characterized as a taxon or a constellation of normal personality traits (Edens, Marcus, Lilienfeld, & Poythress, 2006; Lynam, Caspi, Moffitt et al., 2005; Vassey, Kotov, Frick, & Loney, 2005). This debate remains unresolved. What is clear is that psychopathy can be mapped as a mixture of normal personality dimensions (see chapters 14 and 50; Lynam, Caspi, Moffitt et al., 2005). In addition, differences in brain function relevant to psychopathy can be identified within the healthy population and related to subclinical features of psychopathy (Gordon, Baird, & End, 2004). Although psychopathy can be mapped to a mixture of normal personality dimensions, and community samples high on psychopathic traits can display functional brain differences similar to those seen in incarcerated psychopaths, this does not suggest that psychopathy should necessarily be viewed as “normal.” Cleckley (1941) strongly
asserted that psychopathy represented something distinct from normal variations of personality. As pointed out by Rutter (2005), none of the existing measures of normal personality functioning set out to characterize the emotional dysfunction that defines psychopathy. In addition, we have no data addressing the question of whether the differences in brain function that are relevant to psychopathy need to reach a certain quantitative threshold before we see a true risk for the extreme psychopathic personality that might qualify as a taxon.

**Origins of Psychopathy**

**Genetic Factors**

A recent comprehensive meta-analysis of behavioral genetic studies on antisocial behavior concluded that antisocial behavior is moderately heritable (Rhee & Waldman, 2002). Work on psychopathy, a major risk factor for antisocial behavior marked by both reactive and instrumental acts, has revealed, using self-report measures in adult and adolescent populations, moderate heritability of callous–unemotional related traits, no shared environmental influence and moderate non-shared environmental influence (Blonigen, Hicks, Krueger, Patrick, & Iacono, 2005; Larsson, Andershed, & Lichtenstein, 2006; Taylor, Loney, Bobadilla, Iacono, & McGue, 2003). The heritability estimates were similar or slightly higher than typically found for self-report personality questionnaires (Loehlin, 1992). However, the sample sizes in these adult and adolescent samples were either relatively small or at best moderate. In recent work with around 3500 twin pairs, we have shown that callous–unemotional traits are strongly heritable (67% heritability) at both 7 and 9 years (Viding, Blair, Moffitt, & Plomin, 2005). Moreover, antisocial behavior in the presence of elevated levels of callous–unemotional traits is strongly heritable (81%). However, heritability of antisocial behavior without callous–unemotional traits was only moderate (30%; Viding, Blair, Moffitt et al., 2005). Importantly, in addition, the high heritability of antisocial behavior in children with callous–unemotional traits has been shown to be independent of co-occurring ADHD pathology (Viding, Jones, Frick et al., 2008).

Genes regulating serotonergic neurotransmission, in particular monoamine oxidase A (MAOA), have been highlighted in the search for a genetic predisposition to antisocial behavior (Lesch, 2003). The MAOA gene contains a well-characterized functional polymorphism consisting of a variable number of tandem repeats in the promotor region, with high- (MAOA-H) and low-activity (MAOA-L) allelic variants. The MAOA-H variant is associated with lower concentration of intracellular serotonin, whereas the MAOA-L variant is associated with higher concentration of intracellular serotonin. Recent research suggests that genetic vulnerability to antisocial behavior conferred by MAOA-L may only become evident in the presence of an environmental trigger, such as maltreatment (Caspi, McClay, Moffitt et al., 2002; Kim-Cohen, Caspi, Taylor et al., 2006). Despite the demonstration of genetic influences on individual differences in antisocial behavior, it is important to note that no genes for antisocial behavior exist. Instead, genes code for proteins that influence characteristics such as neurocognitive vulnerabilities which may in turn increase risk for antisocial behavior. Thus, although genetic risk alone may be of little consequence for behavior in favorable conditions, the genetic vulnerability may still manifest at the level of brain or cognition. Imaging genetics studies attest to genotype differences being associated with variation in brain structure and function in non-clinical samples (Meyer-Lindenberg & Weinberger, 2006). We can think of this as the neural fingerprint; ready to translate into disordered behavior in the presence of unfortunate environmental triggers.

Meyer-Lindenberg, Buckholz, Kolachana et al. (2006) recently provided the first demonstration of the MAOA-L genotype being associated with a pattern of neural hypersensitivity to emotional stimuli. Specifically, they reported increased amygdala activity coupled with lesser activity in the frontal regulatory regions in MAOA-L compared to MAOA-H carriers. Meyer-Lindenberg, Buckholz, Kolachana et al. (2006) speculated that their brain imaging findings of poor emotion regulation in MAOA-L carriers relate to threat reactive and impulsive, rather than psychopathic antisocial behavior. They based this speculation on the findings of individuals with psychopathy displaying under-reactivity of the brain’s emotional circuit, particularly the amygdala (Birbaumer, Veit, Lotze et al., 2005; Kiehl, Smith, Hare et al., 2001).

Currently, while the behavioral genetics data suggest heritability of the emotional component of psychopathy, a molecular level account of the disorder remains in its infancy. Suggestions have been made that psychopathy might be related to anomalies in noradrenergic neurotransmission (Blair, Mitchell, & Blair, 2005). It is also interesting to note that a small number of studies have reported increased vulnerability to antisocial behavior in the presence of the MAOA-H allele (Manuck, Flory, Ferrell, Mann, & Muldoon, 2000). These may reflect false positive findings, but it is also possible to speculate that the amygdala hyporeactivity as opposed to hyper-reactivity seen in individuals with psychopathy could be influenced by MAOA-H, rather than MAOA-L genotype. This suggestion remains highly speculative, and as for any behavior, the genetic influences will not be limited to a single candidate gene. Other genes influencing amygdala reactivity, such as genes encoding 5-HTT, could also have a role in psychopathy.

**Environmental Factors**

Many environmental causes have been suggested for an increased risk for aggression and, at least in the lay population, psychopathy. We will consider four sets of potential causes: exposure to extreme threats (e.g., in the context of childhood abuse and/or chronic exposure to violence), incompetent parenting, environmental insults and environmental motivators (e.g., a lack of money; see chapter 25).

**Exposure to Extreme Threats and Incompetent Parenting**

There are considerable data that exposure to extreme threats increases the risk for aggression or being diagnosed with CD.
CHAPTER 51

This is seen as a result of physical and sexual abuse (Dodge, Pettit, Bates, & Valente, 1995; Farrington & Loeber, 2000) as well as a result of exposure to violence in the home or neighborhood (Miller, Wasserman, Neugebauer, Gorman-Smith, & Kamboukos, 1999; Schwab-Stone, Chen, Greenberger et al., 1999). There are also considerable data that exposure to poor parenting increases the risk for aggression or being diagnosed with CD (Snyder, Cramer, Afrank et al., 2005). Moreover, Bowlby attributed “affectionless psychopathy” to family adversity that especially involved family disruption (Bowlby, 1946) and “impaired empathy” is considered an aspect of the “disinhibited attachment” that is characteristic of some children experiencing profound early institutional deprivation (O’Connor & Rutter, 2000; Rutter, 2005). Parental abuse is also frequently reported in forensic samples, including individuals diagnosed with psychopathy (Hare, 2003). A recent study specifically addressed the effect of childhood maltreatment on the different facets of psychopathy and found that maltreatment increases the risk for impulsive and irresponsible lifestyle, but does not have an effect on the core emotional dysfunction in psychopathy (Poythress, Skeem, & Lilienfeld, 2006).

The preliminary work by Poythress Skeem, & Lilienfeld (2006) suggests that the core emotional dysfunction of psychopathy may not be affected by maltreatment. In addition, work by Pollak and colleagues suggests that maltreated children show hyper-reactivity to anger, which is in contrast to hyporeactivity to fear and sadness seen in psychopaths (Pollak & Sinha, 2002). Animal studies can also provide some clues about the effects of maltreatment on emotional reactivity, although such work has to be interpreted with caution with regard to humans. Animal studies clearly show that prolonged threat or stress leads to a long-term potentiation of the neural and neurochemical systems that respond to threat (i.e., the individual becomes more responsive to aversive stimuli; Bremner & Mermetten, 2001; King, 1999). Moreover, animal studies also show that poor parenting is also associated with increased responsiveness to aversive stimuli (Rilling, Winslow, O’Brien et al., 2001; Sanchez, Noble, Lyon et al., 2005). Importantly, this concurs with much of the human literature (Pollak & Sinha, 2002). Thus, traumatic exposure, including exposure to violence in the home or neighborhood, appears to increase the risk for mood and anxiety disorders in general, although not all exposed to trauma will go on to develop these disorders (Charney, 2003; Gorman-Smith & Tolan, 1998; Schwab-Stone, Chen, Greenberger et al., 1999). In other words, animal and much human work indicates that trauma and poor parenting increase emotional responsiveness to aversive stimuli (for an account of why this increased emotional responsiveness to aversive stimuli should be a risk factor for increased levels of reactive aggression and some forms of CD see Blair, Mitchell, & Blair, 2005), whereas a defining feature of psychopathy is the reduction, not elevation, in the individual’s responsiveness to threat (Cleckley, 1941; Hare, 1970). More research is needed to investigate whether maltreated and neglected children displaying poor empathy and attachment problems show a similar neurocognitive profile to that seen in psychopathy. Current literature suggests that for the majority of cases, maltreatment produces a neural and behavioral signature that is different from that commonly observed in individuals with psychopathy. However, it is plausible that both biologically and environmentally “weighted” routes to the same pathophysiology can take place, even if one route is considerably more common than the other (for a discussion of this issue with respect to autism spectrum disorders see chapter 12).

Environmental Insults

Birth complications such as anoxia (lack of oxygen) and pre-eclampsia (hypertension leading to anoxia) are environmental factors that can give rise to brain damage. Minor physical anomalies (MPAs) are relatively minor physical abnormalities consisting of such features as low-seated ears and a furrowed tongue that are associated with disorders of pregnancy and are thought to be a marker for fetal neural maldevelopment towards the end of the first 3 months of pregnancy. They can be caused by environmental factors acting on the fetus such as anoxia and infection (Guy, Majorski, Wallace, & Guy, 1983) or can also indicate genetic liability. Several studies have shown that babies who have birth complications or present with MPAs are more likely to develop CD and delinquency and commit violence in adulthood, particularly when other psychosocial risk factors are present (Hodgins, Kratzer, & McNeil, 2001; Pine, Shaffer, Schonfeld, & Davies, 1997; Raine, 2002; although see, for example, Laucht, Esser, Baving et al., 2000).

Unfortunately, the literature has not considered whether birth complications or MPAs are a risk factor for the emergence of psychopathy or syndromes linked to heightened levels of reactive aggression. However, there is no reason to believe that such environmental insults could not detrimentally affect neural systems associated with the disorder (i.e., they could be causal for the disorder). Future research is needed to clarify this issue.

Environmental Motivation

Lower socioeconomic status (SES) and lower IQ are both associated with an increased risk for antisocial behavior, including the antisocial behavior component of psychopathy (Frick, O’Brien, Wootton et al., 1994; Hare, 2003). The SES data suggest a social contribution to at least the behavioral manifestation of psychopathy. Importantly, some antisocial behavior shown by individuals with psychopathy is instrumental in nature: it has the goal of gaining another’s money, sexual favors or “respect” (Cornell, Warren, Hawk et al., 1996; Williamson, Hare, & Wong, 1987). Individuals can attempt to achieve these goals through a variety of means. Having a higher SES (or for that matter intelligence) enables a wider choice of available routes for achieving these goals than having a lower SES or IQ. Lower SES or IQ limits the behavioral options. A healthy individual of limited SES or IQ may also have a narrow range of behavioral options but will exclude antisocial behavior because of aversion to this behavior formed during socialization. In contrast, individuals with psychopathy
may entertain the antisocial option because they do not find the required antisocial behavior aversive. SES is also likely to impact on the probability of displaying instrumental aggressions by determining relative reward levels for particular actions. If the individual already has $100,000, the subjective value of the $50 that could be gained if the individual mugged another person on the street is low. In contrast, if the individual has only 50 cents, the subjective value of the $50 will be very high indeed (for a discussion of subjective value see Tversky & Kahneman, 1981).

Pathophysiology of Psychopathy

Two levels of accounts are considered: neural (which systems are dysfunctional in individuals with psychopathy) and cognitive (what functional impairments are seen in psychopathy and why should they give rise to symptoms).

Accounts at the Neural System Level

Frontal Lobes

There have long been suggestions that frontal lobe executive function dysfunction is causally related to psychopathy in particular or antisocial behavior more generally (Gorenstein, 1982; Moffitt, 1993; Raine, 2002). Three main strands of data support this contention:

1. Neuropsychological data indicate that individuals with antisocial behavior show impaired performance on classic measures of executive functioning (for reviews of this literature see Kandel & Freed, 1989; Morgan & Lilienfeld, 2000);
2. Neuroimaging data indicate that aggressive individuals are marked by reduced frontal functioning (Goyer, Andreason, Semple et al., 1994; Raine, Meloy, Bihrl et al., 1998; Volkow, Tancredi, Grant et al., 1995);
3. Neurological patients with lesions of orbital frontal cortex, whether these occur early in life or adulthood, present with a heightened risk for aggression (Anderson, Bechara, Damasio, Tranel, & Damasio, 1999; Grafman, Schwab, Warden, Pridgen, & Brown, 1996).

However:

1. Individuals with psychopathy, unlike more general antisocial populations, show no impairment on measures of executive functioning linked to either dorsolateral prefrontal cortex or regions of medial frontal cortex including dorsal regions of anterior cingulate (Blair, Newman, Mitchell et al., 2006; Kandel & Freed, 1989; LaPierre, Braun, & Hodgins, 1995). Impairment, when seen, is seen strictly for measures of executive functioning linked to orbital and inferior frontal cortex (e.g., response reversal; Blair Newman, Mitchell et al., 2006; LaPierre, Braun, & Hodgins, 1995).
2. The neuroimaging data reveal a complex pattern with respect to frontal cortex and psychopathy. The results of early work indexing activity during rest in generally antisocial populations (Goyer, Andreason, Semple et al., 1994; Raine, Meloy, Bihrl et al., 1998; Volkow, Tancredi, Grant et al., 1995) have not been borne out with more recent event-related fMRI studies. More recent studies have indicated the possibility of dysfunction in orbital frontal cortex and anterior cingulate (Birbaumer, Veit, Lotze et al., 2005; Kiehl, Smith, Hare et al., 2001).
3. Many of the functional impairments shown by neurological patients with acquired lesions of orbital frontal cortex are markedly different from those shown by individuals with psychopathy (Blair & Cipolotti, 2000). Moreover, clinically, while neurological patients with acquired lesions of orbital frontal cortex present with an increased risk for reactive aggression but not instrumental aggression (Anderson, Bechara, Damasio et al., 1999; Grafman, Schwab, Warden et al., 1996), individuals with psychopathy are at increased risk for both forms of aggression (Cornell, Warren, Hawk et al., 1996; Williamson, Hare, & Wong, 1987).

We have argued elsewhere that “frontal lobe” explanations of psychopathy need greater specification (Blair, 2004). The current data indicate no impairment in executive functions reliant on dorsolateral prefrontal cortex and medial frontal cortex. However, there are reasons to believe that there may be impairment in executive functions reliant on orbital and inferior frontal cortex. This may indicate orbital and/or inferior frontal cortex dysfunction (Blair, Newman, Mitchell et al., 2006; LaPierre, Braun, & Hodgins, 1995). However, it is worth noting that it may also indicate dysfunction in systems that feed information to orbital and/or inferior frontal cortex. Currently, the fMRI studies that have indicated reduced activity in these regions in adults with psychopathy have all used tasks where there is also reduced amygdala activity and where the amygdala is necessarily involved in the transmission of information to these frontal regions (Birbaumer, Veit, Lotze et al., 2005; Kiehl, Smith, Hare et al., 2001). Therefore, studies that employ tasks that do not recruit amygdala are needed to ascertain whether the differences in orbital and/or inferior frontal cortex are independent from amygdala input.

It is important to note that the executive function consistently identified as impaired in individuals with psychopathy is response reversal (Budhani & Blair, 2005). Response reversal is the ability to make a new response to gain a reward when the old behavior that previously gave rise to the reward no longer does so (Rolls, 1997). It is unlikely that impairment in this executive function is causally related to psychopathy per se. This is because impairment in response reversal is seen in other clinical populations, in particular children with bipolar disorder (Gorrindo, Blair, Budhani et al., 2005). Importantly though, a common feature of both childhood bipolar disorder and psychopathy is an increased risk for reactive aggression (Frick, Cornell, Barry, Bodin, & Dane, 2003; Leibenuit, Blair, Charney, & Pine, 2003). Reactive aggression can be associated with frustration, as well as perceived threat. An individual who cannot change their behavior to accommodate to changing real-life contingencies, an individual who cannot perform response reversal, is someone at increased risk for reactive aggression. It therefore appears plausible that while response reversal impairment is not causally related to the development of the full syndrome of psychopathy, it is causally related to the increased risk for reactive aggression and that
CHAPTER 51

this is also seen in other childhood psychiatric conditions (Blair, Mitchell, & Blair, 2005).

Amygdala

Patrick (1994) originally suggested that amygdala dysfunction might be causally related to the development of psychopathy, and Blair, Mitchell, & Blair (2005) have developed and extended this position. Two main strands of data support the suggestion of amygdala dysfunction in psychopathy:
1. Neuropsychological data indicate that individuals with psychopathy show impairment on tasks indexing the functional integrity of the amygdala. Thus, individuals with psychopathy show impairment in aversive conditioning (Flor, Birbaumer, Hermann, Ziegler, & Patrick, 2002), the augmentation of the startle reflex by visual threat primes (Levenston, Patrick, Bradley, & Lang, 2000), passive avoidance learning (Newman & Kosson, 1986) and fearful expression recognition (Blair Colledge, Murray et al., 2001); and
2. Neuroimaging data indicate that adults with the disorder are marked by reduced amygdala responsiveness during emotional memory (Kiehl, Smith, Hare et al., 2001) and aversive conditioning tasks (Birbaumer, Veit, Lotze et al., 2005; although see Muller, Sommer, Wagner et al., 2003).

Importantly, the impairments seen in individuals with psychopathy closely mirror those seen in patients with amygdala damage. Thus, lesions of the amygdala disrupt aversive conditioning (Bechara, Tranel, Damasio et al., 1995), the augmentation of the startle reflex by visual threat primes (Angrilli, Mauri, Palomba et al., 1996), passive avoidance learning (Ambrogio Lorenzini, Baldi, Bucherelli, Sacchetti, & Tassoni, 1999) and fearful expression recognition (Adolphs, 2002). However, there is a caveat. Patients with acquired damage to the amygdala do not typically show increased levels of aggression. This dissociation between the clinical implications of acquired amygdala damage and psychopathy likely relates to the developmental trajectory of the disorder (Blair, Mitchell, & Blair, 2005).

The Paralimbic Hypothesis

On the basis of neuroimaging data, Kiehl (2006) has argued that, in individuals with psychopathy, there is dysfunction within paralimbic cortex (i.e., amygdala, anterior superior temporal gyrus, rostral and caudal anterior cingulate, posterior cingulate, ventromedial frontal cortex and parahippocampal regions). However, neuroimaging data are notoriously unable to localize deficits; impairment in any region will lead to anomalous activity in any region reliant on the dysfunctional region for input. We can only be sure that an area is dysfunctional in a population if both neuroimaging and neuropsychological data indicate impairment. Indeed, anterior cingulate, at least, does not appear globally impaired in individuals with psychopathy. Damage to anterior cingulate is known to increase the Stroop effect (i.e., the interference by distracter information; Stuss, Floden, Alexander, Levine, & Katz, 2001). However, individuals with psychopathy show no evidence of increases in the Stroop effect; if anything the opposite (Blair, Newman, Mitchell et al., 2006; Hiatt, Schmitt, & Newman, 2004).

Specificity

It is important to note that for any of the brain areas of proposed involvement in psychopathy (e.g., orbitofrontal cortex and amygdala), associations with other psychopathologies also exist. For example, autism has been claimed to reflect, at least in part, aberrant functioning of the orbitofrontal–amygdala circuit to much the same direction as is seen in psychopathy (Bachevalier & Loveland, 2006). As another example, major depressive disorder is also associated with orbitofrontal cortex underactivity (Steele, Currie, Lawrie, & Reid, 2007). Clearly, these two disorders are not synonymous with psychopathy, although they share some features at the neural level and may even share overlapping behaviors. As we highlighted above, it is clearly important to combine information from both neuroimaging and neuropsychology to gain a more thorough understanding of a specific deficit profile. In any, other brain abnormalities associated with a given disorder, and which can potentially influence behavioral outcome, must be accounted for. Thus, with regard to autism, several other key regions, in addition to the orbitofrontal–amygdala circuitry, have emerged as important in providing explanations for the behavioral manifestations of the disorder. Finally, cognitive accounts of the disorder may work hand in hand with the neural system level of explanations to provide differentiation between disorders.

Accounts at the Level of Cognitive Function

Executive Accounts

Executive dysfunction in psychopathy has been linked to impulsivity (Miller, Flory, Lynam, & Leukefeld, 2003; Whiteside & Lynam, 2001). This in turn has been conceptualized as the lack of premeditation (i.e., the “inability to inhibit previously rewarded behavior when presented with changing contingencies”) and the lack of perseverance (the “inability to ignore distracting stimuli or to remain focused on a particular task”; Whiteside & Lynam, 2001). In addition, it can be linked to response set modulation. This is characterized as the “rapid and relatively automatic (i.e., non-effortful or involuntary) shift of attention from the effortful organization and implementation of goal-directed behavior to its evaluation” (Newman, 1998).

Both Lynam’s impulse control and Newman’s response set modulation models can be considered executive accounts because they suggest the existence of general systems operating on multiple domains. These accounts suggest that the emotional deficits seen in individuals with psychopathy are secondary to executive deficits. Both positions should predict that individuals with psychopathy would be impaired on a broad range of tasks; many tasks can be considered to involve inhibition or response set modulation. However, more recent data suggest that there are finer empirical cuts to be made than those predicted by such general models. Thus, for example, dorsolateral prefrontal cortex is involved in processes that allow the alternation of responding to different conceptual categories (shapes versus lines) or spatial locations as a function of contingency change while inferior frontal cortex is involved in...
processes that allow the alternation of responding to different objects within the same conceptual category as a function of contingency change (Roberts, Robbins, & Weiskrantz, 1998). The functions of both these regions of frontal cortex have been characterized in terms similar to those proposed by the impulse control and response set modulation positions. However, whereas individuals with psychopathy show impairment on measures of inferior frontal cortex functioning, they show no impairment for tasks that index the functional integrity of dorsolateral prefrontal cortex (Blair, Newman, Mitchell et al., 2006; LaPierre, Braun, & Hodgins, 1995). In short, even if a characterization of the impairment in individuals with psychopathy in terms of inhibition or response modulation was correct, we argue that it would be necessary to constrain such accounts such that they were not domain general but rather specific to particular neurocognitive systems.

Stimulus–Reinforcement Associations, Fear, Empathy, Moral Socialization and Instrumental Antisocial Behavior

A considerable animal literature shows that the amygdala is necessary for the formation of stimulus–reinforcement associations (Baxter & Murray, 2002; Everitt, Cardinal, Parkinson, & Robbins, 2003). With respect to psychopathy, it has been argued that individuals with psychopathy are impaired in the formation of stimulus–reinforcement associations (Blair, 2004). Impairment in the formation of aversive stimulus–reinforcement associations would give rise to the observed deficits in individuals with psychopathy in aversive conditioning, the augmentation of the startle reflex following the presentation of visual threat primes and passive avoidance learning (Flor, Birbaumer, Hermann, Ziegler, & Patrick, 2002; Levenston, Patrick, Bradley, & Lang, 2000; Newman & Kosson, 1986). In short, this impairment would give rise to the deficits consistent with previous suggestions that there is fear system dysfunction in psychopathy (Lykken, 1957; Patrick, 1994); for a re-evaluation of this literature see Blair (2004) and Blair, Mitchell, & Blair (2005).

One important class of aversive stimuli for socialization is the distress of other individuals, the expressions of fear and sadness (Blair, 2003b). The amygdala is crucially involved in the response to these stimuli (Adolphs, 2002; Blair, 2003b). In line with suggestions of a specific form of empathy deficit, individuals with psychopathy show reduced autonomic responses to the distress cues of other individuals and impaired fearful facial and vocal expression recognition (for a review see Blair, 2003b).

The argument has been made that the expressions of fear and sadness serve as social reinforcers allowing conspecifics to teach the societal valence of objects and actions to the developing individual (Blair, 2003b); actions/objects associated with the sadness/fear of others acquire, in healthy developing children, negative valence. Because of their impairment in the response to the sadness and fear of other individuals and in the formation of aversive stimulus–reinforcement associations, individuals with psychopathy are less able to take advantage of this “moral” social referencing. They should be, and are (Oxford, Cavell, & Hughes, 2003; Wootton, Frick, Shelton et al., 1997), more difficult to socialize through standard parenting techniques. They will not learn to avoid using instrumental antisocial behavior to achieve their goals. This is because of relative in-difference to the “punishment” of the victim’s distress and impairment in learning the association between this “punishment” and the representation of the action that caused the victim’s distress. If confirmed, this observation should have fundamental implications for treatment. In the future, the nature of interventions directed to children with severe conduct problems could come to vary based on the degree to which the specific child exhibits the emotional features of psychopathy.

Treatment of Psychopathy

Critics express concern about labeling children as having psychopathy. This concern emerges mainly because adult psychopaths are presumed to be untreatable (see chapter 50; Hare, 2003). Clinicians rightly wish to avoid applying a label to children that implies they cannot be treated. However, identifying the emotional dysfunction early on can offer an important opportunity for prevention (for a discussion of this issue see Lynam, Caspi, Moffitt et al., 2007). The concern about labeling should not curb clinical research that may lead to treatment options for this vulnerable group of youngsters.

The behavioral manifestation of psychopathy is not always resistant to change. Most clinicians familiar with individuals with psychopathy will have had experience with individuals substantially modifying their behavior to achieve particular goals in institutional settings. This change in behavioral manifestation does not necessarily imply modification of the disorder’s core features, the emotional dysfunction (for a review see Harris & Rice, 2006). However, socially desirable responding could be achieved in individuals with psychopathy even if the core emotional dysfunction is resistant to complete amelioration. Individuals with psychopathy value status, power and dominance and are strong on self-interest and short-term rewards. They are poor at acting on long-term interest and low on empathy and altruism. Despite the demonstrated amygdala dysfunction in this population, several other brain areas, including most of frontal cortex, appear to function normally in psychopaths. It is thus possible to devise cognitive–behavioral intervention programs that capitalize on what is spared in terms of brain function and behavioral goal setting.

Intervention programs for at-risk, generally impoverished children, even those not developed specifically to address childhood aggression and antisocial behaviors, have had long-term effects on reducing the occurrence of conduct problems (New et al., 2002; Zigler, Taussig, & Black, 1992). These programs have provided a mix of child care, family support, parental educational and job training, parent–child education and parent management training, and preschool education to high-risk families with children 0–5 years old (Connor, Carlson, Chang et al., 2006). Only one study to date has investigated
how the emotion dysfunction component of psychopathy mediates the success of parent training (Hawes & Dadds, 2005). This study found that the emotional dysfunction is associated with poorer treatment success. Frick (2001) has suggested that many of the current intervention programs do not incorporate elements that would be particularly important for treating psychopathic antisocial behavior. As such, it is possible to speculate that at least some of the current treatment success statistics may be marred by not accounting for the presence of children who have psychopathy and who may dilute the estimated effect of overall treatment success. Categorizing children with CD into those with and without psychopathy is highly desirable in developing appropriate intervention approaches.

Studies suggest that it is predominantly reactive, impulsive, affective aggression that responds to medication (for a review see Connor, Carlson, Chang et al., 2006). However, most studies do not separate reactive from instrumental forms of aggression and no studies as yet have examined pharmacological interventions on the emotional dysfunction (and the potential consequence of instrumental aggression) seen in psychopathy. In addition to the development of new cognitive–behavioral treatment approaches, this is an area in urgent need of research.

Conclusions

In conclusion, current definitions of psychopathy categorize individuals with psychopathy as a subset of individuals with CD/ASPD. It is thought that their pathological development is related to a specific form of emotional dysfunction: callous and unemotional traits. Behaviorally, individuals with psychopathy are marked by an increased risk for both reactive and instrumental aggression. Importantly, the psychopathy construct has been extremely successful in predicting long-term prognosis, particularly in adult samples. Perhaps the greatest current importance of this construct for child psychiatrists is that it identifies a sample of children who are unlikely to benefit from standard treatment strategies for children with CD/ODD (Hawes & Dadds, 2005).

Behavioral genetic work indicates that callous and unemotional traits are strongly heritable and that antisocial behavior of callous–unemotional children is under considerable genetic influence. However, the corresponding molecular work remains in its infancy. What can be suggested is that the genetic contribution influences at the very minimum the functional integrity of the amygdala and the related circuitry. Because of the amygdala’s important roles in responding to distress cues, fear expressions and the formation of stimulus–reinforcement associations, the capacity of the developing child to acquire morality is severely compromised. The child is able to learn the rewards associated with antisocial behavior but is less sensitive to the punishments (the distress of the victims), increasing the risk that antisocial behavior will be used instrumentally by the child to achieve goals.

Currently, there are no adequate treatment options for this disorder. This should be an area of urgent concern and translational research should focus on capitalizing on the emerging research findings from the cognitive neuroscience of psychopathy.

CHAPTER 51

This chapter consists of two parts. First, we provide an overview on gender identity disorder (GID) in children and adolescents; second, we provide an overview on the paraphilias, with an emphasis on pedophilia because this diagnostic category is common among adolescents with sexual misconduct.

Gender Identity Disorder

Phenomenology

Boys and girls diagnosed with GID display an array of sex-typed behavior signaling a strong psychological identification with the opposite sex (Cohen-Kettenis & Pfäfflin, 2003; Green, 1974; Zucker & Bradley, 1995). Most of the behaviors that characterize GID begin during the preschool years (2–4 years), i.e., during the same period that more typical sex-dimorphic behaviors can be observed in young children (Ruble, Martin, & Berenbaum, 2006).

Epidemiology

Prevalence

Contemporary epidemiological studies on the prevalence of psychiatric disorders in children and youth have not examined GID. Accordingly, estimates of prevalence have had to rely on less sophisticated approaches. It has been suggested that prevalence might be inferred from the number of persons attending clinics for adults that serve as gateways for hormonal and surgical sex reassignment. Because not all gender-dysphoric adults may attend such clinics, this method may well underestimate the prevalence of GID; in any case, the number of adult transsexuals is small – one estimate from the Netherlands suggested a prevalence of 1 in 11,000 men and 1 in 30,400 women (Bakker, van Kesteren, Gooren, & Bezemer, 1993).

More liberal estimates of prevalence can be judged from studies of children in whom specific cross-gender behaviors have been assessed. For example, the standardization study of the Child Behavior Checklist (CBCL; Achenbach & Edelbrock, 1983), a parent-report questionnaire of behavior problems, includes two items that pertain to cross-gender identification: “behaves like opposite sex” and “wishes to be of opposite sex.” In the standardization study, endorsement of both items was more common for girls than for boys, regardless of age and clinical status (referred versus non-referred).

Among non-referred boys (ages 4–11 years), 3.8% received a rating of 1 (somewhat true) and 1.0% received a rating of 2 (very true) for the item “behaves like opposite sex,” but only 1.0% received a rating of 1 and 0.0% received a rating of 2 for the item “wishes to be of opposite sex” (Zucker, Bradley, & Sanikhani, 1997a). The comparable percentages among non-referred girls were 8.3%, 2.3%, 2.5% and 1.0%, respectively. Thus, there appears to be a sex difference in the occurrence of mild displays of cross-gender behavior, but not with regard to more extreme cross-gender behavior. These findings were largely replicated in a large-scale study of Dutch twins at ages 7 and 10 (van Beijsterveldt, Hudziak, & Boomsma, 2006).

Sex Differences in Referral Rates

Among children between the ages of 3 and 12 years, boys are referred clinically more often than girls for concerns regarding gender identity. From one specialty clinic in Toronto, Canada, Cohen-Kettenis, Owen, Kaijser, Bradley, and Zucker (2003) reported a sex ratio of 5.75:1 \((n = 358)\) of boys to girls based on consecutive referrals 1975–2000. Comparative data from the sole gender identity clinic for children in Utrecht, the Netherlands, also favored referral of boys over girls (sex ratio of 2.93:1, \(n = 130\)).

The skewed sex ratio favoring boys may reflect bona fide sex differences in prevalence, but social factors may also have a role. Parents, teachers and peers are less tolerant of cross-gender behavior in boys than in girls, which might result in a sex-differential in clinical referral (Zucker & Bradley, 1995).

In support of this viewpoint, two studies found that girls may need to display more cross-gender behavior than boys before a referral is initiated (Cohen-Kettenis, Owen, Kaijser et al., 2003; Zucker, Bradley, & Sanikhani, 1997a). In both the Toronto and Utrecht clinics, girls were referred at a slightly older age than boys (means 8.1 versus 7.3 years, respectively), despite the fact that the girls showed, on average, higher levels of cross-gender behavior than the boys (Cohen-Kettenis, Owen, Kaijser et al., 2003). However, the sexes did not differ in the percentage who met the complete DSM criteria for GID; thus, there was no evidence for a sex difference in false positive referrals.

Another factor that could affect sex differences in referral rates pertains to the relative salience of cross-gender behavior...
in boys versus girls. For behaviors showing significant between-sex variation, it is almost always the case that girls are more likely to engage in masculine behaviors than boys are likely to engage in feminine behaviors (Zucker, 2005a). Thus, the base rates for cross-gender behavior, at least within the range of normative variation, may well differ between the sexes.

Diagnosis and Assessment

DSM-IV Diagnosis of Gender Identity Disorder

In DSM-IV-TR (American Psychiatric Association, 2000) there were some changes in the conceptualization of GID and in the diagnostic criteria. The DSM-IV Subcommittee on Gender Identity Disorders (Bradley, Blanchard, Coates et al., 1991) took the position that the DSM-III-R diagnoses of gender identity disorder of childhood, transsexualism and gender identity disorder of adolescence or adulthood, non-transsexual type were not qualitatively distinct disorders, but reflected differences in both developmental and severity parameters. As a result, the DSM-IV Subcommittee recommended one overarching diagnosis, gender identity disorder, that could be used, with appropriate variations in criteria, across the life cycle.

In the DSM-IV, there are three criteria required for the diagnosis and there is also one exclusion criterion. The Point A criteria reflect the child’s cross-gender identification, indexed by five behavioral characteristics, of which at least four must be present. The Point B criteria reflect the child’s rejection of his or her anatomic status and/or rejection of same-sex stereotypical activities and behaviors. Point D specifies that the “disturbance . . . causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.” Point C is an exclusion criterion and pertains to the presence of a physical intersex condition (when the clinical signs of GID are present in individuals with a physical intersex condition, the DSM-IV specifies that the residual diagnosis, Gender Identity Disorder Not Otherwise Specified, can be used).

Reliability and Validity

The clinical research literature has paid little attention to reliability of diagnosis for GID. One study showed that, for children, clinicians can reliably make the diagnosis (Zucker, Finegan, Doering, & Bradley, 1984) but, to our knowledge, no study has evaluated the reliability of the diagnosis for adolescents (for further discussion see Zucker, 2006a).

There is a much more extensive literature on the discriminant validity of the GID diagnosis. Over the past 30-plus years, a variety of measurement approaches have been developed to assess the sex-typed behavior in children referred clinically for GID: observation of sex-typed behavior in free play tasks, on semi-projective or projective tasks and on a structured Gender Identity Interview schedule. In addition, several parent-report questionnaires pertaining to sex-typed behavior have been developed. In this line of research, several comparison groups have typically been utilized: siblings of GID probands, clinical controls and non-referred (or “normal”) controls (for a summary and review of measures see Zucker, 1992, 2005a). These studies have demonstrated strong evidence for the discriminant validity of the various measures, with good evidence for sensitivity and specificity. Many of these measures can be used to complement the ordinary clinical assessment involving children and their parents.

Gender Identity Disorder as a Disorder?

In psychiatric nosology, it is common for there to be debate regarding the number of symptoms required for a diagnosis, the exact wording of indicators, validational evidence and so on. Although this has occurred for GID (Langer & Martin, 2004; Wilson, Griffin, & Wren, 2002; cf. Zucker, 2006b), the more common debate is over the general legitimacy of GID as a disorder (Isay, 1997). Critics of the GID diagnosis have made several claims:

1. GID is nothing more than normal variation, albeit extreme, in gender-related behavior (Hill, Rozanski, Carfagnini, & Willoughby, 2007);
2. Children with GID show little evidence of distress and/or impairment and, if they do, it is not inherent to the condition, but merely a reaction to social disapproval (Bartlett, Vasey, & Bukowski, 2000); and
3. Because GID in children is strongly predictive of a homosexual sexual orientation in adulthood, its inclusion in DSM-III was nothing more than a veiled backdoor maneuver to prevent later homosexuality.

As this last claim has been addressed elsewhere (Zucker & Spitzer, 2005), we will appraise here only the first two criticisms and suggest ways in which the diagnostic criteria for GID might be reformed in DSM-V.

GID as Normal Variation in Gender-Related Behavior

Because of the putative conflation of gender identity dysphoria and gender role behavior, particularly in the Point A criterion, one could argue that reform of the criteria is called for. One relatively simple reform would be to raise the threshold for the Point A criterion and require the presence of all five indicators. Thus, it would be necessary for the child to systematically verbalize the wish to be of the opposite sex in order for the Point A criterion to be met.

A more radical reform would be to relegate the indicators of extreme cross-gender role behavior (A2–A5) to the text description of GID, with an explanation that they may not be sufficient, on their own, to indicate the presence of gender dysphoria. The diagnostic criteria could then be modified by the inclusion of multiple indicators of gender dysphoria. To explore this, new psychometric studies would be required: factor analysis can be used to establish the coherence of these putative indicators of gender dysphoria; this would be followed by tests of discriminant validity; and then an empirical determination of the appropriate cutpoint for high sensitivity and specificity.

If such an enterprise proved successful, perhaps this would allay concerns that children with extreme gender non-conformity, but who are not truly gender dysphoric, are being inappropriately diagnosed.

865
CHAPTER 52
Distress and Impairment
The DSM-III-R did not provide guidelines regarding the assessment of distress in the Point A criterion (“persistent and intense distress” about being a boy or a girl) or the ways in which it might be distinct from other operationalized components in the criteria (i.e., the “desire” to be of the other sex; Zucker, 1992). In the DSM-IV, this problem persists, except that it is now located in Point D, and there is the additional problem of defining impairment.

Some critics have argued that the distress and/or impairment that clinicians observe in people with GID are merely a response to the reaction of others (Bartlett, Vasey, & Bukowski, 2000). Consistent with this critique, Stoller (1968) argued that GID in boys was ego-syntonic and that they became distressed only when their cross-gender fantasies and behaviors were interfered with. However, Stoller’s conceptualization was a psychodynamic formulation: he believed that GID was ego-syntonic because the familial conditions that produced it were systematically syntonic. Thus, it is likely that Stoller would have argued that the DSM’s conceptualization of distress was, and is, too narrow.

Other theorists have argued otherwise. For example, Coates and Person (1985) claimed that GID was a “solution” to specific forms of psychopathology in the child, particularly separation anxiety and “annihilation” anxiety, which were induced by familial psychopathology. It is conceivable that both the “primary” and “secondary” views are correct or that one or the other better fits individual cases.

If one considers the developmental adolescent or adult “end-state” of GID (i.e., the strong desire to align the body via contrasex hormones and sex-reassignment surgery: in females, mastectomy, phalloplasty; in males, penectomy/castration, vaginoplasty), it is difficult to argue that cross-gender feelings and behaviors simply constitute normative variation or do not constitute an example of impairment. The required physical interventions are simply too radical to be thought about otherwise.

One indication of impairment is that children with GID have trouble with basic cognitive concepts concerning gender. They are more likely than other children to misclassify their own gender (Zucker, Bradley, Lowry Sullivan et al., 1993), and they appear to have a “developmental lag” in the acquisition of gender constancy (Zucker, Bradley, Kuksis et al., 1999). Given the ubiquity of gender as a social category, this may well lead to affective confusion in self-representation and in social interactions. As noted in the next section, there is evidence that children with GID have poor peer relations and more general behavioral problems, which are possible indices of impairment.

Associated Psychopathology
The most systematic information on general behavior problems in children with GID comes from parent-report data using the CBCL. Clinic-referred boys and girls with GID show, on average, significantly more general behavior problems than do their siblings and non-referred children (Cohen-Kettenis, Owen, Kajijser et al., 2003; Zucker & Bradley, 1995). On the CBCL, boys with GID have a predominance of emotional difficulties whereas girls with GID do not (Cohen-Kettenis, Owen, Kajijser et al., 2003; Zucker & Bradley, 1995).

Psychopathological problems increase with age in boys with GID (Cohen-Kettenis, Owen, Kajijser et al., 2003; Zucker & Bradley, 1995). This could be influenced by peer ostracism. Children with GID experience significant difficulties within the peer group (Cohen-Kettenis, Owen, Kajijser et al., 2003; Zucker, Bradley, & Sanikhani et al., 1997a). Cohen-Kettenis, Owen, Kajijser et al. (2003) found that poor peer relations were the strongest predictor of CBCL behavior problems in both boys and girls with GID, accounting for 32% and 24% of the variance, respectively. Thus, social ostracism may be a potential mediator between cross-gender behavior and behavior problems. It seems likely that marked cross-gender behavior is particularly salient in eliciting negative reactions from peers.

Although we have shown that poor peer relations is an important correlate of general behavior problems in children with GID, this is not meant to imply that it is the only source of these difficulties. Other research has shown that CBCL-measured problems in boys with GID are associated with a composite index of maternal psychopathology, which may reflect generic non-specific familial risk factors in producing psychopathology in general (Zucker & Bradley, 1995) and the predominance of emotional psychopathology may reflect familial risk for affective disorders and temperamental features of the boys (Marantz & Coates, 1991). Thus, it is likely that there are both specific and general risk factors involved in the general psychological problems of children with GID.

Etiological Influences
Biological Mechanisms
The role of prenatal sex hormones in causing the postnatal display of various sex-dimorphic behaviors has been the focus of detailed experimental animal research for almost 50 years (Baum, 2006). In humans, the influence of normative sex differences in prenatal sex hormone exposure is hard to disentangle from normative sex-of-rearing effects; accordingly, researchers have relied on children born with various disorders of sex development (DSDs), previously referred to as physical intersex conditions, to separate the relative influence of biological and psychosocial processes on psychosexual differentiation.

This research provides considerable evidence for an influence of prenatal sex hormones on postnatal sex-dimorphic behavior. For example, chromosomal females with congenital adrenal hyperplasia (CAH), who are exposed to sex-atypical levels of prenatal androgen, show more masculinized gender role behavior in childhood and adolescence and a higher rate of a bisexual and/or homosexual sexual orientation in adulthood (for review see Cohen-Bendahan, van de Beek, & Berenbaum, 2005; Hines, 2004; Zucker, 1999). Nevertheless, most females with CAH show a sex-typical gender identity (e.g., Dessens, Sliper, & Drop, 2005; Meyer-Bahlburg, Dolezal, Baker et al., 2004). It appears therefore that prenatal sex hormones may have a relatively stronger impact on some components
of psychosexual differentiation (e.g., gender role behavior and sexual orientation) than on others (e.g., gender identity).

One of the most dramatic cases in this field was of a biologically normal male (one of a pair of identical twins), whose penis was accidentally ablated during a circumcision at the age of 7 months. Known in the literature as the John-Joan case (and then as David Reimer, the patient’s name), this infant was gender-reassigned to female at the age of 17 months and gonadectomy was performed at age 22 months. Early reports indicated that the patient had differentiated a female gender identity (suggesting a crucial role for socialization influences on gender identity), although she was described as tomboyish in comportment (Money, 1975). However, a long-term follow-up reported that the patient experienced profound conflict as a girl and, in early adolescence, “returned” to living as a boy and, in adulthood, married a woman and adopted her three children (Colapinto, 2000; Diamond & Sigmundson, 1997). Sadly, Mr. Reimer committed suicide in 2004 at the age of 38 (Agrell, 2004). His death followed the suicide of his cotwin 2 years earlier (Jang & Smith, 2004).

The David Reimer case has been used to highlight the importance of biological factors on psychosexual differentiation. Indeed, some have argued that a “normal” male sexual biology cannot be countered by socialization efforts to raise a male as a girl (even with gonadectomy, the use of female sex hormones to induce a feminizing puberty, feminizing surgery on the genitalia, etc.) and that the Reimer case was “proof” for the role of prenatal androgen “imprinting” of a male gender identity.

However, a counter to this position comes from another case of penile ablation reported on by Bradley, Oliver, Chernick, and Zucker (1998). In this case, the circumcision accident occurred at the age of 2 months and the patient was gender-reassigned, along with gonadectomy, at the age of 7 months. In adolescence, the patient began feminizing hormonal and surgical treatment. A follow-up at the age of 26 years showed that the patient had a female-typical gender identity; however, her gender role interests were conventionally masculine and she reported a bisexual sexual orientation in both fantasy and behavior.

Although the Reimer case has had a profound impact on the field, some authors have cautioned against extrapolating too much from it (Meyer-Bahlburg, 2005) and noted that the case has raised as many questions as answers.

When it comes to children with GID, one must appreciate that they invariably do not show signs of a DSD, which would appear to rule out an etiology that involves a marked prenatal hormonal anomaly (Meyer-Bahlburg, 2005). Thus, the search for biological influences on the development of GID must focus on factors that do not affect the configuration of the external genitalia. Prenatal hormonal influences may have a role, but there would have to be some kind of brain-genital dissociation in their impact (e.g., perhaps resulting from timing effects; Gooren, 2006; Goy, Bercovitch, & McBrair, 1988). Given that there are no postmortem studies on brain neuroanatomy in GID children or youth, research has focused either on indirect markers of putative prenatal hormonal influences or on other biological factors. A selective review of relevant studies is provided here.

Molecular and Behavior Genetics

There have been no molecular genetic studies of GID, but several behavioral genetic studies have shown that the liability for cross-gender behavior in the general population has a strong heritable component (van Beijsterveldt, Hudziak, & Boomsma et al., 2006). Another twin study also identified strong shared environmental influences (Knöffel, Iervolino, & Plomin, 2005). Such environmental influences could, of course, pertain to non-genetic biological factors but could also involve postnatal psychosocial factors, some of which may be specific to twins. In any case, it should be recognized that these studies have not identified the specific genetic and environmental factors, or the gene × environmental interactions, underlying the liability to cross-gender behavior. That genetic factors do not account for all of the variance in the liability to cross-gender behavior is demonstrated quite clearly from detailed clinical case reports of identical twins discordant for GID (Segal, 2006).

Activity Level

Activity level (AL) is a dimension of temperament with some evidence for a genetic basis and possibly prenatal hormonal influences (Campbell & Eaton, 1999). In general, boys have a higher AL than girls.

Parents report lower levels of AL in boys with GID compared to controls (Bates, Bentler, & Thompson, 1979; Zucker & Bradley, 1995). Zucker and Bradley also found that girls with GID had a higher AL than control girls.

It is possible that a sex-atypical AL is a temperamental factor that predisposes to the development of GID. For example, a low-active boy with GID may find the typical play behavior of other boys to be incompatible with his own behavioral style, which might make it difficult for him to integrate successfully into a male peer group.

Sibling Sex Ratio and Birth Order

Boys with GID have an excess of brothers to sisters (sibling sex ratio) and a later birth order. Some additional evidence shows that boys with GID are born later primarily in relation to the number of older brothers, but not sisters (Blanchard, Zucker, Bradley, & Hume, 1995; Zucker, Green, Coates et al., 1997b). In the Blanchard et al. study, clinical control boys showed no evidence for an altered sibling sex ratio or a late birth order. These findings mesh nicely with studies of adult males with GID with a homosexual sexual orientation, who also have an excess of brothers to sisters and a later birth order (Blanchard, 2001).

One biological explanation that has been offered to account for these results pertains to maternal immune reactions during pregnancy. The male fetus is experienced by the mother as more “foreign” (antigenic) than the female fetus. Accordingly, it has been suggested that one consequence of this is that the mother produces antibodies that have the consequence of demasculinizing or feminizing the male fetus, but no
corresponding masculinizing or defeminizing of the female fetus (Blanchard, 2001). This model would predict that males born later in a sibship might be more affected, because the mother's antigenicity increases with each successive male pregnancy, which is consistent with the empirical evidence on sibling sex ratio and birth order among GID probands. At present, this proposed mechanism has not been formally tested in humans.

**Psychosocial Mechanisms**

Psychosocial factors, to truly merit causal status, must be shown to influence the emergence of marked cross-gender behavior in the first few years of life. Otherwise, such factors would be better conceptualized as perpetuating rather than predisposing.

**Sex Assignment at Birth**

In some DSDs, sex assignment is delayed and, on occasion, changed from the initial sex assignment. It has been argued that prolonged delay or uncertainty about the child's "true" sex can contribute to gender identity conflict in affected individuals (Meyer-Bahlburg, Gruen, New et al., 1996). Because most children with GID do not have a co-occurring DSD, this does not appear to be a relevant psychosocial factor.

**Prenatal Gender Preference**

It is common for parents to express a prenatal preference for the gender of the expected baby. However, there is no evidence that parents of children with GID are more likely than control parents to report having had a desire for a child of the opposite sex (Zucker, Green, Garofano et al., 1994).

**Social Reinforcement of Cross-Gender Behavior**

The parental response to early cross-gender behavior in children with GID is typically neutral (tolerance) or even encouraging (Mitchell, 1991; Roberts, Green, Williams, & Goodman, 1987; Zucker & Bradley, 1995). Green (1974) concluded that "What comes closest so far to being a necessary variable is that, as any feminine behavior begins to emerge, there is no discouragement of that behavior by the child's principal caretaker" (p. 238, italics in original). The reasons why parents might tolerate, if not encourage, early cross-gender behaviors appear to be quite diverse. Some report being influenced by ideas regarding non-sexist child rearing. In others, the antecedents seem to be rooted in pervasive conflict that revolves around gender issues, including what Zucker and Bradley (1995) characterized as pathologic gender mourning.

**General Psychopathology**

The role of maternal psychopathology in the genesis and perpetuation of GID has received a great deal of clinical and theoretical attention but, again, only limited empirical evaluation and only for boys with GID. One account implicates the father's role by virtue of his absence from the family matrix. Across 10 samples of boys with GID, the rate of father absence was 34.5% (Zucker & Bradley, 1995). It is unlikely that this rate would differ significantly from the rate found in clinical populations in general, if not the general population. Green (1987) found that paternal separations occurred earlier in the families of boys with GID than normal control boys; therefore it is possible that timing is an additional variable to consider. Green also found that the fathers of boys with GID (both father-present and father-absent) recalled spending less time with their sons than did the fathers of control boys during preschool years and at the time of assessment. The inclusion of a clinical control group would be helpful in gauging the specificity of this finding.

**Long-Term Follow-Up**

The "natural history" of GID in children has been confined to clinic-referred samples. Because there are no natural history studies of such children taken from epidemiological samples, one has to be cautious in drawing any broad generalizations from this literature.

**Follow-up Studies of Boys**

Green's (1987) study constitutes the most comprehensive long-term follow-up of behaviorally feminine boys, the majority of whom would likely have met DSM criteria for GID. His study contained 66 feminine and 56 control boys, assessed initially at a mean age of 7.1 years (range, 4–12). Forty-four feminine boys and 30 control boys were available for follow-up at a mean age of 18.9 years (range, 14–24). The majority of the boys were not in therapy between assessment and follow-up. Sexual orientation in fantasy and behavior was assessed by means of a semi-structured interview. Of the previously feminine boys, 75–80% were either bisexual or homosexual at follow-up versus 0–4% of the control boys. Only one
youth, at the age of 18 years, was gender-dysphoric to the extent of considering sex-reassignment surgery.

Data from six other follow-up reports on 55 boys with GID were summarized by Zucker and Bradley (1995). At follow-up (range, 13–26 years), if one excludes 13 uncertain cases, then 27 (64.3%) of the remaining 42 cases had “atypical” (i.e., homosexual, transsexual or transvestitic) outcomes. In these studies, the percentage of boys who showed persistent GID was higher than that reported by Green (11.9% vs. 2.2%, respectively), but the percentage who were homosexual (62.1%) was somewhat lower. Zucker and Bradley (1995) reported preliminary follow-up data, at mean age 16 years, on their own sample of boys first seen in childhood (mean age at assessment, 8.2 years; range, 3–12). Of the 40 boys, 8 (20%) were classified as gender-dysphoric at follow-up. The remaining 80% had a “normal” gender identity. Regarding sexual orientation in fantasy, 20 (50%) were classified as heterosexual, 17 (42.5%) were classified as bisexual/homosexual and 3 (7.5%) were classified as “asexual” (i.e., they did not report any sexual fantasies). Regarding sexual orientation in behavior, 9 (22.5%) were classified as heterosexual, 11 (27.5%) were classified as bisexual/homosexual and 20 (50.0%) were classified as “asexual” (i.e., they did not report any interpersonal sexual experiences).

Cohen-Kettenis (2001) reported preliminary data on a sample of 36 boys first seen in childhood (mean age at assessment, 9 years; range, 6–12) and who had now reached adolescence. Of these, 9 (16.1%) requested sex-reassignment, and all 9 had a homosexual sexual orientation (P. T. Cohen-Kettenis, personal communication, February 1, 2003). Thus, the rate of GID persistence, at least into adolescence, was higher than that reported by Green (1987) and comparable with the rate obtained by Zucker and Bradley (1995).

In taking stock of these outcome data, Green’s study shows that boys with GID were disproportionately, and substantially, more likely than the control boys to differentiate a bisexual/homosexual sexual orientation. The other follow-up studies yielded somewhat lower estimates of a bisexual/homosexual sexual orientation. In this regard, at least one caveat is in order. In the Zucker and Bradley follow-up, the boys were somewhat younger than were the boys followed-up by Green, so their lower rate of a bisexual/homosexual sexual orientation outcome should be interpreted cautiously, especially as one would expect that social desirability considerations would lead to underreporting of atypical sexual orientation. However, even these lower rates of a bisexual/homosexual sexual orientation are substantially higher than the currently accepted base rate of about 2–3% of a homosexual sexual orientation in men (Laumann, Gagnon, Michael, & Michaels, 1994).

A more substantive difference between Green’s study and the other follow-up reports pertains to the persistence of gender dysphoria. Both Zucker and Bradley, and Cohen-Kettenis, for example, found higher rates of persistence than Green. At present, the explanations for this are unclear. One possibility pertains to sampling differences. Green’s study was carried out in the context of an advertised research study whereas the Zucker and Bradley and Cohen-Kettenis samples were clinic-referred. Thus, it is conceivable that their samples may have included more extreme cases of childhood GID than the sample ascertained by Green. Because the Toronto and Dutch groups now have substantially larger samples on which to complete outcome studies, it should be possible to carry out within-group analyses to identify predictor variables (e.g., with regard to persistent GID versus desistent GID).

Follow-up Studies of Girls

Unfortunately, the long-term follow-up of girls with GID remains very patchy. In part, this reflects the comparatively lower rate of referred girls than referred boys with GID in child samples (Cohen-Kettenis, Owen, Kajser et al., 2003). Since the last edition of this volume, the first systematic follow-up of girls with GID has become available. Drummond, Bradley, Badali-Peterson, and Zucker (in press) evaluated 25 girls, originally assessed in our clinic at a mean age of 8.8 years (range, 3–12), at a follow-up mean age of 23.2 years (range, 15–36). Of these 25 girls, three (12%) had persistent GID (at follow-up ages of 17, 21 and 23 years, respectively), two of whom had a homosexual sexual orientation and the third was asexual. The remaining 22 (88%) girls had a “normal” gender identity.

Regarding sexual orientation in fantasy (Kinsey ratings) for the 12 months preceding the follow-up assessment, 15 (60%) girls were classified as exclusively heterosexual, 8 (32%) were classified as bisexual/homosexual and 2 (8%) were classified as “asexual” (i.e., they did not report any sexual fantasies). Regarding sexual orientation in behavior, 11 (44%) girls were classified as exclusively heterosexual, 6 (24%) were classified as bisexual/homosexual and 8 (32%) were classified as “asexual” (i.e., they did not report any interpersonal sexual experiences).

Although these data are preliminary, it appears that there is a range of outcomes, but it is clear that the rates of GID and a bisexual/homosexual sexual orientation without co-occurring gender dysphoria are likely to be higher than the base rates of these two aspects of psychosexual differentiation in an unselected population of women. Using Bakker, van Kesteren, Gooren et al.’s (1993) estimation of GID prevalence in females, the odds of persistent gender dysphoria in Drummond, Bradley, Badali-Peterson et al. was 4084 times the odds of gender dysphoria in the general population. Using prevalence estimates of bisexuality/homosexuality in fantasy among biological females (anywhere between 2% and 5%), the odds of reporting bisexuality/homosexuality in fantasy were 8.9–23.1 times higher than in the general population. The odds of reporting bisexuality/homosexuality in behavior were 6.7–15.5 times higher than in the general population.

In another study, Cohen-Kettenis (2001) reported preliminary data on a sample of 18 girls first seen in childhood (mean age at assessment, 9 years; range, 6–12) and who had now reached adolescence. Of these, 8 (44.4%) requested sex-reassignment and all had a homosexual sexual orientation (P. T. Cohen-Kettenis, personal communication, February 1, 2003). Thus, the
A mother of a 4-year-old boy contacts a well-known clinic that specializes in gender identity problems. She describes behaviors consistent with the DSM diagnosis of GID. A clinician tells the mother: “Well, we don’t consider ‘it’ to be a problem.” The mother then contacts a specialty clinic for children and adolescents and asks: “What should I do?”

A mother of a 4-year-old boy contacts a well-known clinic that specializes in gender identity problems. She describes behaviors consistent with the DSM diagnosis of GID. She says that she would like her child treated so he does not grow up to be gay. She also worries that her child will be ostracized within the peer group because of his pervasive cross-gender behavior. What should the clinician say to this mother?

The parents of a 6-year-old boy (somedically male) conclude that their son is really a girl, so they seek the help of an attorney to institute a legal name change (from Zachary to Aurora) and inform the school principal that their son will attend school as a girl. The local child protection agency is notified and the child removed from his parents’ care (Cloud, 2000). If a clinician was asked to evaluate the situation, what would be in the best interests of the child and family?

A 15-year-old adolescent girl with GID asks to be seen for treatment. She would like cross-sex hormones and a mastectomy immediately. If refused, the patient threatens to kill herself. What should the clinician do?

A 16-year-old adolescent boy with GID asks for SRS. He states that he is sexually attracted to biological males and wants a sex-change because that will make his sexual feelings for males “normal.” He states that homosexuality is against his religious beliefs and is taboo in his culture of origin. What should the clinician do?

Any contemporary developmental clinician responsible for the therapeutic care of children and adolescents with GID will quickly be introduced to these kinds of complex social and ethical scenarios and will have to think them through carefully in formulating a therapeutic plan.

Treatment of Children

In summarizing the treatment literature on GID, one will find not a single randomized controlled treatment trial. However, there have been some treatment effectiveness studies, although much is lacking in these investigations. In general, the practitioner must rely largely on the “clinical wisdom” that has accumulated in the case report literature and the conceptual underpinnings that inform the various approaches to intervention. In an era that emphasizes evidence-based therapeutic, the relatively meager empirical database is a source of frustration for many clinicians.

Behavioral Therapy

There are 13 published single-case reports that employed a behavioral therapy approach to the treatment of GID in children (for review see Zucker, 1985). One type of intervention employed has been termed differential social attention or social reinforcement. This type of intervention has been applied in clinic settings, particularly to sex-typed play behaviors. The therapist first establishes with baseline measures that the child (either when alone or in the presence of a non-interacting adult) prefers playing with cross-sex toys or dress-up apparel rather
than same-sex toys or dress-up apparel. A parent or stranger is then introduced into the playroom and instructed to attend to the child’s same-sex play (e.g., by looking, smiling and verbal praise) and to ignore the child’s cross-sex play (e.g., by looking away and pretending to read). Such adult responses seem to elicit rather sharp changes in play behavior.

There have been two main limitations to the use of social attention or reinforcement in treating cross-gender behavior. First, at least some of the children studied reverted to cross-sex play patterns in the adult’s absence or in other environments, such as the home; second, there was little generalization to untreated cross-sex behaviors (Rekers, 1975).

Such problems have led behavior therapists to seek more effective strategies of promoting generalization. One such strategy, self-regulation or self-monitoring, has the child reinforce himself or herself when engaging in a sex-typical behavior. Although self-monitoring also resulted in substantial decreases in cross-sex play, the evidence is weak that generalization is better promoted by self-regulation than by social attention (Zucker, 1985).

The behavior-therapy literature has produced no new case reports for over 20 years although its principles are often used in broader treatment approaches that involve the parents. This void is rather curious, because contemporary behavioral approaches, such as cognitive–behavioral therapy, are now used so widely with other disorders.

Behavior therapy with an emphasis on the child’s cognitive structures regarding gender could be an interesting and novel approach to treatment. There is now a fairly large literature on the development of cognitive gender-schemas in typically developing children (Martin, Ruble, & Szkrybalo, 2002). It is possible that children with GID have more elaborately developed cross-gender schemas than same-gender schemas and that more positive affective appraisals are differentiated for the former than for the latter (e.g., in boys, “girls get to wear prettier clothes” versus “boys are too rough”). A cognitive approach to treatment might help children with GID to develop more flexible and realistic notions about gender-related traits (e.g., “boys can wear pretty cool clothes too” or “there are lots of boys who don’t like to be rough”), which may result in more positive gender feelings about being a boy or being a girl.

**Psychotherapy**

There is a large case report literature on the treatment of children with GID using psychoanalysis, psychoanalytic psychotherapy or psychotherapy (for references see Zucker, 2001, 2007). The psychoanalytic treatment literature is more diverse than the behavior therapy literature, including varied theoretical approaches to understanding the putative etiology of GID (e.g., classic object relations and self-psychology). Unfortunately, this literature has not developed very far in providing systematic documentation of therapeutic effectiveness.

Apart from the general developmental perspective inherent in a psychoanalytic understanding of psychopathology, one might add to this a gender-specific perspective on development (Martin, Ruble, & Szkrybalo, 2002). Many developmentalists note that the first signs of normative gender development appear during the toddler years, including the ability to correctly self-label oneself as a boy or a girl. Money, Hampson, and Hampson (1957) postulated a sensitive period for gender identity formation, which suggests a period of time in which there is a greater malleability or plasticity in the direction that gender identity can move. Thus, early gender identity formation intersects quite neatly with analytic views on the early development of the sense of self in more global terms. It is likely therefore that the putative pathogenic mechanisms identified in the development of GID are likely to have a greater impact only if they occur during the alleged sensitive period for gender identity formation.

**Treatment of the Parents**

Two rationales have been offered for parental involvement in treatment. The first emphasizes the hypothesized role of parental dynamics and psychopathology in the genesis or maintenance of the disorder. From this perspective, individual therapy with the child will probably proceed more smoothly and quickly if the parents are able to gain some insight into their own contribution to their child’s difficulties. Many clinicians who have worked extensively with gender-disturbed children subscribe to this rationale (Newman, 1976; Zucker, 2001, 2007). In this context, a treatment plan requires as much of an assessment of the parents as it does of the child, as is the case with many child psychiatric disorders. Assessment of psychopathology and the marital relationship in the parents of children with GID reveals great variability in adaptive functioning, which may well prove to be a prognostic factor.

The second rationale is that parents will benefit from regular formalized contact with the therapist to discuss day-to-day management issues that arise in carrying out the overall therapeutic plan. Work with parents can focus on the setting of limits with regard to cross-gender behavior, such as cross-dressing, cross-gender role and fantasy play, and cross-gender toy play and, at the same time, attempting to provide alternative activities (e.g., encouragement of same-sex peer relations and involvement in more gender-typical and neutral activities). In addition, parents can work on conveying to their child that they are trying to help him or her feel better about being a boy or a girl and that they want their child to be happier in this regard.

Although many contemporary clinicians have stressed the important role of working with the parents of children with GID, there is scanty empirical evidence on efficacy. The most relevant study found some evidence that parental involvement in therapy was significantly correlated with a greater degree of behavioral change in the child at a 1-year follow-up, but this study did not make random assignment to different treatment protocols, so one has to interpret the findings with caution (Zucker, Bradley, Doering, & Lozinski, 1985).

**Supportive Treatments**

In the past few years, clinicians critical of conceptualizing marked cross-gender behavior in children as a disorder have...
CHAPTER 52

provided a dissenting perspective to the treatment approaches described so far (Menivielle & Tuerk, 2002; Menivielle, Tuerk, & Perrin, 2005). These clinicians conceptualize GID or pervasive gender-variant behavior from an essentialist perspective (i.e., that it is fully constitutional or congenital in origin) and are skeptical about the role of psychosocial or psychodynamic factors. For example, Menivielle and Tuerk (2002) noted that, while it might be helpful to set limits on pervasive cross-gender behaviors that may contribute to social ostracism, their primary treatment goal was “not at changing the children’s behavior, but helping parents to be supportive and to maximize opportunities for the children’s adjustment” (p. 2002). This perspective therefore appears to encourage some parents to take an approach that is rather different from the more “traditional” therapeutic models: there are now several examples reported on in the media in which parents of very young children enforce a social gender change (e.g., registering a biological male child in school as a girl; Brown, 2006; Santiago, 2006).

Because comparative treatment approaches are not available, it is not possible to say whether or not this supportive or “crossgender affirming” approach will result in both short-term and long-term outcomes any different from the more traditional approaches to treatment.

Treatment of Adolescents

In adolescents with GID, there are three broad clinical issues that require evaluation:
1. Phenomenology pertaining to the GID itself;
2. Sexual orientation; and

Apart from the GID itself, gender-dysphoric adolescents with a childhood onset of cross-gender behavior typically have a homosexual orientation (i.e., they are attracted to members of their own “birth sex”). Some such adolescents may not report any sexual feelings, but follow-up will typically find the emergence of same-sex attractions. Thus, the clinician must evaluate simultaneously two dimensions of the patient’s psychosexual development: current gender identity and current sexual orientation.

The psychotherapy treatment literature on adolescents with GID has been very poorly developed and is confined to a few case reports (Zucker, 2006a; Zucker & Bradley, 1995). In general, the prognosis for adolescents resolving the GID is more guarded than it is for children. From a clinical management point of view, two key issues need to be considered:
1. Some adolescents with GID are not particularly good candidates for therapy because of comorbid disorders and general life circumstances;
2. Some adolescents with GID have little interest in psychologically oriented treatment and are quite adamant about proceeding with hormonal and surgical sex reassignment.

Prior to recommending hormonal and surgical interventions, many clinicians encourage adolescents with GID to consider alternatives to this invasive and expensive treatment. One area of inquiry can therefore explore the meaning behind the adolescent’s desire for sex reassignment and if there are viable alternative lifestyle adaptations. The most common area of exploration in this regard pertains to the patient’s sexual orientation. Some adolescents with GID recall that they always felt uncomfortable growing up as boys or as girls, but that the idea of “sex change” did not occur until they became aware of homoerotic attractions. For some of these youngsters, the idea that they might be gay or homosexual is abhorrent.

For adolescents in whom the gender dysphoria appears chronic, there is considerable evidence that it interferes with general social adaptation, including general psychiatric impairment, conflicted family relations and dropping out of school. For these youngsters, the treating clinician can consider two main options:
1. Management until the adolescent turns 18 and can be referred to an adult gender identity clinic; or

Gooren and Delemarre-van de Waal (1996) and Cohen-Kettenis and van Gooroon (1998) recommended that one option with gender-dysphoric adolescents is to prescribe puberty-blocking luteinizing hormone-release agonists (e.g., depot leuprolide or triptorelin) that make it easier to pass as the opposite sex. Thus, in male adolescents such medication can suppress the development of secondary sex characteristics, such as facial hair growth and voice deepening, which make it more difficult to pass in the female social role. Cohen-Kettenis and van Gooren (1997) and Smith, van Gooroon, & Cohen-Kettenis et al. (2002) reported that early cross-sex hormone treatment for adolescents under the age of 18 years, who were free of gross psychiatric comorbidity, facilitated the complex psychosexual and psychosocial transition to living as a member of the opposite sex and resulted in a lessening of the gender dysphoria. Although such early hormonal treatment is controversial (Beh & Diamond, 2005), it may well be the treatment of choice once the clinician is confident that other options have been exhausted (Cohen-Kettenis, 2005).

Paraphilic Sexual Disorders

Diagnosis

Paraphilias can broadly be classified into those that involve atypical sexual targets or those that involve atypical sexual activities. Atypical sexual targets include sexually immature persons (pedophilia), non-human animals (zoophilia) and inanimate objects (fetishism); atypical activities include the infliction of pain or humiliation on another (sadism), experiencing pain or humiliation (masochism) or exposing one’s genitals to unsuspecting strangers (exhibitionism). A wide variety of paraphilias have been described in the clinical and research literatures, but most are rare. The most commonly seen paraphilias in clinical or correctional settings are those that involve illegal behavior if they are acted upon, such as pedophilia and the commission of sexual offences against children, or sadism and the commission of violent sexual offenses.

The DSM-IV-TR lists a number of the more commonly known paraphilias, including pedophilia, sadism and fetishism;
the paraphilias listed in the 10th revision of the ICD-10 are quite similar in content (World Health Organization, 1997). For example, the ICD-10 defines pedophilia as “a sexual preference for children, usually of prepubertal or early pubertal age” while the DSM-IV-TR elaborates by defining sexual preference in terms of timeline and manifestation, and adding criteria regarding the age difference between the person and the child or children (the person is at least age 16 years and at least 5 years older than the child or children).

**Epidemiology**

Neither the incidence nor prevalence of paraphilias is known. Epidemiological surveys of the general population, with the specific questions that are needed to identify paraphilias – particularly questions about the persistence and intensity of sexual thoughts, fantasies, urges, arousal or behavior involving the paraphilic target or activity – have not yet been conducted. Almost all of the research on paraphilias has been conducted with clinical or correctional samples, and most of that work has involved adult sex offenders rather than adolescent sex offenders, or other minors. Surveys of convenience samples of young adults suggest that paraphilias are rare (Templeman & Stinnett, 1991). Researchers have not asked similar questions of adolescents.

**Assessment**

**Interviews and Questionnaires**

In order to diagnose a paraphilic sexual disorder, a thorough sexual history is needed. Such histories are typically obtained through clinical interview. Respondents are asked questions about their sexual thoughts, interests and behaviors, especially with regard to atypical sexual targets or activities. Comprehensive interviews also include questions intended to help clinicians rule out other explanations for atypical sexual thoughts, urges, fantasies or behavior. For example, some individuals with obsessive-compulsive disorder may report being disturbed by thoughts about molesting a child (see, e.g., Gordon, 2002). The differential diagnosis is made by determining if the thoughts are associated with sexual arousal or pleasure and by inquiring about other symptoms of obsessive-compulsive disorder.

Interviews can be very informative, but there are potential problems with recall and other biases in gathering data on sexual behavior in this way (Wiederman, 2002). Questions about sexual history are sensitive and many interviewees may minimize or deny certain sexual interests or behaviors, especially those that could result in social ostracism. For example, a study found that male adolescents were more willing to disclose criminal acts they have committed than the fact that they have masturbated, even though many of them had engaged in both behaviors (Halpern, Udry, Suchindran, & Campbell, 2000). The validity of self-report may be increased if a rapport is established, as can occur after involvement in treatment (Worling & Curwen, 2000).

One way to reduce the reluctance of individuals to disclose sexual interests or behavior in interviews is to administer questionnaires. For example, Koss and Gidycz (1985) found that male respondents were more likely to admit engaging in sexually coercive acts on a questionnaire than in an interview. Using questionnaires also addresses the potential problem of interviewers who skip or forget important questions. An example of a measure that has been developed for adolescents is the Sexual Fantasy Questionnaire, which contains items about atypical sexual fantasies (Daleidin, Kaufman, Hilliker, & O’Neil, 1998).

**Other Sources of Information**

Sexual history information can also be obtained from other sources, including interviews with an adolescent’s present sexual partner, if available, and a parent or guardian of children or younger adolescents. However, such information is usually limited because the minor will often be reluctant to disclose sexual urges, fantasies or thoughts to others, even with intimate others and even when such urges involve conventional targets or activities. A review of clinical or criminal justice records can also be very helpful. Clinicians can use information about sexual victim characteristics to make the diagnosis of pedophilia, because pedophilia is more likely to be present among sex offenders who have very young victims, boy victims and victims outside the offender’s immediate family (Seto, Murphy, Page, & Ennis, 2003).

Data on the sexual behavior problems of children can be collected from maternal observations through the Child Sexual Behavior Inventory, which lists a variety of both typical and atypical sexual behaviors and asks mothers or other female caregivers to rate their frequency (Friedrich, 1997; Friedrich, Fisher, Dittner *et al.*, 2001). Childhood sexual behavior problems are positively correlated with non-sexual behavior problems as measured by the CBCL. Some sexual behaviors are common among young children (e.g., touching sex parts at home, undressing in front of others), but aggressive sexual behaviors and more intrusive behaviors are rare.

**Phallometry and Viewing Time**

Phallometry involves the measurement of penile responses to sexual stimuli that systematically vary on the dimensions of interest, such as the age and sex of the figures in a set of slides depicting female children, adolescents and adults, and male children, adolescents and adults. Phallometry was developed as an assessment method by Freund (1963). Phallometric responses are recorded as increases in either penile circumference or penile volume; bigger increases in circumference or volume are interpreted as evidence of greater sexual arousal to the presented stimulus. Erectile response (except for erections that occur during sleep) is a specifically sexual measure, unlike other psychophysiological responses, such as pupillary dilation, heart rate, viewing time and skin conductance (Zuckerman, 1971). Phallometric indices of responding discriminate sex offenders from men who have not committed sexual offences and predict sexual recidivism. Other investigators have shown that phallometry can similarly distinguish men who admit to sadistic fantasies, cross-dress or expose their genitals in public from...

Seto, Lalumière, and Blanchard (2000) evaluated the use of phallometric testing for adolescent sex offenders with child victims. Because an age-matched comparison group was not available, these adolescents were compared with young adults between the ages of 18 and 21 who had not committed sexual offences involving children. As a group, adolescents with male victims had relatively higher responses to pictures of children than the young adult comparison participants. Adolescents with both male and female children as victims responded more to pictures of children than to pictures of adults. Further evidence for the validity of phallometry in adolescent sex offenders comes from Blanchard and Barbaree (2005), Gretton, McBride, O'Shaughnessy, and Kumka (2001) and Robinson, Rouleau, and Madrigano (1997).

Another objective measure that is increasingly used with adolescent sex offenders is viewing time. The procedure involves showing a series of pictures depicting girls, boys, women or men; these pictures can depict clothed, semi-clothed or nude figures. Respondents are either asked to examine the pictures to answer later questions or they are asked to rate each picture (e.g., how attractive the depicted person is). Respondents are instructed to proceed to the next picture at their own pace and are expected to be unaware that the key dependent measure is the amount of time they spend looking at each picture. Viewing time is correlated with self-reported sexual interest and phallometric responding among non-offending volunteers recruited from the community (Quinsey, Ketetsis, Earls, & Karamanoukian, 1996).

Several studies have shown that adult sex offenders with child victims can be distinguished from other men by the amount of time they spend looking at pictures of children relative to pictures of adults (Harris, Rice, Quinsey, & Chaplin, 1996) or by a combination of viewing time and additional questionnaire responses (Abel, Jordan, Hand, Holland, & Phipps, 2001). However, Smith and Fischer (1999) were not able to demonstrate discriminative validity in a study of adolescent sex offenders and non-offenders using viewing time without additional questionnaire responses. No published studies have yet demonstrated that scores on viewing time measures, whether alone or in combination with self-report, predict recidivism among adolescent (or adult) sex offenders. Another potential problem for viewing time measures is that they may become vulnerable to faking once the client finds out that viewing time is the key variable of interest.

**Associated Psychopathology**

Kafka (1997, 2003) noted that paraphilias and related sexual disorders are often comorbid with mood disorders. In conjunction with evidence on the impact of antidepressant medications on sexual behavior, Kafka (1997) suggested that there is evidence that paraphilias and mood disorders share a common serotonergic diathesis. Consistent with this idea, we recently completed a meta-analysis of studies that compared adolescent sex offenders with adolescents who committed other kinds of offences (Seto & Lalumière, 2004). We found that adolescent sex offenders reported significantly more anxiety or depression than other offenders, suggesting variables in this domain might have a unique role in explaining sexual offending. However, the timing of symptoms was not clearly distinguished in the studies that we reviewed. The symptoms could have preceded the sexual offences, but they could also be a consequence of being identified as a sex offender (e.g., becoming more anxious and depressed after being arrested and charged for a sexual offence), given the extremely negative social views about sexual offending, even when compared to other forms of crime. Research on the association between paraphilias and mood disorders in samples outside of clinical or correctional settings is needed to determine if this link is an artifact of where the research has been conducted.

There is also evidence that sexual behavior problems are frequently comorbid with non-sexual behavior problems (Friedrich, Grambsch, Broughton et al., 1991; Friedrich, Fisher, Dittner et al., 2001). Thus, children with sexual behavior problems and adolescent sex offenders may meet diagnostic criteria for attention deficit/hyperactivity disorder, oppositional defiant disorder or conduct disorder (Seto & Lalumière, 2004). France and Hudson (1993) reviewed studies on this topic and concluded that up to half of adolescent sex offenders would meet diagnostic criteria for conduct disorder.

Paraphilias are often comorbid, such that engaging in one form of paraphilic behavior greatly increases the likelihood of engaging in another (Abel, Becker, Cunningham-Rathner, Mittelman, & Rouleau, 1988; Bradford, Boulet, & Pawlak, 1992). We have recently demonstrated that exhibitionistic and voyeuristic behavior also co-occurred more often than expected by chance in a nationally representative sample of young men between the ages of 18 and 21 from Sweden (Langström & Seto, 2006). The co-occurrence of paraphilic behaviors suggests there may be a common cause to the paraphilias (which does not rule out specific factors). There are no data of this kind for adolescents.

**Etiology**

Different theories have been proposed to explain the etiology of paraphilias. We focus here on theories that posit conditioning has a role, and theories that suggest paraphilias are the result of neurological perturbations. We then discuss the implications of recent findings on the association between childhood sexual abuse and pedophilia.

**Conditioning**

It has been proposed that masturbatory conditioning has a role in the development of paraphilias (McGuire, Carlisle, & Young, 1965). Some individuals, for unspecified reasons, pair cues of unusual initial sexual experiences with the sexual pleasure elicited by these early experiences, and learn to associate these cues with the powerful reinforcement of orgasm. However, there is equivocal evidence about the ability to condition increases in sexual arousal in humans. Rachman and Hodgson (1968) reported significantly increased sexual arousal
to pictures of boots among normal volunteers in a set of frequently cited experimental studies examining the development of boot fetishism, but these studies did not have control conditions. Lalumière and Quinsey (1998) and Hoffmann, Janssen, and Turner (2004) found a significant effect of conditioning on sexual arousal among male volunteers, while Plaud and Martini (1999) reported mixed results in a conditioning study of nine male volunteers.

The efficacy of conditioning approaches for changing sexual arousal patterns has been reviewed elsewhere (Barbaree & Seto, 1997). Overall, this research suggests that conditioning can have an effect on the suppression of sexual arousal of adolescent or adult sex offenders, but it is unclear how long these changes are maintained, what mechanisms are actually responsible for the changes in sexual arousal patterns and whether the changes reflect an actual shift in sexual interests or greater voluntary control over sexual arousal when assessed in the laboratory (Lalumière & Earls, 1992).

Conditioning might have a role in maintaining rather than initiating paraphilic sexual arousal. Dandescu and Wolfe (2003) found that atypical sexual fantasies preceded and accompanied the first sexual offence reported by a sample of 57 sex offenders with child victims; the sexual fantasies then increased in frequency after the first sexual offence. Approximately two-thirds of the offenders reported having any “deviant sexual fantasies” prior to their first contact with a child, while 81% reported having such fantasies afterwards. This finding suggests that the sexual arousal and gratification experienced during the first sexual offence increased the frequency of sexual fantasies among men who already had such fantasies.

These research findings suggest that conditioning is unlikely to have a significant role in the onset of paraphilias. Experimental efforts to increase sexual arousal have produced small effects, and it is unclear how long conditioned changes in sexual responding (e.g., suppression of sexual arousal to child stimuli through aversive conditioning) can be maintained. If conditioning does have a role in the development of paraphilia, as suggested by Dandescu and Wolfe’s (2003) study, then there is probably an interaction between conditioning experiences and other predisposing factors.

Neurological Perturbations

Brain abnormalities have long been suspected as a cause of paraphilias. Information on brain functioning can be obtained both directly and indirectly. Indirectly, investigators have compared the performance of sex offenders with child victims with other groups of men on measures of intelligence and other aspects of cognitive functioning. Cantor, Blanchard, Robichaud, and Christensen (2005) conducted a meta-analysis of 165 adult samples and 71 adolescent samples. For the adults, there was a significant difference between sex offenders and others, with sex offenders scoring lower on measures of intelligence than other offenders, who, in turn, scored lower than non-offending controls. For the adolescents, there was a significant difference between sex offenders and other offenders.

Among the sex offenders, Cantor et al. found that intelligence scores appeared to be related to the proportion of the sample who were pedophilic, because sex offenders with child victims scored lower than sex offenders without any child victims, and there was a positive relationship between the age cut-off used to define child victims and mean intelligence score; in other words, samples composed of men who offended against younger children tended to produce lower mean IQ scores than samples composed of men who offended against older children.

In earlier studies, this same research group also found that pedophilic sex offenders were more likely to report experiencing head injuries before age 13, but did not differ in reports of head injuries after age 13 (Blanchard, Christensen, Strong et al., 2002; Blanchard, Kuban, Klassen et al., 2003). The fact that there was no difference in reports of head injuries after age 13 counters the alternative explanation that pedophiles have a retrospective reporting bias in recalling head injuries, because there would be no reason to think that head injuries before the age of 13 are more socially acceptable than head injuries later in life. The fact that there was no difference after age 13 also suggests there is a critical age window in terms of the impact of head injury on the development of pedophilia (and perhaps other paraphilias). This is an intriguing possibility because of other work that suggests the time before and during puberty is critical in the development of sexual preferences. Of course, this assumes that the relationship between head injury and pedophilia is causal. It is possible that a third variable explains both the higher incidence of head injury and pedophilia; for example, prenatal neurological perturbations may both increase accident-proneness, resulting in a higher risk for head injury, as well as increase the likelihood that an individual will be pedophilic.

Researchers have also attempted to assess brain structure directly, especially in the frontal (associated with executive control) and temporal regions (associated with emotional processing and regulation of sexual behavior). Recently, Cantor, Kabani, Christensen et al. (2007) discovered a significant difference in white matter, such that pedophiles have less white matter than non-pedophilic men, particularly in two tracts: the right superior occipitofrontal fasciculus and the right arcuate fasciculus. These white matter tracts connect areas that are involved in determining if a stimulus is sexually relevant, suggesting that pedophiles are somehow deficient in how they process and integrate sexual cues.

Cycle of Sexual Abuse

The most frequently discussed factor in explanations of adolescent sexual offending is sexual abuse history (Knight & Sims-Knight, 2003). Seto and Lalumière (2004) conducted a meta-analysis of studies that compared adolescent sex offenders with other adolescent offenders, and found that adolescent sex offenders were almost five times as likely to have a history of sexual abuse. This was found whether the analysis involved studies that relied on self-report or on other sources of information (e.g., clinical files, official records). Moreover, adolescent
sex offenders who have been sexually abused show relatively greater sexual arousal to children or coercive sex than those who have not been abused (Becker, Hunter, Stein, & Kaplan, 1989). Among children, Friedrich, Grambsch, Damon et al. (1992) showed that scores on the Child Sexual Behavior Inventory could discriminate children who had been sexually abused from those who had not. Hall, Matthews, and Pearce (1998) found, in a sample of 99 sexually abused boys and girls between the ages of 3 and 7, that those who became sexually aroused during the sexual abuse were more likely to engage in sexual behavior problems involving others \( (n = 62) \) than those who did not \( (n = 37) \).

The sexually abused–sexual abuser hypothesis suggests that male children who are sexually abused are more likely to engage in sexual offending later in life. Burton (2003) described plausible mechanisms linking sexual abuse and later sexual offending: modeling of the perpetrator’s behavior, conditioning as a result of pairing any sexual stimulation caused by the sexual abuse with cues such as the type of acts that occurred, and changing cognitions about the acceptability of adult–child sex.

The mechanisms underlying the association between childhood sexual abuse and sexual behavior problems among children and adolescent sexual offending are not known (Widom & Ames, 1994). A number of investigators have suggested that aspects of the sexual abuse such as the victim–perpetrator relationship, nature of sexual abuse, duration and timing of the sexual abuse are important (Burton, 2003). There must be individual characteristics that increase both vulnerability to childhood sexual abuse and the likelihood of adolescent sexual offending, because many sexually abused children do not go on to commit sexual offenses later in life, and many adolescent sex offenders have no known history of sexual abuse.

**Developmental Course**

A developmental perspective is important because there are myriad differences between children, adolescents and adults, and because there is both persistence and desistance in sexual offending across the lifespan. Retrospective studies suggest approximately half of adult sex offenders report that their first sexual offense was committed as a juvenile (Abel, Osborn, & Twigg, 1993), and up to half of adolescent sex offenders have engaged in sexual misconduct under the age of 12 (Burton, 2000; Ryan, Miyoshi, Metzner, Krugman, & Fryer, 1996; Zolondek, Abel, Northey, & Jordan, 2001). In prospective studies, however, only a minority (perhaps 10–15%) of adolescent sex offenders commit another sexual offense over 5 years of opportunity (for review see Caldwell, 2002). The proportion of children with sexual behavior problems who persist and commit a sexual offense as an adolescent is also relatively small (Carpentier, Silovsky, & Chauffin, 2006). Taken together, these data indicate that many children with sexual behavior problems and many adolescent sex offenders desist. For many children, their sexual behavior problems may represent a reaction to sexual abuse they have experienced, sexual precocity and normative sexual play. For many adolescents, their sexual offenses may represent opportunistic and relatively transient antisocial behavior. A small group of children and adolescents, however, will persist in committing sexual offenses into adulthood. The adolescents who will develop paraphilias are more likely to persist.

Of particular relevance is a study reported by Zolondek, Abel, Northey et al. (2001) of 485 adolescent males between the ages of 11 and 17, referred for assessment or treatment of possibly paraphilic interests or behavior. The youths completed a questionnaire with questions regarding sexual interests and experiences as part of their assessment. Twenty-six percent acknowledged engaging in fetishistic behavior, 17% acknowledged voyeuristic acts and 12% acknowledged exhibitionistic behavior. The average age of onset across paraphilic behaviors was between 10 and 12 years, which is younger than the average age of onset found in retrospective studies of adults (Abel, Becker, Mittelman et al., 1987). These data are consistent with the idea that the onset of paraphilias is likely around the time of puberty, just as many people are becoming aware of their sexual preference for males or females.

**Treatment**

**Pharmacological Treatment**

The common aim of drug therapies in the treatment of pedophilia is to suppress sexual response involving children. Much of the initial interest was in antiandrogens to reduce sexual response, but clinicians and researchers have more recently focused on serotonergic agents. Because of the impact of reducing androgens on physical development, antiandrogens are very rarely prescribed for minors, except in cases where the sexual behavior is very problematic (e.g., very violent sexual assaults on young children) and cannot be controlled by other means.

It is a logical hypothesis that antiandrogens would have an impact on paraphilic sexual responses, because testosterone has a critical role in male mammalian sexuality (Davidson, Smith, & Damassa, 1977). The earliest clinical study was reported by Laschet and Laschet (1971), who treated more than 100 paraphilic men; most were pedophiles or exhibitionists. Today, the most commonly prescribed agents are cyproterone acetate (CPA) or medroxyprogesterone acetate (MPA), both of which interfere with the action of testosterone. CPA blocks intracellular testosterone uptake and thus reduces plasma testosterone, while MPA reduces gonadotropin secretion. The use of either drug in the treatment of paraphilias is off-label, meaning it is not specifically approved by regulatory bodies for this purpose. Side effects of antiandrogens include headaches, dizziness, nausea, gynecomastia, depression and osteoporosis. As a result of these potentially serious side effects, and the fact that some patients do not want to experience a massive reduction in their sex drive, treatment attrition and compliance are significant issues in antiandrogen treatment. For example, in Hucker, Langevin, and Bain (1988), only 11 of 18 men completed the 12-week trial.

There is some support for the efficacy of antiandrogens in reducing the frequency or intensity of sexual urges and
arousal, but there has been a dearth of larger, better controlled outcome studies. Gijs and Gooren (1996) reviewed the literature evaluating the effects of CPA and MPA, focusing on methodologically stronger studies that included features such as random assignment, a placebo condition and double-blinding. They identified four controlled studies of CPA and six such studies of MPA. All four studies of CPA reported that treated men had a significant reduction in sexual response, while only one of the six MPA studies showed a significant difference between men in the treatment and comparison conditions.

Serotonin is involved in the regulation of human sexual behavior, and antidepressant medications that have a serotonergic effect have long been known to reduce sexual desire and delay ejaculation in males (for a review see Meston & Gorzalka, 1992). Some clinical investigators have gone further and suggested, with little evidence, that selective serotonin reuptake inhibitors (SSRIs), such as fluoxetine and bupropine, can specifically affect sexual arousal to children without affecting sexual arousal to adults (Kafka, 1991).

The interest in serotonergic agents for the treatment of paraphilias appears to be almost entirely based on uncontrolled case studies or open trials (Gijs & Gooren, 1996); there has been only one experimental study that compared desipramine and chlorpromazine in a double-blind crossover trial that was preceded by a single-blind placebo condition (Kruesi, Fine, Valladares, Phillips, & Rapoport, 1992). Kruesi, Fine, Valladares et al. reported a significant reduction of self-reported paraphilic behavior (predominantly exhibitionism, transvestic fetishism, telephone scatalogia and fetishism) with either drug, but their result was difficult to interpret because only 8 of 15 paraphilic men completed the trial; four patients were dropped because they responded to the placebo and three did not complete the drug trial. Including the patients who responded to placebo would have attenuated, and perhaps eliminated, the apparent effect of the drugs on self-reported paraphilic behavior.

Despite the intuitive appeal of pharmacological interventions to reduce sexual drive and thus the likelihood of (illegal) paraphilic behavior, reviews of outcome studies suggest that there is no strong empirical support for the idea that such interventions can reduce sexual recidivism.

**Psychosocial**

Aversive conditioning techniques were used as early as the 1950s and 1960s for paraphilic interests such as fetishism and transvestic fetishism (Raymond, 1956). In the behavioral treatment of paraphilias, aversion techniques are used to suppress sexual arousal to the atypical target or activity, while masturbatory reconditioning techniques are used to increase sexual arousal to acceptable targets (peers or adults) and activities (consenting sexual activities). In aversion procedures, unpleasant stimuli such as mild electric shock or ammonia odors are paired with repeated presentations of sexual stimuli depicting the paraphilic target or activity. In a variation called covert sensitization, the aversive stimulus is imagined (e.g., being discovered by family, friends or coworkers while engaging in paraphilic behavior). Overall, the existing research suggests that behavioral techniques can have an effect on sexual arousal patterns, but it is unclear how long these changes are maintained and whether they result in actual changes in interests, as opposed to greater voluntary control over pedophilic sexual arousal (Lalumière & Earls, 1992).

Cognitive–behavioral treatments (CBT) aim to teach individuals how to manage their sexual urges. Published evaluations have reported promising results. Carpentier, Silovsky, & Chaifin (2006) reported on a long-term evaluation of 135 children with sexual behavior problems, compared with 156 children from the same out-patient clinic. The children with sexual behavior problems were randomly assigned to a play therapy group or a CBT group. Both treatments were manualized and ran for 12 hour-long sessions. The CBT group was highly structured and focused on education and behavior management. The play therapy group was less structured and more reflective, although it focused on many of the same themes: sexual behavior problems, boundaries, parenting skills and sex education. Children assigned to the CBT group were significantly less likely than children assigned to the play therapy group to sexually offend (defined as an arrest for a sexual offence or a child welfare report of sexual abuse perpetration) during the 10-year follow-up period. In fact, the rate of sexual offending among children in the CBT group was not significantly different from the comparison group without any sexual behavior problems.

Borduin, Henggeler, Blaske, and Stein (1990) reported a significant effect of treatment in a small sample of adolescent sex offenders, using a multisystemic treatment that targeted factors associated with criminal behavior, including antisocial attitudes and beliefs, associations with antisocial peers and substance abuse (for a review see Andrews & Bonta, 2002). Multisystemic treatment is also distinguished by being skills-focused, involving both the adolescent and his or her family, and paying careful attention to program fidelity and individualization. Multiple studies have shown that multisystemic treatment can significantly reduce recidivism and other negative outcomes among serious adolescent offenders (Henggeler, Schoenwald, Borduin, Rowland, & Cunningham, 1998). Borduin and Schaeffer (2001) replicated the Borduin, Henggeler, Blaske et al. (1990) study by showing that this multisystemic treatment had a large impact on sexual recidivism in a larger sample of 48 juvenile sex offenders, even though it was not designed specifically for this group.

**Conclusions**

There are many unanswered questions about the onset, development and prognosis of paraphilias. There has been relatively little research conducted on adolescents, perhaps reflecting a discomfort with the idea that some adolescents and older children engage in problematic sexual behavior as a result of atypical sexual interests that are very likely to be stable. As
a result, this chapter has drawn upon relevant studies of adult sex offenders. This is not to suggest that children with sexual behavior problems or adolescent sex offenders are likely to have paraphilias. In fact, it is likely that most do not, given the high rate of desistance from childhood to adolescence, and from adolescence to adulthood. A small minority do persist, however, and are likely to continue engaging in problematic sexual behavior without intervention.

There is emerging evidence to support the idea that there may be neurodevelopmental or neurological risk factors for pedophilia. Given the high comorbidity of paraphilias, it is likely that other paraphilias are similarly influenced.

As for many other disorders, we know more about the assessment than the treatment of paraphilias. Further research on paraphilias will be expedited by the development of age-appropriate measures of sexual interests. Viewing time is a particularly promising technology.

Unlike the adult literature, however, there are some promising results in the treatment of sexual behavior problems in children and sexual offending among adolescents. These treatments share a common focus on skills, behavior and problem-solving, and involve parents or other caregivers. Further advances in treatment will benefit from a greater understanding of the etiology and developmental course of paraphilias.

CHAPTER 52

This chapter covers disruptive behavior problems, including oppositional and attentional difficulties; emotional problems such as fears, phobias and depression; and feeding problems in the age period 0–5 years. It will begin by considering common developmental aspects and causal explanations of early behavioral problems, followed by describing, for each type of disorder, classification, prevalence and stability. Finally, we discuss treatment. Other problems common in the early years are discussed in chapters on sleep (see chapter 54), attachment disorder (see chapter 55) and developmental disorders (see chapters 3, 34, 46 and 47). Cross-reference is also made to chapters on similar disorders in older children.

The term “disorder” is used cautiously in this age group, with some skepticism about its validity (Campbell, 2002). Evidence for stability and prognostic significance of preschool problems is not particularly strong, especially in the under-threes. Comorbidity is very high, and there are also concerns about distinguishing normal from abnormal behavior in this period of rapid developmental change, and about labeling very young children with disorders. However, there may also be disadvantages of not defining disorders in young children, including failure to recognize distress and provide appropriate help (Carter, Briggs-Gowan, & Davis, 2004; Egger & Angold, 2006). The latter is particularly important, given that there is a good deal of evidence about effective interventions for this age group, particularly for disruptive behavior problems.

In view of these uncertainties about defining disorders, most studies in the 0–5 age group use dimensional approaches to defining and measuring problem behavior. Accordingly, we use the term “disruptive problems” to refer to a constellation of oppositional or attentional symptoms, and the term “emotional problems” to refer to depressive and anxious-type symptoms. Studies based on dimensional approaches include children with severe or milder problems, often defined by clinical cutoff on symptom questionnaires. Where studies use diagnostic criteria, we use DSM and/or ICD disorder terminology. The period of infancy refers to 0–1 years, toddlerhood 1–3 years and preschool 3–5 years.

Developmental Perspectives on Problem Behavior in Early Childhood

It is important to recognize the rapid pace of growth and maturation that takes place from birth to age 5, which has multiple implications for assessment and treatment. For the primary types of problem behavior discussed in this chapter (i.e., disruptive and emotional problems), identification and diagnosis based purely on child behavior have been shown to have limited stability and prognostic implications until at least 24 months of age (Campbell, Shaw, & Gilliom, 2000; Keenan, Shaw, Walsh, DelliQuadri, & Giovannelli, 1997). For assessing risk of clinically significant child problem behavior in the 0–2 age group, greater emphasis has been placed on parenting and factors that might compromise parental functioning (e.g., depression, social support, teen parenthood; Shaw, Dishion Supplee et al., 2006), as well as factors that might compromise the developing brain (e.g., prematurity; prenatal drug use). Child problem behavior shows increasing stability beginning in the toddler period. Whereas a substantial percentage of children will “outgrow” these problems, longitudinal studies suggest that 50–60% of children showing high rates of disruptive behavior at age 3–4 will continue to show these problems at school age (Campbell, Szumowski, Ewing et al., 1982; Campbell, Pierce, Moore et al., 1996; Campbell, Shaw, & Gilliom, 2000; Richman, Stevenson, & Graham, 1982). In a recent study of low-income boys, among those identified above the 90th percentile on disruptive symptoms at age 2, 60% remained above the 90th percentile and 100% (all 18) remained above the median at age 6 (Shaw, Gilliom, & Giovannelli, 2000; Shaw, Gilliom, Ingoldsby et al., 2003).

The low stability of behavior problems between toddlerhood and later childhood has implications for using the term “disorder” in referring to these problems in very early childhood (Campbell, 2002; Egger & Angold, 2006). It may be somewhat less problematic in the preschool range. There is currently much debate about the appropriateness of using traditional diagnostic categories, particularly for infants and toddlers. Rapid developmental change within the period 0–5 makes it particularly hard to distinguish normal from abnormal behavior, and to set age-appropriate criteria for classification systems. Thus, having six temper tantrums a day might be bothersome but normal at 22 months, but could contribute to a diagnosis of oppositional defiant disorder (ODD) in a 4-year-old. Similarly,
BEHAVIORAL PROBLEMS

a 2-year-old showing difficulty separating from a parent in the first week of daycare would be less worrisome than a 5-year-old showing similar reactions over many weeks.

Clearly, diagnostic systems need to be able to take these developmental variations into account. Systems for assessing preschoolers go some way to solving this problem, using criteria that are more age-appropriate, and basing assessments on observations and reports of child behavior in multiple settings (i.e., home and preschool, from parents and teachers). Recent advances in the field include the Research Diagnostic Criteria–Preschool Age (RDC-PA) which has attempted to modify DSM criteria to be suitable for preschoolers (Task Force on Research Diagnostic Criteria, 2003). However, the Preschool Age Psychiatric Assessment (PAPA; Egger & Angold, 2004), which is a structured parent-interview schedule for ages 2–5. However, these systems cannot easily solve the problem that meaning and significance of problem behavior shift rapidly even within this period, and within a given cultural or family setting. Systems for very young children, such as the diagnostic classification: 0–3 (DC: 0–3) (Zero to Three, 1994), tend to place more emphasis on aspects of the parent–child relationship, rather than focusing solely on child behavior, with an increasing focus on behavior as children approach school age. However, evidence for validity of 0–3 diagnostic categories, including stability and, in some cases, links to later disorders of the same name (e.g., infantile “anorexia”; Chatoor & Ganiban, 2004) is not strong.

Based on the relative instability of problem behavior during early childhood, it should not be surprising to learn that many children demonstrate multiple types of problem behavior, including co-occurring disruptive and emotional problems (e.g., oppositionality coupled with depression or attention deficit/hyperactivity disorder [ADHD]). Egger and Angold (2006) reported that 50% of preschoolers showing a disorder in their community sample also showed one or more co-occurring disorders. Similar rates of comorbidity were found in their community sample also showed one or more co-occurring problems (e.g., infantile anorexia; Chatoor & Ganiban, 2004) is not strong.

Theoretical perspectives

Preschool behavior problems are influenced by both biological and environmental factors, as manifest in individual differences in child characteristics (e.g., temperamental dimensions of activity, sociability, attention) and the quality of the caregiving environment. Genetic and prenatal environmental factors are influential in this age period (see chapters 23 and 30). We distinguish between risk factors, in the presence of which the probability of showing a disorder is raised; precursors, where there is continuity between an early problem (e.g., preschool disruptive problems) and a later one (e.g., conduct disorder); and the presence of formal disorder. Extreme difficult temperament is often viewed as a risk factor for later behavior problems (Hill, 2002), although at moderate levels of difficulty and without other indicators of child or family risk, such individual differences are likely to reflect developmentally normative patterns rather than necessarily implying risk for disorder.

In recent years, there has been increasing recognition of the multiple interacting factors that contribute to divergence in outcomes of infants who demonstrate early problems in feeding, emotionality or disruptive behavior (Campbell, Shaw, & Gilliom, 2000). This change in focus can be traced to the pioneering efforts of Thomas, Chess, and Birch (1968), who emphasized the goodness-of-fit between parent and child temperament, to Bell’s (1968) work on children’s effects on parents, and Sameroff and Chandler’s (1975) transactional model of parent–child interaction. Thus, assessment and intervention efforts across problem behavior types have focused on changing child behavior, parent behavior and resources, and the quality of parent–child interaction. As children under 5 years are so dependent on their caregiving environment, there is an emphasis on identifying risk factors in the family and the wider caregiving context (e.g., quality of daycare or non-parental caregiving) which moderate the course of early problem behavior.

In early childhood intervention, similar parent management strategies are often used to manage apparently dissimilar problems (e.g., infant feeding or sleeping problems, preschool disruptive behavior). That similar intervention strategies are used to treat these various problem behaviors should not be surprising, as self-regulation skills develop rapidly during this age period. Self-regulation involves the ability to control impulses and expressions of emotion; thus, children with difficulties in self-regulation might show a range of problems, including higher rates of tantrums, irritable mood and oppositionality, and disturbances in sleep, eating, activity or attention. Despite the range of symptoms, there may be common maintaining mechanisms. All of these problems might elicit similar levels of frustration in parents, their responses leading to a worsening of child symptoms, in a cycle of coercive interaction (Patterson, 1982; Shaw & Bell, 1993).
In recent decades, there has been much speculation about the need to ensure that children’s early years are not marked by environmental adversity, because of the fear of irreversible harm, as evidenced in animal studies. Unfortunately, relevant human data are limited. There is some evidence to suggest that exposure to psychosocial adversity during the toddler period shows stronger predictions to later outcomes than exposure in later periods (Appleyard, Egeland, van Dulmen, & Sroufe, 2005; Shaw, Gilliom, & Giovannelli, 2000). Thus, in the study by Appleyard et al. (2005) of children from low-income families, a cumulative index of contextual adversity in early childhood continued to be associated with adolescent antisocial behavior after accounting for the effects of contextual risk in middle childhood. However, in most cases, study designs have not permitted examination of whether there are critical periods for the operation of risk factors, where, based on timing of exposure, there might be differential effects on child adjustment.

**Clinical Problems**

**Disruptive Behavior**

Disruptive behavior, sometimes referred to as externalizing or “acting-out” problems, includes attentional and oppositional problems and their corresponding disorders, ADHD and ODD (Lahey, Loeber, Quay, Frick, & Grimm, 1992). As conduct disorder (CD) includes more serious forms of aggression, property destruction and theft, it is rarely applied to preschoolers. Disruptive problems represent the most frequent type of problem behavior in early childhood, particularly after the second year when parental expectations for children to comply with rules and contain aggressive behavior increase. Tremblay (1998) reported that by age 17 months, 70% of children take toys away from other children, 46% push others to obtain what they want and 21–27% engage in one or more of the following with peers: biting, kicking, fighting or physically attacking. Tremblay also reported that aggression occurs more frequently for infants with siblings, especially for girls, providing daily opportunities for conflicts over possessions. Relative to emotional problems, much more research has been conducted on the stability, course and predictors of disruptive problems in early childhood and about 50% of oppositional 3-year-olds continue to have these problems in the school years (Campbell, Shaw, & Gilliom, 2000).

Using DSM-IV criteria, generated from a structured interview with parents, the prevalence of preschool ODD in a US sample was estimated at 7%, and ADHD at 3% (Egger & Angold, 2006). Other studies broadly concur, although some questionnaire studies arrive at higher estimates, depending, not surprisingly, on the choice of definition, cut-off and informant (Koot, 1993; Richman, Stevenson, & Graham, 1982). In the toddler and preschool years, sex differences are not as marked as in older children. Boys’ higher rates of disruptive behavior seem to emerge during the later preschool period, with studies documenting absence of sex differences from ages 1 to 3 (Achenbach, 1992; Keenan & Shaw, 1994; Richman, Stevenson, & Graham, 1982), followed by increasing sex differences from age 4 to 5 (Lavigne, Gibbons, Christoffel et al., 1996; Rose, Rose, & Feldman, 1989), although this was not found for ODD by Egger and Angold (2006).

**Attention Deficit/Hyperactivity Disorder**

Core features include inattention, impulsivity and hyperactivity (Barkley, 1998). In terms of etiology, models tend to focus on different biological factors, including activity, impulse and attention control (see chapter 34; Barkley, 1997; Rothbart, Ellis, Rueda, & Posner, 2003). As with older children, most preschoolers with ADHD show other difficulties, most typically conduct problems (Barkley, 1997; Shaw, LaCourse, & Nagin, 2005). This co-occurrence carries risk for more severe and chronic adjustment problems in adolescence and adulthood (Moffitt, 1990; Weiss & Hechtman, 1993).

**Oppositional Problems**

These include defiant, angry, annoying, non-compliant and sometimes aggressive behaviors. For a diagnosis of ODD, behaviors need to occur more commonly than is typical for that age, persist for more than 6 months, and impair the child’s functioning (American Psychiatric Association, 2000; Campbell, 2002). During toddlerhood, despite the high frequency of aggressive-like and oppositional behavior, many of these behaviors tend to be tolerated by parents because of children’s limited ability to understand the consequences of their actions. However, with emerging cognitive maturation during this period, parental tolerance for disruptive behavior decreases, particularly when children cannot refrain from showing this behavior with peers and adults outside of the home (e.g., in daycare).

**Causes and Correlates of Disruptive Behavior Problems**

Causal models emphasize the dynamic interplay of child, parenting and contextual factors (Sameroff & Chandler, 1975), with individual differences in disruptive behavior often being magnified by ineffective parent management strategies (Campbell, Pierce, Moore et al., 1996; Shaw, Gilliom, Ingoldsbys et al., 2003). Most of this research has focused on early predictors of conduct problems rather than ADHD, but one recent study found similar types of predictors for both conduct problems and ADHD (Shaw, LaCourse, & Nagin, 2005). Predictive validity for early child markers of more serious disruptive behavior begins to emerge around age 2 (Keenan, Shaw, Walsh et al., 1997; Shaw, Gilliom, Ingoldsbys et al., 2003), with clearer predictions from age 3 to later, more serious forms of antisocial behavior (Caspi, Henry, McGee, Moffitt, & Silva, 1995; Henry, Caspi, Moffitt, & Silva, 1996).

Parenting models have been developed from attachment and social learning perspectives, with attachment models emphasizing unresponsive caregiving during infancy (Greenberg, Speltz, & DeKlyen, 1993; Sroufe, 1997), and social learning models focusing on the development of coercive cycles in which parents unwittingly reinforce and maintain child disruptive behavior by using inconsistent and harsh management strategies.
(Patterson, 1982; Shaw & Bell, 1993). Research has consistently validated associations among low-quality parent–child relationships in the early years, the use of unresponsive or harsh parenting practices, and disruptive behavior in preschool and later years (Loeber & Dishion, 1983; Lyons-Ruth, 1996; Shaw, Keenan, & Vondra, 1994; Shaw, Winslow, Owens et al., 1998). Positive parenting skills (e.g., anticipating the child’s troublesome moments, providing joint play activities) may be particularly important in the toddler years, as they can help to divert children from problem behavior at an age when children have limited skills for self-management of boredom and tempting impulses (Gardner, 1994; Gardner, Sonuga-Barke, & Sayal, 1999; Gardner, Ward, Burton et al., 2003; Gardner, Shaw, Dishion et al., 2007; Martin, 1981). Rather different parenting skills become important in middle childhood, where increasing independence requires greater monitoring of children across multiple settings, and planning for preventing problems that may occur in the parent’s absence.

The wider family and caregiving environment can also influence the development of early emotional and behavioral problems. The nature of sibling relationships, for example, appears to be influenced by factors such as the temperament of each child, and the quality of other relationships in the family, such as parent–child and marital relationships (Dunn, 1993). Sibling relationships often encompass a complex mix of supportive and conflictual dimensions, and appear to be important for development. For example, Garcia, Shaw, Winslow, and Yaggi (2000) found that sibling conflict at age 5 was predictive of later disruptive problems at home and school, after accounting for earlier parenting and child behavior.

As young children spend more time outside the home, researchers have addressed whether and how daycare may affect early problem behavior. Early studies of daycare were mixed in quality of the methods used, quality of the daycare studied and the results found. A recent US study of daycare effects (over 1000 children) found that more hours spent in any kind of non-maternal care from infancy to age 54 months was associated with higher ratings of oppositional problems, more so for ratings made by alternative caregivers and teachers than parents (NICHD Early Child Care Research Network, 2003). These effects, albeit statistically significant, tended to be modest in magnitude and did not predict trajectories of clinically meaningful problem behavior. The quality of early child care has also bee found to discriminate conduct problems in a large sample of children from low-income families (Votruba-Drzal, Coley, & Chase-Landsdale, 2004). Results indicated that many hours of low-quality care was associated with higher oppositional problems at school entry, whereas high-quality care served a protective function. Fewer behavior problems have also been found in children in high-quality day care, compared to home care, in Sweden, even at 10-year follow-up (Andersson, 1992). Overall, quality and, to some extent, amount of care, have been found to influence the course of early disruptive problems.

In general, risk factors for early disruptive behavior are similar to those for later CD (see chapter 35), including parental attributes (e.g., mental illness; see chapter 27) and contextual factors (e.g., socioeconomic status; Shaw, Keenan, & Vondra, 1994; Shaw, Winslow, Owens et al., 1998; Tremblay, Nagin, Seguin et al., 2004). Cumulatively, these data suggest that several targets have been established for prevention and intervention studies (see chapter 61; Olds, 2002), some of which might be appropriate before a child is born.

**Emotional Problems**

Emotional problems such as anxiety, depression and post-traumatic stress in preschoolers have been much less studied than disruptive problems. There are a number of reasons for this, including the inability of young children easily to communicate about their emotions, or for adults to notice them as problematic. Furthermore, there are difficulties in distinguishing developmentally normal emotions (e.g., fears, crying) from more severe and prolonged anxiety or misery that might constitute a disorder. This is especially difficult in the early years, when children undergo rapid changes in the development of emotions, and in their ability to communicate these to others. There is probably insufficient evidence at present to decide whether diagnosing emotional disorders is valid and useful in the 0–5 year range.

**Classification Systems**

Many DSM categories, including social phobia, generalized anxiety and depression apply across the range of child to adulthood, and are therefore not designed to take preschool developmental factors into account. One exception is Separation Anxiety Disorder, which applies only to children. It is defined as “developmentally inappropriate and excessive anxiety concerning separation from home or from those the child is attached to” (APA, 2000). However, there are still problems in applying this diagnosis to very young children because normative expectations of responses to separation from caregivers change so much across the first 3 years. Thus, in the 0–3 system, this constellation is not considered abnormal and therefore is not included as a disorder. In all cases it is important to take into account the child’s developmental stage in assessing whether a problem is of concern. The majority of children show fears at some stage in development, and typical fears change with age. Thus, fear of strangers is very common in late infancy, and fear of animals in toddlerhood. Whether they constitute a clinical problem (Campbell, 2002) depends also on factors such as persistence, and how much they impair the child’s and family’s well-being, for example if the child is persistently unable to engage in normal activities (e.g., going to daycare or the park).

**Stability**

Many emotional problems in this age range are thought to represent transient reactions to stressful life events, rather than disorders per se. Relative to studies of disruptive problems, there is a paucity of research on the stability of early emotional problems for young children. In one study, stability of preschool depression over 6 months was high among 3-
CHAPTER 53

5-year-olds (Luby, Heffelfinger, Mrakotsky et al., 2002), but there are no data on the long-term prognosis for these children. Both predictive validity and functional impairment are important in validating a diagnostic category, and in the case of depressed preschoolers, there is preliminary evidence that these children show moderate to high levels of impairment in their daily functioning (Egger & Angold, 2006).

Prevalence
Studies of preschool children using DSM-III and DSM-IV criteria have estimated prevalence of emotional disorder diagnoses; these tend to be low for each category: separation anxiety (0.3–5%), social phobia (2–4%), specific phobia (0–2%) and depression (0–2%; Egger & Angold, 2006; Lavigne, Gibbons, Christoffel et al., 1996). However, in Egger and Angold’s study, which included multiple types of problem behavior, rates of any emotional disorder were as high as for disruptive disorders, both around 10%. As found in middle childhood, prevalence of depression and anxiety did not differ by gender (Keenan, Shaw, Walsh et al., 1997). Sex differences tend to emerge around puberty. Comorbidity between depression and ODD was very high in one study of 2- to 5-year-olds (Egger & Angold, 2006), raising questions about whether these are separate disorders.

Causes and Correlates of Emotional Problems
As with disruptive behaviors, causes are likely to be multifaceted, and to reflect the interplay between child and parent genetic factors, parenting and the wider social environment around the child. As with other aspects of emotional problems, there have been few studies of multiple etiological factors, especially in preschool children. Studies have suggested quite high heritability for some preschool emotional problems (Eley, Bolton, O’Connor et al., 2003). Where risk factors have been studied in preschoolers, broadly these appear similar to those found in studies of older children (Luby, Heffelfinger, Mrakotsky et al., 2003). Maternal transmission of anxiety also seems to be an important factor, not only via genetic factors, but also through processes such as modeling and an anxious style of parenting (see chapter 27). Individual differences in children’s temperament (see chapter 14) also have been linked to early emotional problems, most notably for children who are behaviorally inhibited (Hirshfeld-Becker, Biederman, & Rosenbaum, 2004). Behavioral inhibition is defined as the tendency to react to novelty with unusual fear, cautiousness and withdrawal, and appears to be moderately stable across early childhood (Kagan, 1999; Kagan, Reznick, & Snidman, 1988). Biederman, Hirshfeld-Becker, Rosenbaum et al. (2001) found that behavioral inhibition assessed during early childhood was associated with increased risk for anxiety disorders 5 years later. Another recent study examined predictors of trajectories of boys’ anxiety from ages 2 to 10 years, and subsequent emotional disorders in early adolescence (Feng, Shaw, Lane, Alarcon, & Skuban, 2006). Consistent with Kagan’s work, shy temperament at age 2 tended to differentiate between initial high- and low-anxiety trajectory groups, whereas early maternal negative control and maternal depression were associated with increasing trajectories and elevated anxiety symptoms in middle childhood. Follow-up to adolescence indicated that child factors such as temperament contributed strongly to diagnoses of anxiety disorders, whereas both child and parent factors (e.g., negative control) contributed to boys’ depression.

Eating and Feeding Problems
Normal patterns of feeding change greatly between individuals and across time in the developmental period 0–5. The same can be said for disorders of eating and feeding, which present in a wide variety of ways (Stein & Barnes, 2002). Thus, in the early months, babies may fail to thrive for a number of reasons, or show signs of infantile colic. In the preschool years, food refusal or excess fussiness may be linked to other toddler oppositional behaviors, and intervention may need to consider parental management of child behavior more broadly. Feeding problems are common, but are more prevalent in children with developmental disabilities, pointing to the combination of physical health, family factors and developmental delay that are often involved in feeding problems. Their multifactorial origins can make it hard to define which problems belong within the realm of child psychiatry, rather than pediatrics, as many feeding problems that are primarily physical (e.g., failure to thrive [FTT] as a result of oral–motor dysfunction in cerebral palsy) may or may not have a substantial component exacerbated by family stress or poor parenting skills. The picture is further complicated by the fact that etiology is often unknown (e.g., in FTT, colic). While bearing in mind this caution, we will focus on problems thought to have a primarily psychosocial cause.

Classification and Prevalence
There is no standard system for classifying all types of feeding problems in the 0–5 period. DSM-IV includes the categories pica, rumination and “feeding disorder of infancy and early childhood,” defined as persistent failure to eat adequately, with weight loss or failure to gain weight that is not caused by physical illness, and onset before age 6. Various systems of classification have been proposed, but some make unwarranted assumptions about etiology, for example Chattoor & Ganiban (2004), who classify disorders by psychogenic or other cause (e.g., “feeding disorder of caregiver–infant reciprocity,” or “post-traumatic feeding disorder”). This chapter covers the most common problems in this age group, including colic, FTT and food refusal. Feeding problems have been estimated to affect up to 30% of infants (Jenkins, Bax, & Hart, 1980). However, given the lack of standard criteria for definition, figures vary quite widely across studies. Similarly, investigation of prognosis and causes of feeding problems is hampered by lack of a clear classification system.

Infant Colic
The causes of colic are unclear and, as a result, it has been classified variously as a feeding, regulatory or crying problem. Wessel, Cobb, Jackson, Harris, and Detweiler’s (1954) classic “rule of three” definition involves “paroxysms of irritability,
fussing, crying lasting more than 3 hours a day, on more than 3 days in 1 week” and continuing for more than 3 weeks, between the ages of 1 and 4 months. Colic is common, reported as occurring in 10–20% of babies in large community surveys (Crowcroft & Stachan, 1997). There may be little justification for using the term “colic” for a phenomenon that might be more parsimoniously viewed as persistent unexplained infant crying (St. James-Roberts, 2004). There are a number of theories of etiology, focusing on gastrointestinal dysfunction, central nervous system immaturity, and parental stress and anxiety. However, there is very little conclusive evidence to support these theories (Stifter & Wiggins, 2004), or to validate treatments that follow from them (Garrison & Christakis, 2000). Irrespective of cause, colic is a significant cause of parental stress and low confidence. A recent working party (Barr, St. James-Roberts, & Keefe, 2001) concluded that colic could most usefully be seen as a problem resulting from early individual differences in reactivity and the development of regulation. Although colic is seen by parents and professionals as a physical problem, rarely is there any known underlying condition, such as gastrointestinal disorder.

Failure to Thrive
