Rutter’s Child and Adolescent Psychiatry
Rutter’s Child and Adolescent Psychiatry
Companion CD-ROM

The CD accompanying this book contains:
• The complete text
• A full text search function
This CD is suitable for both PC and Mac
Rutter’s Child and Adolescent Psychiatry

Edited by

Michael Rutter  CBE, MD, FRCP, FRCpsych, FRS, FMedSci, FBA
Professor of Developmental Psychopathology
MRC, Social Genetic and Developmental Psychiatry Centre
Institute of Psychiatry, King’s College London
London, UK

Dorothy V. M. Bishop  MA, DPhil, FBA, FMedSci
Professor of Developmental Neuropsychology
Department of Experimental Psychology
University of Oxford, Oxford, UK

Daniel S. Pine  MD
National Institute of Mental Health (NIMH)
Intramural Research Program
National Institutes of Health
Bethesda, MD, USA

Stephen Scott  FRCP FRCPsych
Professor of Child Health and Behaviour
& Consultant Child and Adolescent Psychiatrist
Department of Child and Adolescent Psychiatry
Institute of Psychiatry, King’s College London
London, UK

Jim Stevenson  BA, MSc, PhD, CPsychol, FBPsS
Professor of Psychology
School of Psychology
University of Southampton
Southampton, UK

Eric Taylor  MA, MB, FRCP, FRCpsych, FMedSci
Professor of Child and Adolescent Psychiatry
Department of Child and Adolescent Psychiatry
Institute of Psychiatry, King’s College London
London, UK

Anita Thapar  MBBCH, FRCPsych, PhD
Professor of Child and Adolescent Psychiatry
Department of Psychological Medicine
Cardiff University
Cardiff, UK

FIFTH EDITION

Blackwell Publishing
Contents

Contributors, vii
Preface to Fifth Edition, xiii
Preface to First Edition, xv

Part I: Conceptual Approaches
1 Developments in Child and Adolescent Psychiatry Over the Last 50 Years, 3
   Michael Rutter and Jim Stevenson
2 Classification, 18
   Eric Taylor and Michael Rutter
3 Neurodevelopmental Disorders: Conceptual Issues, 32
   Dorothy Bishop and Michael Rutter
4 Clinical Assessment and Diagnostic Formulation, 42
   Michael Rutter and Eric Taylor
5 Using Epidemiological and Longitudinal Approaches to Study Causal Hypotheses, 58
   E. Jane Costello
6 Using Epidemiology to Plan Services: A Conceptual Approach, 71
   Michael Rutter and Jim Stevenson
7 Children’s Testimony, 81
   Maggie Bruck, Stephen Ceci, Sarah Kulkofsky, J. Zoe Klemfuss and Charlotte Sweeney
8 Legal Issues in the Care and Treatment of Children with Mental Health Problems, 95
   Brenda Hale and Jane Fortin
9 What Clinicians Need to Know about Statistical Issues and Methods, 111
   Andrew Pickles
10 Health Economics, 123
   Martin Knapp
11 What Can We Learn from Structural and Functional Brain Imaging? 134
   Christopher Frith and Uta Frith
12 Neurobiological Perspectives on Developmental Psychopathology, 145
   Charles Nelson and Shafali Jeste
13 Development and Psychopathology: A Life Course Perspective, 160
   Barbara Maughan and Michael Rutter
14 Temperament and Personality, 182
   Avshalom Caspi and Rebecca Shiner
15 Sociocultural/Ethnic Groups and Psychopathology, 199
   Anula Nikapota and Michael Rutter
16 Basic Neuropsychopharmacology, 212
   Nora Volkow and James Swanson
17 Clinical Neurophysiology, 234
   Torsten Baldegew and Stewart Boyd
18 Psychological Treatments: Overview and Critical Issues for the Field, 251
   John Weisz and Sarah Kate Bearman

Part II: Clinical Assessment
19 Use of Structured Interviews and Observational Methods in Clinical Settings, 271
   Ann Le Couteur and Frances Gardner
20 Using Rating Scales in a Clinical Context, 289
   Frank C. Verhulst and Jan Van der Ende
21 Psychological Assessment in the Clinical Context, 299
   Tony Charman, Jane Hood and Patricia Howlin
22 Physical Examination and Medical Investigation, 317
   Gillian Baird and Paul Gringras

Part III: Influences on Psychopathology
23 Genetics, 339
   Anita Thapar and Michael Rutter
24 Behavioral Phenotypes and Chromosomal Disorders, 359
   David H. Skuse and Anna Seigal
25 Psychosocial Adversity and Resilience, 377
   Jennifer Jenkins
26 Acute Life Stresses, 392
   Seija Sandberg and Michael Rutter
27 Impact of Parental Psychiatric Disorder and Physical Illness, 407
   Alan Stein, Paul Ramchandani and Lynne Murray
28 Child Maltreatment, 421
   David P. H. Jones
29 Child Sexual Abuse, 440
   Danya Glaser
30 Brain Disorders and their Effect on Psychopathology, 459
   James Harris
31 Psychopathology in Refugee and Asylum Seeking Children, 474
   Matthew Hodes
32 Residential and Foster Family Care, 487
   Alan Rushton and Helen Minnis

Kenneth J. Zucker PhD
Psychologist-in-Chief, Centre for Addiction and Mental Health; Head, Gender Identity Service, Child, Youth, and Family Program, Toronto, Canada
Preface to the Fifth Edition

In most respects, this Fifth Edition follows the tradition laid down by previous editions. However, it is different in several key respects. Most obviously, there has been a major increase in the number of editors. We wished to make the editorial team both international and interdisciplinary because the authorship has been both for quite some time. Most especially, we wanted to expand the range of expertise covered by the editors in order that we could have rigorous detailed peer review of all chapters. In this edition, each and every chapter (including those by editors) has had detailed critique from at least three (usually four or five) editors. As a result, all chapters have been revised to deal with editorial criticisms and suggestions. This means that chapters in this volume were peer reviewed with the same detailed rigor as would be the case for any high-standard scientific journal.

Throughout the various editions of the book, there has been a committed attempt to integrate scientific and clinical perspectives. In this edition, however, we have made a number of substantial changes in order to do this in a much more thorough fashion. The first section of the book, comprising 18 chapters, deals with conceptual approaches. The purpose of these chapters was not to provide an encyclopedic summary of what is known on different areas of science or different methods of interventions but rather to convey a lively picture of the concepts, principles and approaches in each case and to indicate why each was important and relevant for clinical practice. Some of the topics were covered in previous editions but several are new to this edition. Thus, there are chapters on how epidemiological/longitudinal methods may be used both to study causal hypotheses and to plan services. There is a chapter on what clinicians need to know about statistical methods and issues, another chapter deals with the field of health economics and another on what can be learned from structural and functional imaging. Other chapters include development and psychopathology, temperament and personality, basic psychopharmacology, psychological treatments, clinical neuropsychology and brain development. The opening chapter in this conceptual section deals with developments in child and adolescent psychiatry over the last 50 years. Previous editions have included chapters on history but this time we thought it appropriate to try to bring things up-to-date. Inevitably, in dealing with very recent history, we are having to discuss developments that are too new to have stood the test of time but we have sought to highlight what seemed to us some of the important landmarks. As before, there are chapters on classification and diagnosis, children’s testimony and legal issues in the care and treatment of children with mental health problems and on culture, ethnicity and psychopathology. With respect to classification, there is a new chapter dealing with the concept of neurodevelopmental disorders that has come into increased prominence in recent times.

There is a short section with four chapters on clinical assessment in which the new approach has been focusing on the particular way in which structured techniques (with respect to interviews, questionnaires and psychometrics) can be applied in the clinical context. As before, there is a chapter on physical examination and medical investigations.

The next section of 11 chapters concerns influences on psychopathology. Most of these have parallels in previous editions but, this time, more attention has been paid to providing an understanding of the ways in which the possible influences might work and on testing for mediating effects. The section also includes a new chapter on psychopathology in refugee and asylum seeking children, as this is a group that has come to increasing attention in recent years.

The aim of all the chapters up to now has been an understanding of mechanisms rather than a detailing of effects in individual disorders, because we thought these were better covered in the separate chapters on clinical syndromes. However, in order to ensure that the chapters on specific disorders did, indeed, provide an up-to-date account of relevant findings, all authors were asked to pay particular attention to evidence on genetic influences, on imaging findings, on developmental features and on treatment methods – because for all of these there have been major advances since the last edition. The coverage of different clinical syndromes is fairly similar to that in previous editions, although it will be obvious that the information provided has moved on in important ways, but there is a new chapter on psychopathy (because its application to childhood seems to be of increasing interest) and on behavioral problems in infancy and in preschool children.

The final section of the book deals with a range of different approaches to treatment. In some respects, there were parallel, comparable chapters in previous editions but there are several innovations. Thus, community-wide and targeted interventions now have separate chapters and more attention is paid to some of the principles in these types of prevention. The chapter on physical and pharmacological treatments is complementary to that on basic psychopharmacology in that it looks at the ways in which clinicians need to think about
PREFACE TO THE FIFTH EDITION

the use of medication. There is also a new chapter on the organization of mental health services – again, focusing on the principles rather than on the details which vary so greatly across countries.

As with previous volumes, we have made quite a few changes in authorship both to bring in new blood and to include experts who have something special to offer. Well over half the chapters have a new main author and, if co-authors are also considered, the number of new authors is even greater. We are grateful to the good work provided by authors of previous editions but we also welcome the great strengths provided by the new team of authors. We feel ourselves fortunate in having succeeded in obtaining world leaders as the authors for most chapters.

Finally, Michael Rutter would like to express deep thanks to his fellow editors. The editorial team has been a pleasure to work with, has hugely helped with providing a distribution of workload but, even more importantly, has contributed ideas, fresh ways of thinking about things and a much greater breadth and depth of expertise.

The Editors

Acknowledgments

We are most appreciative of all the authors’ high level of expertise and effort and of their constructive responsiveness in dealing with the many editorial suggestions on new material that needed adding, topics that required strengthening, extension of the international coverage that was desirable, clarifications that would help readability and integration across chapters. We have indeed been most fortunate in having such a strong team of leaders of the field. We would also like to take this opportunity of expressing our immense gratitude to Professor Lionel Hersov who first had the idea for this textbook, and who was a tower of strength in preparing the first three editions before he decided to stand down from the fourth. We hope that he will be pleased to see what the book has grown into.

The production of this book has been very much a team effort and the book would not have been possible without the excellent team that we have had. Most of all, special thanks are due to Sandra Woodhouse who exercised overall administrative responsibility for the complex process of working with coordinating editors, in checking chapters prior to submission to the publishers, and in dealing with the copyediting and proofreading. She was adept at spotting when problems were arising and in sorting them out. The editorial team owes much to Jenny Wickham who had the main responsibility of dealing with Michael Rutter’s joint chapters and those for which he was coordinating editor. In this way, she played a key role in the overall cohesive and effective editorial team. We are also most indebted to Rob Blundell of Wiley-Blackwell who oversaw the book from start to finish and who stepped in to undertake detailed checking and rechecking of proofs when that process ran into temporary difficulties. Thanks are also due to John Forder who was an exceptionally astute and thorough proof reader and to Jonathan Burd for his professionalism in preparing the index.
Preface to the First Edition

These are exciting times for anyone working in the field of child psychiatry. A wider understanding of child development now throws a clearer light on deviations from the normal pattern; knowledge of the nature and causes of psychiatric disorders in childhood is steadily increasing; new and effective methods of treatment are evolving; and clinical and education services for children with mental disorders are growing in scope and sophistication. The first academic departments of child psychiatry in the UK are now established to meet the needs for teaching and research and to add to the existing body of knowledge. A serious concern to raise training standards in the specialty has led to recommendations on the range of content of training and a national exercise to visit and appraise all training schemes is under way.

For these reasons the time seemed ripe for a new and different textbook of child psychiatry. Our aim has been to provide an accurate and comprehensive account of the current state of knowledge through the integration of research approaches and findings with the understanding that comes from clinical experience and practice. Each chapter scrutinizes existing information and emphasizes areas of growth and fresh ideas on a particular topic in a rigorous and critical fashion, but also in practical vein to help clinicians meet the needs of individual children and their families.

In planning the book we had to decide how to choose authors of individual chapters. Obviously we wanted colleagues who had made important contributions in their fields of interest and who could write with authority and knowledge. We were fortunate in our choice and we are deeply indebted to all of them. We also decided that it would be appropriate to invite contributions from those who had worked at The Bethlem Royal and The Maudsley Hospital or its closely associated postgraduate medical school, The Institute of Psychiatry. Over the years “The Maudsley” has played a major role in training psychiatrists from all parts of the world and members of its staff have been among the leaders in both research and clinical practice. The fact that we have all worked at the same institution has produced some similarities: a firm acceptance of the value of interdisciplinary collaboration; an intense interest in new ideas and creative thinking; a commitment to the integration of academic and clinical approaches; a concern for empirical findings; and a belief in the benefits that flow from open discussion between people who hold differing views. As all of us work with children we have a common concern with developmental theories and with the process of development. However, as will also be apparent, we do not share any single theoretical viewpoint. A variety of theoretical approaches are represented in the chapters which also reflect a differing emphasis on biological, sociocultural, behavioural and psychodynamic aetiologies and formulations.

It is also fitting that this book should be based on The Joint Hospital as it has played such an important part in the development of child psychiatry. Children with psychiatric disorders were first seen at The Bethlehem Royal Hospital as long ago as 1800 and Henry Maudsley was unusual among the psychiatrists of his day in appreciating the importance of psychiatric disorders arising in childhood. In his Physiology and Pathology of Mind, published in 1867, he included a 34-page chapter on “Insanity of early life.” The Maudsley Hospital first opened its doors just over half a century ago, children have always been included among its patients and the Children’s Department became firmly established during those early years. Since then, and especially with the first British academic appointment in child psychiatry at the Institute of Psychiatry in the 1950s, it has trained many child psychiatrists who now practise in all parts of the globe.

The book is organized into five sections. The first eight chapters review different influences on psychological development in childhood and are followed by three that discuss the foremost developmental theories. A third section describes some of the crucial issues in clinical assessment and the fourth deals systematically with the various clinical syndromes and their treatment. The final section comprises six chapters that bring together knowledge on some of the main therapeutic approaches. We have sought to include most of the topics and issues that are central to modern child psychiatry, but there has been no attempt to cover all known syndromes and symptoms. Instead, the focus has been on concepts and methods with special emphasis on those areas where development of new ideas or knowledge has been greatest.

We hope that the book’s contents will be of interest and use to all those professionally concerned with the care, study and treatment of children with psychiatric disorders. We will be satisfied if, in the words of Sir Aubrey Lewis, it also helps the psychiatrist in training to acquire “reasoning and understanding” and fits him “to combine the scientific and humane temper in his studies as the psychiatrist needs to.”

M. Rutter
L. Hersov

Plate 12.2 The formation of the neural tube. The left side of the figure illustrates this in cartoon form, whereas the right side displays an electron micrograph of the same process. Moving from top to bottom shows the initial formation of (a) the neural plate and (b) the neural groove.

Plate 16.1 (a) A simplified diagram of the molecular targets that participate in synaptic neurotransmission and that are relevant for the effects of medications, illustrated for dopamine (DA), to show their concentration in the human brain as assessed with positron emission tomography. Courtesy of Fowler and colleagues at Brookhaven National Laboratory.
Plate 16.1 (b) Top left panel shows brain images for the distribution of [11C] methylphenidate (MPH) in the brain and right panel shows the time activity curves for [11C] MPH in striatum alongside the temporal course for the self-reports of “high” after 0.6 mg/kg i.v. MPH. Bottom left panel shows brain images for the distribution of [11C] cocaine in the brain and right panel shows the time activity curves for [11C] cocaine in striatum alongside the temporal course for the self-reports of “high” after 0.5 mg/kg i.v. cocaine. Note that, while it is the fast uptake of the drugs in brain that correlates with the “high” their rate of clearance does not. This is particularly apparent for MPH where the “high” is of short duration despite the slow clearance of the drug from the brain. After Volkow et al.
Plate 16.1 (c) Left panels show the images of the distribution of $^{18}$F haloperidol and that of the dopamine (DA) D$_2$ receptor radioligand $^{18}$F N-methyl spiroperidol (NMSP). Note the widespread binding of $^{18}$F haloperidol in brain and the restricted binding of NMSP to the basal ganglia, which is where the DA D$_2$ receptors are located. Right panel shows the time–activity curves of $^{18}$F haloperidol in the brain of a control subject who is not being treated with haloperidol alongside the time–activity curves of a subject who is being treated with haloperidol, tested while on the medication and 2 days after its discontinuation. Note the much faster clearance of $^{18}$F haloperidol from brain in the medicated patient from the non-treated control and also note the slowing of its clearance even after 2 days of discontinuation. NMSP images are courtesy of Brookhaven National Laboratory and $^{18}$F haloperidol data is from Schlyer et al. (1992).

Plate 16.1 (d) Left panel shows brain images of the distribution of the antidepressant drug $^{11}$C N-methyl-mirtazapine and right panel shows the time–activity curves for its concentration in the various brain regions, from Marthi et al. (2004). With permission of Springer Science and Business Media.
Plate 16.2 (a) Left panel shows images obtained with \[^{11}C\] cocaine used as a dopamine transporter ligand obtained 120 minutes after placebo and after 20 mg oral methylphenidate (MPH). Right panel shows the levels of dopamine transporter (DAT) blockade as a function of doses of oral MPH adjusted to the weight of the subjects (top) and the concentration in plasma of \(d\)-threo MPH (active enantiomer of MPH). Note the significant decrease in the binding of \[^{11}C\] cocaine in striatum even after a 20-mg oral dose of MPH. Notice also that typical doses of oral MPH blocked DAT. After Volkow et al. (1998).
Plate 16.2 (b) Left panel shows $[^{18}F]$ N-methyl spiroperidol (NMSP) images of a control and of a subject being treated chronically with haloperidol. Right panel shows the relationship between plasma haloperidol concentrations and dopamine (DA) $D_2$ receptor blockade.

Plate 16.2 (c) Left panel shows images obtained with $[^{11}C]$ raclopride after placebo and 120 minutes after oral MPH (60 mg). Note the decrease in the binding in striatum after MPH secondary to DA increases. Right panel shows measures of DA $D_2$ receptor availability in striatum after placebo and after MPH. The difference in the measures of $B_{max}/K_d$ is used as a measure of relative changes in DA. Regression plots between the level of DAT blockade and the changes in DA induced by 60 mg oral MPH. Note that the variability in the changes in DA cannot be accounted for by the differences in DAT blockade. From Volkow et al.
Plate 17.1 Hierarchical processing stages are characterized by distinct ERP patterns which are generated in distinct neuroanatomic regions (after Halgren & Marinkovic, 1995). The brain regions implicated in generation of specific event-related potential (ERP) components are outlined schematically in the corresponding color.

1 Sensory ERP components (P1, N1, P2) are generated in primary (outlined in light blue) and secondary sensory cortices.
2 An orienting complex, consisting of N2 (or MMN), P3a and slow wave (SW) is generated in medial (cingulate gyrus) and lateral frontal and posterior parietal cortices (outlined in dark blue).
3 Endogenous N4 and P3b components, associated with event integration, are generated in the hippocampus, amygdala (shaded in red) and associated inferotemporal and lateral orbitofrontal cortices (outlined in red).
4 The response-locked readiness potential (RP) during response preparation can be recorded in central cingulate gyrus and associated supplementary and premotor cortices (outlined in green).
5 ERP components correlated with performance monitoring, such as the error-related negativity (ERN), are generated in the anterior cingulate cortex (outlined by a broken green line).

Other ERP components mentioned in the text, such as slow cortical potential shifts (SCP) and language-related ERP are not shown here for clarity. The timescale is approximate and ERP are shown with negativity upward.

Plate 16.2 (d) Metabolic response to MPH and placebo under double-blind conditions with expectation varied. Note that MPH had a larger effect on brain metabolism when it was expected than unexpected. The overall effects were in areas devoid of dopamine transporters (cerebellar vermis, thalamus and occipital cortex) and the brain response to MPH was enhanced in the left lateral orbital–frontal cortex when the drug was unexpected, suggesting involvement of a cortical–striatal–thalamic brain circuit.
Conceptual Approaches
1

Developments in Child and Adolescent Psychiatry Over the Last 50 Years

Michael Rutter and Jim Stevenson

State of Child and Adolescent Psychiatry 50 Years Ago

The development of child and adolescent psychiatry in the first half of the 20th century was well described by Achenbach (1974), Cameron (1956), Kanner (1959), Parry-Jones (1989) and Warren (1974) with respect to both its strengths and limitations. The establishment of community child guidance clinics, much influenced by the Mental Hygiene movement, had the value of viewing psychopathology in the context of young people’s real-life circumstances. The cost, however, was that there was both geographical and professional isolation from general psychiatry, pediatrics and academic research. Most treatment tended to be very open-ended and prolonged, usually without a well-defined focus (Rutter, 1982a). There tended, also, to be a rigid separation in the functioning of the unholy trinity of the psychiatrist, the psychologist and the psychiatric social worker. In addition, there was a tendency to blame parents for the disorders of their children – as indexed by concepts of the schizophrenogenic mother (Jackson, 1960) and “refrigerator” parents (Bettelheim, 1967), in relation to schizophrenia and autism, respectively. The dominant theories were the several varieties of psychoanalysis (Eisenberg, 2001), clinical practice was mostly not evidence-based, and there was a paucity of specific treatments (Chess, 1988). Furthermore, very little attention was paid to diagnosis. The prevailing terminology concerned “maladjustment” and official classifications referred only to “behavior disorders of childhood.”

However, very important changes were afoot (Rutter, 1998). Although systematic diagnosis was not yet in fashion, Kanner (who wrote the first definitive English-language textbook in 1935) had already done much to foster critical thinking about different patterns of psychopathology and to encourage a questioning approach (as exemplified by his 1969 paper on differential diagnosis). Also, his first description of autism (Kanner, 1943) not only provided a model of top-level clinical observation, but established the reality of a disorder that was distinctively different from others. Similarly, approaching diagnosis psychometrically rather than clinically, Hewitt and Jenkins (1946) wrote a pioneering monograph identifying different patterns of psychopathology. The tide was beginning to turn with respect to both diagnosis and classification in both child and adult psychopathology (Meehl, 1954).

Although biological causes had only a very limited role in clinical thinking at that time, Pasamanick and Knobloch (1966), in relation to their concept of a continuum of reproductive casualty, postulated the importance of prenatal and perinatal risk factors. Studies of children with epilepsy as, for example, by Pond (1961) and by Ounsted (1955) were also influential in pointing to the interplay between biological and psychosocial risk factors. The concept of so-called “minimal brain dysfunction” was beginning to be established. It did not stand the test of empirical investigation (Rutter, 1982b) but, nevertheless, it did force people to pay attention to biological risk factors. In the realm of treatment, the value of stimulants in the treatment of children with hyperkinetic disorders was beginning to be appreciated and, in adult psychiatry, neuroleptics were starting to be developed for the treatment of schizophrenia. At about the same time, there was the birth of behavioral therapies (Wolpe, 1958). At first, these were largely considered in relation to adults, rather than children, but the application to children soon followed (Rachman, 1962; Yule & Berger, 1972).

Academic child and adolescent psychiatry scarcely existed in the 1950s although there were some chairs in the subject in North America and mainland Europe and there were the beginnings of systematic clinical research (Hersov, 1986; Remschmidt & van Engeland, 1999; Schowalter, 2000).

However, the report that probably did most to change the field in a radical fashion was Bowlby’s (1951) review of “maternal deprivation” for the World Health Organization. Spitz and Goldfarb had previously drawn attention to the damaging effects of institutional care but Bowlby drew on a much wider range of evidence and did most to pull together the ideas. For quite a while, his views were treated with extreme hostility by both academic psychologists and by psychoanalysts. The former pointed to the weakness of much of the research and the latter to the heresy that the causal factors lay in real-life experiences rather than internal conflict. Despite the controversies, Bowlby’s observations on young children’s responses to separation from their parents led to enduring changes in hospital practice. Professionals, almost for the first time, were forced to become aware of young
children’s sensitivities and of the importance of personal social relationships. The pioneering films by Robertson and Robertson (1971) were particularly influential in persuading people of the reality of many of the features that Bowlby was emphasizing.

### Developments in Empirical Research Over the Last 50 Years

The fruits of empirical research over the last 50 years are considered in more detail in chapters throughout this book. Here, however, we seek to highlight some of the key developments in research strategies and research concepts, as well as giving credit to some of the pioneers who played a crucial part in taking the field forward (see also Clarke & Clarke, 1986; Hersov, 1986).

#### Longitudinal Studies

The value of long-term follow-up studies was most clearly established in Robins’ now classic study of deviant children grown up (1966). Her findings demonstrated the important links between conduct disorders in childhood and antisocial personality disorders in adult life; they also showed for the first time how psychopathology in childhood was associated with a much increased risk of adverse environments in adulthood. The several Californian longitudinal studies were important in showing the value of prospective longitudinal studies (Elder, 1974, 1998) and the first British national birth cohort study, established by James Douglas in 1946, blazed the trail for long-term longitudinal epidemiological studies (Douglas, 1964). In more recent times, the Dunedin (Moffitt, Caspi, Rutter et al., 2001) and Christchurch (Ferguson & Horwood, 2001) longitudinal studies have been particularly influential in showing the value of an hypothesis-testing approach and in demonstrating the importance of having multiple sources of measurement. Cohen’s “Children in the community” longitudinal study, too, was very informative on psychopathological progressions over time (Cohen & Brook, 1987; Cohen & Cohen, 1996). Accordingly, as a consequence, there is now a substantial body of knowledge on the continuities and discontinuities between psychopathology in childhood and adult life (Rutter, Kim-Cohen & Maughan, 2006; see chapter 13, this volume). The follow-up study of the Glueck’s sample of delinquent boys, undertaken by Laub and Sampson (2003) requires specific mention both because of the quite extraordinary duration of the follow-up (to age 70) and also because of its creative and rigorous combination of quantitative and qualitative approaches in order to gain an understanding, not only of risk and protective factors in relation to antisocial behavior, but also of the mechanisms through which they might operate. One key development was the recognition of the value of archival longitudinal data because of what could be gained from secondary analyses by researchers bringing new perspectives to the topic. Elder (1974, 1998) was a pioneer in that connection.

#### Epidemiology

With respect to epidemiology, the Isle of Wight studies (Rutter, 1989b; Rutter, Graham & Yule, 1970; Rutter, Tizard & Whitmore, 1970) showed how this could be useful for both the testing of causal hypotheses and for the planning of services. It was innovative in using systematic standardized interview techniques of tested reliability, in showing the value of using children as informants with respect to their own psychopathology, in demonstrating the frequency of mixed patterns of symptomatology (now more usually considered under the concept of comorbidity), in indicating the relatively strong associations between psychopathology and reading difficulties, in noting the differences between psychopathology beginning in childhood and that beginning in adolescence, and in observing the relatively low level of agreement among reports from different informants even when each had been shown to be reliable.

The Waltham Forest longitudinal epidemiological study was similarly important in noting that, contrary to the given wisdom of the day (and some opinions even now), psychopathological problems in the preschool period were often precursors of later psychiatric disorder (Richman, Stevenson & Graham, 1982). The clinical follow-up study undertaken later by Campbell (1994) gave the same message. More recently, a large-scale study of the prevalence of mental health problems in the UK has provided national benchmark estimates of the level of service needs in the population (Meltzer, Gatward, Goodman et al., 2000). All of the epidemiological studies noted the high proportion of individuals with manifest disorders who were not receiving treatment.

#### Measurement

Several developments warrant mention in the domain of measurement. To begin with, there was widespread appreciation that it was essential in interviewing to use systematic standardized approaches (see chapter 19). Two rather different ways of providing standardization have been employed. In North America, this was achieved through the use of a uniform set of structured questions giving rise to “yes” or “no” answers with respect to particular well-defined elements of psychopathology. The Diagnostic Interview Schedule for Children (DISC) and Diagnostic Interview for Children and Adolescents (DICA) represent methods of this kind (Reich, 2000; Shaffer, Fisher & Lucas, 1999; Shaffer, Fisher, Lucas et al., 2000). In the UK there tended to be a preference for investigator-based methods in which standardization is achieved by explicit specification of the psychopathological concepts and of the rules for their coding. This approach also differs in that the objective is the attaining of detailed descriptions of actual real-life behavior, rather than affirmative or negative answers to closed questions. Child and Adolescent Psychiatric Assessment (CAPA) provides the prototype for this approach in the field of general psychopathology (Angold, Prendergast, Cox et al., 1995) and the Autism Diagnostic Interview-Revised (ADI-R) does so in the field of symptomatology associated with autism (Rutter, Le Couteur & Lord, 2003). The 1950s had
seen the demonstration of the limitations of retrospective recall (Radke-Yarrow, Campbell & Burton, 1970) and this led to a preference for longitudinal data when they were possible. On the other hand, there was a recognition that, even with longitudinal data, there had to be a degree of retrospective recall. More recent reviews have shown both the value and the limitations of retrospective and prospective data (Hardt & Rutter, 2004). From a methodological point of view, Caspi, Moffitt, Thornton et al.’s (1996b) development of the life history calendar approach constituted an important step forward.

Somewhat similar developments took place in the design of questionnaires. On the whole, the UK preference has been for shorter scales and the US preference for longer ones. However, it has been shown that the agreement between the two tends to be quite high (Goodman & Scott, 1999) and with all scales there has been an appreciation of the importance of having measures that have parallel versions for parents, teachers and the children themselves. Key players in these developments include Achenbach and Edelbrock (1981) in the USA, and Rutter (1967) and Goodman, Ford, Simmons et al., (2003) in the UK. Another development, however, was the appreciation of the need for questionnaires that focused on specific features, as well as those that focused on general psychopathology. These are considered in more detail in chapter 20.

In parallel with the interviews to assess psychopathology, there was development of interviews to assess aspects of family functioning. Brown and Rutter (1966) and Rutter and Brown (1966) showed that reliable ratings were possible on quite subtle features such as warmth and hostility and that attention needed to be paid to tone of voice as well as the words used. This led to the development of measures of marital quality (Quinton, Rutter & Rowlands, 1976) and of negative expressed emotion (Brown & Rutter, 1966; Rutter & Brown, 1966). At first, the latter was based on lengthy interviews but briefer versions of reasonable reliability and validity were later developed (Magaia, Goldstein, Karno et al., 1986; Sandberg, Rutter, Giles et al., 1993).

In the field of observational studies, probably the most important development was the recognition of the value of using standardized situations as a way of providing a “press” for eliciting a particular behavior. Mary Ainsworth’s development of the “Strange Situation” measurement of attachment security/insecurity (Ainsworth, Blehar, Waters et al., 1978) and the Autism Diagnostic Observation Schedule (Lord, Rutter, DiLavore et al., 2001) for assessing autistic features constitute particularly good examples of this approach.

Binet had pioneered the measurement of intellectual level early in the 20th century. However, the field was taken forward in a major way by the scales developed by Wechsler for the measurement of intelligence in adults and in children (Wechsler, 1986, 1992). New standards were set and, through the establishment of separate verbal and visuospatial factors, the means were provided for the quantification of more specific cognitive skills and for the study of particular patterns of cognitive strengths and limitations (see chapter 21). Similarly, Neale (1958) pioneered measures of reading that differentiated between accuracy and comprehension, and Reynell (1969) did much the same with respect to her differentiation of language expression and comprehension. Basic research on memory functions was undertaken by Baddeley (1990) and by Tulving (1983) and there was the burgeoning development of a range of specialized tests of various neuropsychological functions – many at first to be used with adults and later extended to children (CANTAB, 1987; Connors, 1992; Reitan & Wolfson, 1993; Robbins, James, Owen et al., 1998).

## Diagnosis and Classification

In the 1950s, knowledge on diagnosis and classification in the whole of psychiatry was extremely limited. Robins and the Washington University group (Feighner, Robins, Guze et al., 1972; Robins & Guze, 1970) pioneered the revolution in thinking on the topic – arguing forcefully for the importance of diagnostic distinctions, providing standardized measures of psychopathology and demonstrating how the validity of diagnostic distinctions could be put to the test. The original work concerned adult disorders but the application to mental disorders in childhood soon followed (Cantwell, 1988; Rutter, 1965). The end product was the highly systematized classifications of DSM-IV (American Psychiatric Association, 2000) and ICD-10 (World Health Organization, 1996). There can be no doubt that these constituted hugely important advances, but they carried with them the disadvantage of implying that the diagnostic differentiations were much more valid than the evidence justified. A better balance has now been achieved between an appreciation of the value of rules and operationalization of concepts on the one hand, and, on the other, a recognition that the existing schemes are no more than a best guess that will have to be modified as new research findings become available. The issues are more fully discussed in chapters 2 and 4.

### Clinical Delineation of Hitherto Unrecognized Disorders

It is important to appreciate too that clinical observations have had a crucial role in the identification of diagnostic patterns. The best example of this is provided by Kanner’s (1943) delineation of the syndrome of autism, with a scrupulously careful and astute detailed account of the clinical features shown by 11 children – almost all of which have been validated by subsequent systematic research. However, there are many other examples (see chapter 4). The key point is that clinical discoveries are still being made and that each of these original observations necessarily led to a two-way interplay between research and clinical practice (Rutter, 1998).

### Psychosocial Influences

Several different types of advances have been important in providing an understanding of how family influences may affect psychopathology. Brown, working with adults, introduced the crucial methodological and conceptual checks needed to test for the causal impact of negative life events (Brown & Harris, 1989). Hetherington’s (1989, 2005) longitudinal studies of the effects of divorce and remarriage showed the value of multimodal
methods of measurement and highlighted some of the key mediating mechanisms and sources of individual differences. Harlow and Harlow’s (1965) experiments with rhesus monkeys, although somewhat controversial by contemporary ethical standards (Blum, 2003), were crucially important in showing that the influences involved intimate relationships (“love” in Harlow & Harlow’s language) and not just “stimulation” or feeding. Hinde’s studies with the same species were equally important in a different way, through the elegance of his experimental control and his demonstration of the effects of mother–infant separation in much more ordinary naturalistic circumstances (Hinde & McGinnis, 1977). Patterson (1981) was equally pioneering in his combination of quantitative observational studies and studies of intervention with humans. The result of these various developments has been an appreciation of the reality of family influences, together with an acceptance that the magnitude of effects has been exaggerated in the past (Rutter, 2005a).

In parallel with studies of the family, a range of studies has also demonstrated the importance of school influences (Rutter, Maughan, Mortimore et al., 1979; Rutter & Maughan, 2002), of peer group influences (Dodge, Dishion & Lansford, 2006) and of community effects (Sampson, Raudenbush & Earls, 1997). The old style exclusive focus on parenting has given way to a realization of the much broader operation of psychosocial influences outside, as well as inside, the family. Bronfenbrenner (1979) was especially influential in pointing to the interplay between these various social systems. More recently, there has been demonstration of the impact of prenatal, as well as postnatal stress effects (McEwan & Lasley, 2002), of prenatal effects of physical toxins (Rutter, 2005b) and of the effects in adolescence of heavy cannabis use (Arseneault, Cannon, Witton et al., 2004). The sometimes long-term sequelae of physical and sexual child abuse have become better recognized (see chapters 28 and 29) and it has come to be appreciated that multiple indirect causal pathways may be involved (Rutter, 1989a), as well as more direct effects on brain functioning (Rutter, 2006b).

Testing Causal Hypotheses
Over the course of the 20th century, there accumulated a substantial literature on environmental risk and protective factors for mental disorders and, at first, it was assumed that the statistical association represented environmental risk mediation. Two key papers provided a major challenge to these associations. First, Bell (1968) noted that the associations could reflect children’s influences on family interactions and functioning, as well as socialization effects deriving from children’s upbringing in the family. This seminal paper had been preceded by Thomas, Chess, Birch et al.’s (1963) demonstration of the importance of children’s temperamental features (at that time termed “primary reaction patterns”). Second, Plomin brought together an impressive body of evidence showing that some of the effects of environmental risk factors were actually genetically mediated (Plomin & Bergeman, 1991). At first, many psychosocial researchers were reluctant to accept the validity of both challenges but eventually the message was accepted and greater reliance came to be placed on the range of epidemiological and/or longitudinal designs that could deal with the possibilities of child effects and of genetic mediation (Campbell & Stanley, 1963; Rutter, 1981; Rutter, Pickles, Murray et al., 2001; Rutter, 2007; Shadish, Cook & Campbell, 2002; see chapter 5). The result was a convincing demonstration of the reality of environmental risk and protective effects, combined with a realization that many of the effects were quantitatively quite small (a recognition that paralleled the comparable conclusion on the effects of individual genes – see below).

Animal Experiments
Up until very recently, child psychologists and psychiatrists have paid rather little attention to animal studies. Bowlby (1969) deserves high credit for his integration of human and animal studies in his consideration of the development of selective social attachments. Mention has already been made of the parenting studies of Harlow and Hinde. Suomi (2005) has carried the monkey studies forward in important ways through his investigation of the operation of gene–environment interactions, and Meaney (2001), through rodent studies, has revolutionized thinking on the ways in which early nurturing experiences may change gene expression – and hence alter genetic effects (Rutter, 2006a). Gross and Hen’s (2004) mouse studies of the serotonergic system were important in showing how early postnatal developmental processes have a key role in later anxiety-like behavior. Amaral and Corbett’s (2003) ablation studies of the amygdala in monkeys has cast new light on the role of this part of the brain in social stress reactions, and Insel and Young’s (2001) studies of voles have provided vital clues on possible genetic influences on social relationships. As indicated by the important studies of Rett syndrome, animal models have also been shown to be crucially important in testing hypotheses on gene actions (Guy, Hendrich, Holmes et al., 2001; Zoghbi, 2003). In addition, animal experiments have demonstrated the effects of experiences on brain structure and function (Greenough, Black & Wallace, 1987; Rosenzweig, Krech, Bennett et al., 1962).

Factors Within the Child
Temperament
The last 50 years have also seen the emergence of a strong interest in temperamental features as influences on psychological development and psychopathology. Three main approaches may be identified. First, Thomas, Chess, Birch et al. (1963) and Thomas, Chess & Birch (1968) used an inductive approach to parent reports to develop nine individual categories concerned with adaptation to the environment, and also composite constructs of “easy” and “difficult” child features. Second, Buss and Plomin (1984) used a more psychometric approach to pick out temperamental features that were both manifest early in life and also subject to strong genetic influences. Kagan and Snidman (2004) pioneered the combination of observational and physiological measures and argued that although temperamental
features could be dimensionally measured, they might operate more as categories at the extremes of the distribution. Caspi, Moffitt, Newman et al., (1996a) have also been especially influential through their demonstration of the long-term continuities from as early as age 3 years. Stevenson and Graham (1982) have queried whether the differentiation between temperament and psychopathology is valid, and Rutter (1987a) has highlighted the need to study the interconnections between temperament, broader concepts of personality and constructs of personality disorder.

Cognitive Features
In the 1960s, the ingenious and creative experimental studies of Hermelin and O’Connor (1970) were pioneering in showing that experimental methods could be applied even to young, handicapped, non-verbal children with autism, and in pointing to the likelihood that cognitive deficits would underlie the social impairments that were characteristic of autism. Their research paved the way to the more recent studies of “theory of mind” deficits, lack of central coherence and impairments in executive planning (Baron-Cohen, 1997; Frith, U., 2003; Happé, 1994). Somewhat similar attempts were made to identify specific cognitive deficits thought to underlie attention deficit/hyperactivity disorders (ADHD) (see chapter 34) and schizophrenia (see chapter 45). The results of research have proved somewhat more difficult to interpret in these two fields, but there is no doubt that the study of cognitive deficits is proving to be a most fruitful line of research (Pennington, 2002). The early studies did not address the neural basis of the deficits but that has changed with the availability of functional brain imaging and the recognition that cognitive neuroscience needs to integrate brain and mind (see below).

In parallel but separate from the study of cognitive deficits, there has been investigation of the possible role of cognitive biases in the origins of antisocial behavior (Dodge, Bates & Pettit, 1990; Dodge, Pettit, Bates et al., 1995), of depression (Beck, Rush, Shaw et al., 1979; Teasdale & Barnard, 1993) and in the development of internal working models of attachment relationships (Bremherton, 2005; Main, Hesse & Kaplan, 2005). There is now ample evidence of the existence of biased processing, and there is recognition of the likely psychopathological importance of such biases (Rutter, 1987b), but there continues to be a remarkable paucity of studies that have put causal hypotheses regarding the possible etiological role of cognitive biases to the test. That constitutes a major unmet research challenge for the future.

Brain Imaging
Major technological advances have made it possible to undertake quantified structural and functional brain imaging studies – particularly using magnetic resonance imaging (MRI) methods (see chapter 11). Claims have sometimes been made that the functional studies show the brain in action, but this conveys a somewhat misleading impression in that they do not identify the specific neural mechanisms. What they do do, however, is show the parts of the brain involved in particular mental tasks, or influenced by particular chemical substances. Provided that the studies are undertaken with the necessary experimental controls and the necessary between-task and between-group contrasts, they are invaluable in showing differences between psychopathological groups in the ways in which tasks are dealt with (see chapter 11). Thus, the functional imaging studies of individuals with autism have been informative in showing not just weak activation of the brain areas ordinarily involved in “mind reading” (which is poor in autism), but normal functioning in areas dealing with earlier aspects of sensory processing (Frith, C., 2003). The implication is that the deficit in autism probably lies in an impairment in neural connectivity rather than a deficit in any one localized brain area. Studies comparing the activation of brain systems associated with pharmacological and psychological interventions (Goldapple, Segal, Garson et al., 2004) have been informative in noting both similarities and differences in the medianation of therapeutic effects. The combination of molecular genetic and functional imaging strategies has been particularly informative in understanding inter-individual differences in human memory performance and memory-related brain activations (de Quervain & Papassotiriopoulou, 2006) and in demonstrating that the moderation of responses to stress and adversity brought about by a genetic variant of the serotonin transporter promoter operates in normal individuals and not just those with clinical depression (Hariri, Drabant, Munoz et al., 2005). Also, developmental studies using imaging methods are beginning to cast valuable light on the development of the brain (Gogtay, Giedd, Lusk et al., 2004; Shaw, Greenstein, Lerch et al., 2006) and of the changes in the brain following the onset of an overt schizophrenic psychosis (Rapoport, Addington, Frangou et al., 2005).

EEG Methods
During the 1970s and 1980s, optimistic claims were made regarding the potential of neurometrics – meaning the quantified application of electroencephalographic (EEG) methods (Prichép, 1983). The optimism has not been borne out by subsequent research, but functional imaging using magnetoencephalography (MEG) is providing the means to study the temporal processing of tasks, which complements the spatial processing studies by MRI. Its use is too recent to assess its potential but it appears more promising than neurometrics. In addition, evoked potentials and a range of other EEG techniques have proved their usefulness (see chapter 17).

Neurochemistry
Neurochemistry, too, suffered from premature claims – as exemplified, for example, by the so-called “pink spot” supposed to be characteristic of schizophrenia. The problem was that most of the research constituted little more than a gigantic fishing expedition based on the most rudimentary understanding of neurochemistry. During the last 50 years, however, there has been a dramatic growth in the understanding of neurotransmitters and their functions (Andreasen, 2001) and there is now the potential for a much more
focused hypothesis-testing approach which is likely to pay rich dividends (see chapter 16).

Genetics
Finally, there has been the tremendous growth in the recognition of the importance of genetic influences on psychopathology, and in the understanding of how they operate (see chapter 23). At first, there was considerable resistance to suggestions that genetic factors might be important but, over the years, the weight of evidence from twin and adoptee studies of high quality made it impossible not to recognize that there were important genetic influences on all forms of human (and animal) behavior (Plomin, DeFries, McClearn et al., 2001; Rutter, 2006a). Perhaps inevitably, this was accompanied by an unfortunate genetic evangelism seeking to dismiss the role of environmental influences, and to imply a much more deterministic role of genetics than is in fact the case. Nevertheless, the reality is that there is the imprint of genetic influences on almost all aspects of psychological functioning. The difference from the evangelism concerns the appreciation that many genetic influences are indirect, operating through gene–environment correlations and interactions. Hence, rather than separating disorders into those due to nature and those due to nurture, most disorders reflect a complex multifaceted co-action between the two (Rutter, 2006a; Rutter, Moffitt & Caspi, 2006). The potential of genetics has increased enormously through the possibility of identifying individual susceptibility genes (numerous pioneers were crucial in that connection; Rutter, 2006a), and through the appreciation of the value of studying gene–environment correlation and interactions (Eaves, Last, Martin et al., 1977; Plomin, DeFries & Loehlin, 1977; Rutter & Silberg, 2002). Empirical advances have come especially from the human epidemiological studies of Caspi, McClay, Moffitt et al. (2002), Caspi, Sugden, Moffitt et al. (2003) and Caspi, Moffitt, Cannon et al. (2005), the imaging studies of Weinberger and colleagues (Hariri & Weinberger, 2003; Hariri, Drabant & Weinberger, 2006) and the animal studies of Suomi (2005).

Randomized Controlled Trials
Preceding the work on “natural experiments” to test causal hypotheses was the recognition that, if the effects of planned interventions were to be tested in rigorous fashion, randomized controlled trials were essential, and the means to conduct them in a systematic fashion had to be developed. The key point underlying this recognition was the appreciation that it was likely that the individuals volunteering to receive some new treatment were likely to differ systematically from those who declined the treatment. The solution had to lie in random assignment to the new treatment and to the old treatment with which it was to be compared (Everitt & Pickles, 1999). In medicine as a whole, in the UK Hill (1965) was a pioneer in showing what was needed, and Cochrane (see Starr & Chalmers, 2003), also in the UK, was instrumental in pointing out the dangers of reliance only on published studies, because of the bias against publishing negative findings. Cochrane-style reviews of evaluations have come to be accepted as the standard. The USA has led the field in its recognition of the need for multicenter collaboration in order to test the effects of treatment and in its willingness to provide the funds to do this, such as the MTA trial on ADHD (see chapter 34) and the trial of antidepressants (see chapter 37). Harrington and others in the UK have also played a crucial part in undertaking randomized controlled trials and in emphasizing their importance (Harrington, Whitaker, Shoebridge et al., 1998a; Harrington, Kerfoot, Dyer et al., 1998b; Harrington, Whitaker & Shoebridge, 1998c). In the USA, Rapoport deserves particular credit, not just for the methodological rigor of her studies, but, more particularly, for her recognition of the need to test whether beneficial effects of medication were diagnosis-specific (Rapoport, 1980; Rapoport, Buchsbaum, Zahn et al., 1978). Earlier on, Eisenberg warrants special mention for a study that showed the negative effects of withdrawal or refusal of treatment, as distinct from treatment not being available as part of a randomized controlled trial (Molling, Lockner, Sauls et al., 1962). Almost all the early drugs used in psychiatry were discovered serendipitously, with little input from biological studies (Ayd & Blackwell, 1970). The field is now quite different as a result of the burgeoning of knowledge on neurotransmitters (see chapter 16).

More recently, Weisz highlighted the major differences between treatments delivered by experts in a research setting and what are supposed to be the same treatments administered on a community-wide basis by generalists rather than specialists – the results of the latter being much weaker in almost all cases (Weisz, Weersing & Henggeler, 2005). Weisz also has been influential in pointing out that only a tiny proportion of studies have included any kind of measurement of the factors mediating benefits (Weersing & Weisz, 2002a,b).

Treatment Advances
Both psychological and drug treatments have changed out of all recognition over the last 50 years. In the mid 20th century neither had much to offer, whereas now there is a substantial range of interventions bringing proven benefits. Initially, psychological methods were mainly based on a psychoanalytic approach focused almost exclusively on mental conflict and mental mechanisms rather than on real-life experiences; with a focus on the past rather than the present; and with an avoidance of any consideration of problem-solving strategies. Alternatively, they involved a rather general “supportive” function without specific focus or goals. Behavioral methods then came on the scene with their rather mechanistic application of learning principles to bring about specific changes in symptomatic behavior. They provided a huge challenge as a result of the limited evidence that they could be effective in the short term, and the much shorter duration and greater focus of the methods. In addition, they brought the claim of being based on a scientific foundation and the potential for identifying the mechanisms underlying treatment efficacy.

For some while, the psychodynamic and behaviorist camps
seemed to be in open conflict with one another. Six developments played a key part in changing that situation. First, systematic studies – such as that undertaken by Reid and Shyne (1969) – showed that, on the whole, time-limited focused psychotherapeutic methods were more effective than open-ended unfocussed ones. Second, Malan (1979) argued for the value of, and pioneered the use of, briefer psychotherapeutic techniques (with adults, but the point also applies to childhood). Third, both family therapy (see chapter 65) and attachment-based concepts (Holmes, 2001) forced greater attention to the here and now of social interactions and of problematic behavior. Fourth, psychologists began to develop interventions based on problem-solving approaches of various kinds. Fifth, psychologists and psychiatrists came to recognize the important role of cognitive processes and to develop cognitive methods of behavioral treatment (see chapter 63). Sixth, behaviorists similarly came to recognize the need to take into account both thought processes, and past, as well as present, experiences.

Important differences remain among psychological treatments but, to a far greater extent than previously, they have become more evidence-based and wider ranging in their methods. Amongst other things, this has meant that many interventions now include work in schools and in the community as well as work in the clinic, whether individual or family oriented.

Pharmacological treatments have undergone equally great changes. Fifty years ago dextroamphetamine was the only drug used with children (to treat hyperkinesis) and, with adults, chlorpromazine and reserpine were just about the only neuroleptics available. Neither antidepressants nor anxiolytics had come on the scene. Strikingly, then and to a considerable extent even recently, nearly all of the major classes of useful therapeutic drugs were discovered by chance rather than through basic biological research (Ayd & Blackwell, 1970). Of course, basic research into neurotransmitters has revolutionized our understanding of how drugs might work (see chapter 16) and clearly there is the potential for a much more rational development of new classes of drugs, but for the most part that has yet to happen. Later chapters review the evidence on what can be achieved by pharmacological treatments; here we simply draw attention to a few major themes.

In many respects, the most important change in therapeutic practice lies less in the details of individual methods than in the acceptance that practice needs to be evidence-based. This has led to the development of specific treatment guidelines such as those produced by the National Institute for Health and Clinical Excellence (NICE) in the UK (e.g., 2005), and in the USA by the Food and Drug Administration (FDA) (e.g., 2004), the American Academy of Pediatrics (e.g., 2001) and the American Academy of Child and Adolescent Psychiatry (e.g., Dulcan, 1997). Meta-analyses have been informative, not only in the assessment of efficacy, but also in the identification of risks, as with suicidality and antidepressant drugs (Hammad, Laughren & Racoosin, 2006).

Apart from the vast body of research on the use of stimulants to treat ADHD, most of the research with children has involved extrapolations from studies of adults. That has meant that, until very recently, drug companies have not bothered to test their products with children and very little is known on the extent to which benefits and side-effects are the same for children as for adults. The findings with antidepressants, although far from conclusive, suggest there may be important differences – as do the findings with regard to stimulants and cannabis. The effects of age differences, and the mechanisms they reflect, constitute a still largely neglected (but crucially important) research area. As a consequence of this neglect, most drugs used to treat children have not been specifically approved for use in this age group. Fortunately, the situation is being remedied in many countries and there is now at last an official pediatric formulary in the UK (British National Formulary for Children, Costello, 2005). The USA passed legislation in the late 1990s requiring manufacturers to assess the efficacy and safety of drugs likely to be used with children, and this led to increased drug company research on psychotropic drugs applicable to children (Wolraich, 2003).

As in adults, most psychiatric disorders in children are recurrent or chronic. Yet we know relatively little about the effects of drug treatments on long-term outcome. Also, there are sizeable groups of child disorders for which there is no very satisfactory drug treatment. That applies, for example, to autism spectrum disorders, conduct disorders, most anxiety disorders and substance abuse. Of course, there are drugs that bring about limited symptom relief in these disorders but their effects on the basic condition are unimpressive. It is notable that there are considerable international variations in the extent to which drugs are used to treat childhood psychopathology. Thus, their use in the USA is much greater than in the UK (Bramble, 2003; Wolraich, 2003).

As a result of these considerations, although we are very positive about the future of pharmacotherapy, our optimism is guarded and is accompanied by the view that if real progress is to be achieved, there will need to be much more fundamental research into drug actions in children, as well as into the neural underpinning of disorders, and also more experimental studies examining the complex (and sometimes seemingly contradictory) connections between the nature and timing of the neurochemical effects and the behavioral responses (Bundgaard, Larsen, Jorgensen et al., 2006).

Perhaps an even greater need, with respect to both psychological and pharmacological treatments, concerns the development of an understanding of the mechanisms underlying the large individual differences in treatment response. Pharmacogenomics should help but its achievements so far have been quite modest.

Theories

In many respects, one of the biggest changes during the last 50 years has been the demise of the “big” theories purporting to explain the whole of life and seeking to provide support through the provision of a religious certainty. That was the style of psychoanalysis when one of us (M.R.) first entered psychiatry and it was followed by the somewhat similar style
Nevertheless, developmental psychopathology has provided an
invaluable research and conceptual perspective that has proved
to be as relevant for adult as for child psychiatry (Rutter, in
press). There has been an explicit focusing on continuities and
discontinuities in risk processes and psychopathology across
the lifespan and between normality and disorder. Amongst
other things, this has led to a recognition of the importance
of early neurodevelopmental impairment in schizophrenia
and of early life experiences in the genesis of depression, as
well as the high frequency with which adult mental disorders
have their first onset in childhood (see chapter 13).

The Growth of Academic Child and
Adolescent Psychology and Psychiatry

As several reviews have documented, academic child and
adolescent psychiatry was already being established in both
Europe and North America during the first half of the 20th
century (Remschmidt, 1996; Schowalter, 2000), but it really
took off after World War II when it came to be recognized
as a specialty in most major countries, professional appoint-
ments began to be established (so that they now exist in most,
but not all, medical schools), official training standards were
established during the 1960s–1980s, and there was a tremend-
ous increase in the number of scientific publications and
in the availability of research training fellowships (Hersov,
1986). In that connection, reference must be made to the role
of the Journal of Child Psychiatry and Psychology (JCPP) and
the Journal of the American Academy of Child and Adolescent
Psychiatry. The JCPP, although developed by a pioneering
psychoanalyst, Miller, was crucial in its explicit rejection of
adherence to any particular theory and in its interdisciplinary
coverage. It has gone from strength to strength since its
launch in 1956. The American Academy journal took much
longer to achieve the same breadth of approach but now it
too aspires to the same aims. Both journals have been import-
ant in seeking to emphasize research–clinical links.

It is clear that a child and adolescent psychopathology has
gained greatly in academic strength over the last 50 years.
Several features have probably played a part. Most especially,
child psychiatry has gained enormously from the central
involvement of leading psychologists in most of the key
research developments. Sometimes this involved interdisci-
plinary collaboration but, especially in the USA, the psycho-
pathological advances took place independently of psychiatry
and outside medical schools. The research contributions of
psychologists have most especially concerned autism, ADHD,
antisocial behavior, depression, psychological treatments, gen-
etics and brain imaging – to give just a few examples. Some
of the pioneers have been recognized already in this chapter
and the role of others pervades all chapters of this book. Also,
many clinicians have received formal research training –
sometimes through training fellowships and sometimes through
working in research units and centers. In addition, researchers
have been quick to see the need and value of basic science and
of methodologies derived from basic science – such as quanti-
tative and molecular genetics, structural and functional brain
imaging, and experimental strategies, as well as hypothesis-testing approaches in epidemiological and longitudinal research.

Academic impetus has come from the centers, formal and informal, established by research pioneers who fostered the careers of numerous younger researchers (usually spanning a range of disciplines). The child psychiatry research societies (providing both mutual support and leadership) set up during the 1980s in both the UK and Germany served a similar role. What is striking in viewing the field as a whole is the extent to which concepts and findings in child psychiatry have made an impact on general psychiatry, and vice versa. A degree of autonomy in child and adolescent psychiatry has clearly been beneficial but its close research integration with the rest of psychiatry, with psychology and, to a lesser extent, with pediatrics has been equally crucial.

**Children’s Understanding and Role in Decision-Making**

Fifty years ago, scarcely anyone considered it either necessary or worthwhile to solicit children’s views on their placement when their parents’ marriage broke up, or on their medical treatment or on their participation in research. Today, it is widely accepted that it is essential and useful to determine children’s views in relation to treatment (British Medical Association, 2000) and to research (Royal College of Psychiatrists’ Working Party, 2001). The same applies to placements following family break-up. This massive change in view has derived in part from the growing body of evidence that even very young children can, and do, conceptualize and understand. Of course, compared with adults they are more limited in their ability to look back, look forward and anticipate long-term consequences, but their cognitive capacities clearly mean that their voices must be heard and taken into account as part of shared decision-making on all major issues, while at the same time recognizing that too much responsibility should not be placed on their shoulders.

All of this represents real progress, but both dilemmas and inequities remain. A key dilemma concerns the age of criminal responsibility, which varies incredibly widely across the world. The point is that whereas even preschool children have quite a well-developed sense of what is right and wrong, nevertheless, their overall ability to be fully responsible is less than that of most adults. Even more crucially, their actions will be influenced by their immaturity and their response to criminal court proceedings means that their needs should play a part in deciding how they should be dealt with (Commission of Families & the Well-Being of Children, 2005).

The chief inequity is that in many countries (including the UK and USA) it is illegal, as well as unacceptable, for adults to assault another adult but it is not illegal for parents to beat their children if “reasonable chastisement” can be claimed. In short, children have fewer human rights in that connection than do adults. The tide is turning in many European countries (as it did earlier with respect to corporal punishment in schools), but societies continue to be reluctant to abandon the notion that children are their parents’ property, with their parents having very wide permission to treat them in any way that they think fit. Much remains to be done.

**Ethics**

Across the whole of medicine there has come an appreciation of the need to pay serious attention to ethical issues in both treatment and research, and to accept that ethical review needs to be undertaken by interdisciplinary committees that are independent from the research and the researchers. This is not something specific to child psychiatry, although there is the particular need to be aware of the possible problems in adults taking decisions on behalf of children (Royal College of Psychiatrists’ Working Party, 2001). There is an awareness of the realities of research fraud and plagiarism (Giles, 2005), of experts in their court reports making unacceptable claims, of researchers destroying data to avoid them being examined when an accusation of fraud has been made (White, 2005), of acceptance of grants from grant-giving bodies having unaccept-able aims (such as racism), or having a long-standing record of suppressing unwanted research findings (as with tobacco funding; Glantz, Barnes, Bero et al., 1995), or concealing the source of their research funding. Strong concerns have also been expressed with regard to the role of pharmaceutical companies concealing findings, exerting influence on academic institutions and ghost-writing papers under the name of academics who have not had access to the data (Healy, 2004; but see Diller, 2006 for a balanced discussion of the issues).

We accept that there have been abuses but, equally, we think that some of the concerns have been somewhat unbalanced. Moreover, the involvement of drug companies in product development is essential and many companies have responded appropriately by taking steps to ensure fair practice. Unquestionably, standards have risen in a most important way. There is an emphasis on a required transparency with respect to both the conduct of research and its funding. Also, there is a general acceptance that there must be efficient research governance to ensure that ethical standards are maintained.

Equally, however, there is now a growing appreciation that it is in everyone’s interest that high-quality research be undertaken if our preventive and therapeutic services are to be improved in the future. Accordingly, there is some danger that mindless bureaucratic rules will prevent, or at the very least make very difficult, some of the types of research that are most needed (Academy of Medical Sciences, 2006). In many countries, including both the USA and the UK, consumer groups have had a very positive influence in urging that top-quality research is needed and that the challenge is to ensure that it is undertaken to the highest ethical standards. In that connection, a problem-solving approach is required. Consumer groups have also had a powerful advocacy role in pointing out the shortcomings in service provision and in making initiatives to improve services. Thus, in the UK this has been
CHAPTER 1

evident with respect to Young Minds (dealing with child and adolescent psychopathology generally) and both the National Autistic Society (NAS) and the Association For All Speech-Impaired Children (AFASIC) – to give but two examples of groups with more focused interests. The availability of the Internet has also meant that patients and their families are now much better able to come to clinics with both knowledge and incisive questions.

Organization of Services

The last 50 years has seen major changes in the organization and content of clinical services. It is not possible to provide a statement of universal trends because there are such great differences between countries (Remschmidt & van Engeland, 1999). Thus, for example, as Chess (1988) and Eisenberg (1986) described so vividly, in the 1950s and 1960s, American psychiatry (child and adult) was totally dominated by psychoanalysis, associated with an assumption that almost all causation was environmental, and that parents were largely to blame for the problems of their children. This was followed by a massive swing to biological models, leading Eisenberg (1986) to express concern that a “brainless” psychiatry was being replaced by a “mindless” psychiatry. Today, the use of drugs occupies a prominent place in therapeutic interventions in the USA to a degree that would have been inconceivable in the 1950s and 1960s. By contrast, despite a broadening of approaches and the development of community services, and psychodynamically oriented treatments, psychoanalysis continues to occupy a predominant position in French child psychiatry (Jeammet, 1999).

Nevertheless, despite these (and numerous other) divergencies, some important trends can be discerned that apply widely, albeit not universally. It has come to be generally accepted that there is an interplay among multiple causal influences – genetic, environmental and developmental – and that all adequate clinical services must provide a range of therapeutic interventions. Nevertheless, in most parts of the world, there is a continuing shortage of clinicians (of any discipline) who have been trained to an appropriate level in the growing list of treatments of demonstrated efficacy. Although the days are numbered for the single-therapy clinician who believes that one method serves all needs, such practitioners are still numerous.

There has also been a substantial growth in research-led specialist clinics devoted to the care of individuals with particular kinds of psychopathology and to the development of improved methods of treatment for such conditions; clinics for autism spectrum disorder, for ADHD, for conduct disturbances, for eating disorders, for obsessive-compulsive disorders and for depression all constitute examples of this kind. There can be little doubt that this constitutes a most beneficial advance, but it is important to ensure that a specific focus does not lead to neglect of a broad approach to the problems presented by individual patients. It is necessary also to consider what should be the future of the generalist clinician. We suggest that, as with the rest of medicine, it is likely that most clinicians will (and should) develop special areas of interest and expertise. We hope, however, that this will not lead to exclusionary approaches because there will always be a need to recognize that reasons for referral do not boil down to a list of predecided diagnoses.

The growth of these specialist clinics has led to an awareness that, for many conditions, it may not be desirable for an arbitrary division on age grounds between child/adolescent and adult psychiatry. Thus, a young person with a serious eating disorder needs to be assessed and treated by an eating disorder specialist who spans age groups, without regard for whether they are above or below the age of 16 (or whatever bureaucratic cut-off is in operation). There are special skills involved in dealing with children, and certainly it will usually be desirable to have in-patient units that cater specifically for different levels of maturity. Nevertheless, there is a need for an integration between child and adult psychiatry because of the research evidence that the majority of major mental disorders in adult life had their onset in childhood or early adolescence (Rutter, Kim-Cohen & Maughan, 2006).

Despite this desirable blurring of age boundaries, there has also been the growth of at least one relatively new age specialization – infant psychiatry. The positive aspect of this development has been the appreciation that very young children can and do suffer from mental disorders which require skilled assessment and treatment. The less desirable feature has been the often heavy, exclusive reliance on psychoanalysis and attachment theory, and the weak links with developmental pediatrics. It is also striking that there has not been the development of good services for young adults who suffer from the continuation of a neurodevelopmental disorder (see chapters 13 and 3). That is something that will have to be remedied in the years ahead.

There has been an appreciation that it is desirable that many mental health problems should be dealt with at the primary care level, without referral to specialized clinics. The use of community psychiatric nurses, school counselors and primary care consultative services are all examples. There has been a paucity of adequate evaluations of their efficacy and this is much needed, but the general notion of intervening early as part of universal services seems sound. The key challenge is to ensure that those providing these early interventions are appropriately trained and supervised, with adequate access to consultative advice when needed. It is also relevant that there have been major developments in special educational services (see chapter 74).

In some countries (such as the UK), a model of a multiltier service has developed, with different levels of expertise at each tier (Hill, 1999). In principle, that sounds desirable but it is less clear how well it works in practice. It was preceded by a breaking down of the divisions that had grown up between community child guidance clinics and hospital-
based psychiatric out-patient clinics. Increasingly, staff work in both settings. Once again, however, the aspiration of good integration between the two has not always resulted in the desired practice.

Two negative influences on service development need to be mentioned. First, economic goals have come to have an increasing dominance. In many places this has meant that clinicians are discouraged from participating in research because it is not a part of their clinical contract. Equally, however, clinical researchers are expected to provide clinical services that bring in funds, rather than those that make sense in relation to research and development goals. Second, in some countries (perhaps especially the UK), professional advancement for social workers and nurses has depended on their taking administrative responsibility rather than on their clinical skills as applied to the development of better methods of treatment.

Finally, we note that not all aspects of child and adolescent mental health services have developed equally strongly. In many places, forensic psychiatry, services for individuals with substance use disorders and services for those with an intellectual disability remain rather Cinderella-like subspecialties. It appears that, to a large extent, this is a consequence of a weaker integration between research and practice. There are positive developments in each of these areas but much remains to be done.

Conclusions

The last 50 years has seen an amazing revolution in child psychiatry, a revolution that parallels that in the rest of psychiatry. As a consequence, the body of knowledge, and the range of therapeutic interventions, have increased in a way that would have seemed scarcely conceivable 50 years ago. We welcome these many gains but we draw attention to four key issues. First, it is crucial to appreciate the giant strides made by the iconoclastic pioneers of half a century ago. Today, the need for researchers who will question the given wisdom of the day is just as great as it ever was. Second, the advances in basic science have opened up vital avenues of development for clinical practice, and it is essential that these are pursued in a vigorous fashion. Equally, however, we need to recognize that the pathways work in both directions. Namely, some of the creative ideas stem from clinical science as well as from basic science, and clinical science involves far more than the translation of findings from the laboratory to interventions at the bedside. Third, the supposed division between basic science and clinical science is somewhat artificial. Some of the most important science represents an amalgam of the two (Rutter, 2005c). Finally, we need to appreciate the crucial role of clinical observations. Their value has been dramatically evident in the identification of new syndromes but it is equally important in thinking about causal processes and about clinical interventions. The interplay between clinical practice and empirical research is two-way, not unidirectional.

CHAPTER 1

Classification

Eric Taylor and Michael Rutter

Purposes

Classifications are tools for thought and communication. They have to serve many purposes: communication among clinicians and researchers, application of research to clinical problems, guidance on practice, explanations to patients, and clinical reimbursement. For all these purposes, a good scientific classification should have the virtues of clarity, comprehensiveness, acceptability to users and fidelity to nature; also a scheme should change as understanding alters. Different purposes, however, call for different types of ordering.

Research into the psychopathology of young people requires groups of children who are reasonably homogenous with respect to what is being investigated, and replicability is crucial. It often does not matter very much if many cases are left unclassified, so long as those that are classified are classified accurately (but note the problems inherent in a focus on uncommon “pure” cases; see chapter 3). In mature sciences, a classification can itself be a scientific tool, as in cladistics, where the relations of bodily structure among animals are a means for studying evolutionary descent. This is occasionally the case in psychopathology – similarities between obsessions and stereotypies led to trials of a treatment for obsessive-compulsive disorder (OCD) in autism (Hollander, Phillips, Chaplin et al., 2005), and similarities between the symptoms of mania and attention deficit/hyperactivity disorder (ADHD) led to cross-disorder studies (Tillman, Geller, Craney et al., 2003). Researchers may not themselves need some of the practical implications of classification, but they do want their conclusions to guide practice, and therefore they wish to choose classes that practitioners will also recognize and use.

Clinical practitioners need to know how to apply research findings to an individual case, so a widely accepted classification scheme is indispensable. For them, a scheme leaving many cases unclassified has serious drawbacks because it cuts the bridge between their practice and the research that should inform it. Indeed, if research definitions have drifted too far from clinical ones, it may be quite misleading to generalize lessons from strictly defined research groups to broader and vaguer clinical ones. Clinical treatment has to define who does not need intervention as well as who does, so impairment is sometimes a necessary part of definition. Other clinical needs for classification – for example, in communication among clinicians, statistical record keeping and audit – mean that homogeneity of groups in severity and responsiveness to intervention may be more important than homogeneity with respect to cause.

Epidemiology and public health raise another set of requirements. Simplicity and robustness become more important than in clinical and research settings (where detailed and expert assessments are feasible). Impairment is not necessarily to be included. In defining populations at risk, or requiring early intervention, it may be important to include cases of disorder who are not yet impaired (cf. the use of statins to prevent coronary artery disease, or immunization against infections).

Communication with users and carers often has to interpret between classifications. Lay concepts of disorder are often different from those of professionals. A striking example was shown by Klasen and Goodman (2000), who elicited ideas about ADHD from parents that were based on the concept of a neurological disorder, contrasting markedly with those of primary care physicians, who used concepts of continuous variation and psychosocial influence. The public may try to make diagnoses explain the condition, whereas professionals are seeking only to describe.

Administration and management also need to classify. Those who purchase clinical care require ways of understanding costs, prices and outcomes for different kinds of clinical problem. Diagnoses are not a very good way of doing this, but other means of prediction such as “case complexity” have fared poorly and the combination of type and severity of condition remains the most widely used.

The variety of purposes has led the World Health Organization to a “family of classifications” adapted to different settings (Sartorius & Janca, 1996). They must not, however, be allowed to diverge too much. They all need to communicate with each other and to address essentially the same ideas. They all need a comparable approach to what is and what is not considered to be a disorder. They are all based upon cases and not people. There is very much more to be said about people than their casehood, and the extra requirements for a clinical formulation are dealt with in chapter 4.
DSM and ICD

ICD-10 (World Health Organization, 1996) and DSM-IV-TR (American Psychiatric Association, 2000) constitute the two major psychiatric classifications used throughout the world. Their predecessors (ICD-9 and DSM-III) were very different from one another and strenuous efforts were made to bring ICD-10 and DSM-IV much closer together. Those efforts were successful in achieving better international understanding and communication. Nevertheless, some differences remain in principle as well as in detail. DSM-IV, for example, has one scheme that is designed for both research and routine clinical usage, whereas ICD-10 has separate (but interlinked) schemes for these two rather different purposes, the research version being closer to DSM-IV. Comorbidity is dealt with in DSM-IV by making multiple diagnoses; in ICD-10 by making more use of combination categories and exclusion criteria to arrive at a single diagnosis where possible.

There is something to be said in support of deliberate differences when evidence is lacking to decide which of two alternatives is to be preferred. Further research comparing the two systems should provide for an empirically based choice in the future. For example, the two schemes differ in the rules to be followed in the diagnosis of attention deficit/hyperactivity disorder (ADHD – the term in DSM-IV) and hyperkinetic disorder (the ICD-10 term). The symptom lists are almost identical, but the two systems have different requirements for pervasiveness across situations, whether all problems or only some need to be present, and on the use of exclusion criteria in relation to comorbidity. The consequence is that ICD-10’s hyperkinetic disorder is a subcategory of DSM-IV’s ADHD; the grounds for translating one into the other are reasonably clear, and research findings to compare the two can be informative (Santosh, Taylor, Swanson et al., 2005).

The two schemes also differ in how they deal with emotional disorders with an onset in childhood. ICD-10 makes a distinction between separation anxiety that represents an exaggeration or prolongation of a normal stage of emotional development (operationally defined as requiring an onset before age 6 years and absence of a generalized anxiety disorder), whereas DSM-IV makes the diagnosis solely on the basis of symptom pattern without regard to either age of onset or generalized anxiety. The validity of the different diagnostic approaches could be compared, although so far little research has addressed this rather fundamental question. Unfortunately, in addition to these deliberate differences, there are other minor differences that, although trivial in themselves and seemingly inadvertent in their origins, have been found to have major implications – as shown, for example, by the findings with respect to post-traumatic stress disorder (PTSD). A difference between the two schemes in relation to just one item (numbing of general responsiveness) had a dramatic effect on concordance between the two schemes (Andrews & Slade, 1998).

In the future development of both classification schemes, we hope that international comparability can be achieved, with agreement between ICD-11 and DSM-V where that is possible; and where it is not, clear rules for translation. This chapter indicates several areas of uncertainty where research could lead to sounder judgment about how to arrange the taxons. Issues include how to conceptualize problems; how to deal with associated problems and overlapping conditions; changes related to age; and how far notice needs to be taken of advancing neurobiological knowledge.

Types

Classifications themselves can helpfully be classified into the following.

Types of Classification

Categories and Dimensions

The choice of a categorical or a dimensional system of ordering has generated much debate (Sonuga-Barke, 1998). A thoroughgoing categorical arrangement is often described, although only by its detractors, as a medical model. This is a highly misleading view of medicine, which incorporates dimensional as well as categorical approaches. One example would be that of blood pressure, which is a dimension distributed continuously in the population; elevated blood pressure (hypertension) is a diagnostic category, but it is based on the quantitative idea of the degree of elevation that entails significant risk and at which treatment is justified. Another example is that of anemia – not only are levels of hemoglobin continuously distributed, but the level that is judged to be a problem to treat will depend upon other factors, such as the cause and the society in which it is encountered.

Nevertheless, it is plain that there are many constraints on clinicians’ thinking that favor a set of categories. The output from many clinical encounters is a set of categorical decisions: a child either is, or is not, prescribed a drug – or admitted into a treatment program – or taken into care. It is therefore convenient (although obviously not essential) for diagnostic thinking to fall into the same mode. The convenience may be more apparent than real. It invites an immediate abuse – in which the treatment is determined directly and exclusively by the diagnosis. This possibility becomes all too real in some types of practice. The need of busy clinicians for simple rules of thumb, and the wish of some purchasers of health care to restrict treatment to mechanically defined groups and protocols, can lead to a lack of careful planning of care for the individual case.

It is sometimes said that categorical thinking is inherent in the human mind. It arises in the first months of life (Blewitt, 1994), and characterizes the lay theories through which non-experts perceive psychological abnormality (Schoeneman, Segerstrom, Griffin et al., 1993). Even if this is the natural tendency of the mind, especially when coping with complex information under pressure to make decisions, it is not necessarily the best approach. Artificial intelligence can increasingly
be used to assist in handling complex information sets, and need not be constrained by human infirmity.

Categories have other practical advantages (Klein & Riso, 1996); a single term, if carefully chosen, carries a great deal of meaning very conveniently and will be much more tractable in communication with parents and teachers than a large set of dimensional scores. These advantages have ensured that diagnostic schemes are mostly categorical; and dimensional ordering is for the most part either secondary or rather tentative and speculative (e.g., Appendix B of DSM-IV).

By contrast, when dealing with genetic and environmental risk factors, researchers usually find dimensional relations between risks and manifest disorders. Individual alleles are either present or absent, but their consequences are graded. Indeed, the distinctions between categories and dimensions should not be exaggerated. Generally, each can be translated into the other. A category can be expressed as a set of dimensional scores; and a profile of dimensional scores is a category. The degree to which an individual case fits a category can itself be a dimensional construct. Sometimes it is preferable to use both ways of thinking about a single domain. IQ is better conceived as a dimension when the purpose is to predict educational achievement, but low IQ (e.g., below 50) is better thought of categorically when the purpose is to consider whether structural disorder of the brain is likely to be present (see below). Hypertension is conveniently regarded as a diagnostic category when the purpose is to select cases for treatment; as a dimension when analyzing the physiological reasons for changes in blood pressure; and as a category again when considering the different factors determining variations in the most severely affected cases at the top of the range.

In spite of the difficulties involved, the testing of assumptions about the nature of the underlying problems is useful. One classic research strategy has been to examine distributions of cases along a continuum of severity to see if there is a discontinuity between normality and pathology (such as would be implied by a bimodal distribution). This often suggests continuity – but the power of tests for mixed distributions is low (Meehl, 1995) and even very large numbers of cases can fail to give unequivocal answers.

Some investigators have compared the effect size of a continuous measure with a categorical one in predicting an external association such as outcome. For example, Fergusson, Horwood & Lynskey (1993) argued on this basis that a dimensional measure of disruptive behavior in childhood gave a better prediction of adolescent outcome than a discrete category of childhood disorder. This may say more about the power of alternative statistical methods than about taxonomy, and it ignores the possibility that a strongly predictive category of antisocial behavior may be present, but one that is based upon the type of problems rather than the severity of disruptiveness. This was the conclusion of Bergman and Magnusson (1997) in another longitudinal study, predicting antisocial outcome, which included a wider range of possible predictors, physiological as well as behavioral. Moffitt (1993) also concluded, from analysis of the longitudinal course of a population cohort of boys, that an antisocial outcome in adult life was characteristic, not so much of the boys who had been the most disruptive adolescents, but those who had had the combination of early onset and neurodevelopmental impairments.

Another research strategy has been to examine the distribution of cases against a measure of presumed etiology and to seek a point of discontinuity; for example, in comparing successive levels of definition of hyperactivity against measures of neurodevelopmental delay and reporting that the putative risk factor was more common only in the most severe subgroup of “hyperkinetic disorder” (Taylor, Sandberg, Thorley et al., 1991). This strategy has not given unequivocal results. Latent class analyses, for example, have suggested not only the presence of subtypes of ADHD but also that they tended to breed true within families (e.g., Rasmussen, Neuman, Heath et al., 2004). The argument was for etiologically distinct classes. On the other hand, Gjone, Stevenson and Sundett (1996) addressed a similar question by comparing group heritability with individual heritability of ADHD symptoms in a twin study using multiple regression techniques: the extent to which co-twins showed a regression to the mean in their scores did not function differently at the extremes of the distribution. This was in keeping either with a more dimensional view (with heritability similar across the whole continuum) or with a single, very common category. The issues are not resolved, even for this rather well-studied condition.

In the current state of knowledge, clinicians are likely to use a mixture of dimensional and categorical ideas. They will seek to fit a child’s problems into an economical description of a pattern of disorder or several coexistent patterns. They will also grade some of their problems – the severity of the behavioral deviance, the level of impairment and the extent of risk factors. The level of IQ will be taken into account when judging whether neurodevelopmental impairments (such as those of language, attention or social communication) can be considered as deviant. The analysis of a case of schizophrenia will include differentiation of the severity of positive and negative symptoms. They should aim to elicit and record the full range of problems presented by an individual child and their context, and should not seek only to classify on a single axis.

There are many other examples in medicine of dimensional approaches being used as a supplement to a categorical classification. Oncologists regularly grade the degree of malignancy of tumors, and cardiologists measure the degree of occlusion of coronary arteries and the degree of exercise tolerance. The multiaxial system in child psychiatry (World Health Organization, 1996) provides a similar facility with respect to degree of social impairment and intellectual level, and DSM-IV provides a means of coding the severity of disorders, as well as the extent to which a disorder is in remission.

When a category is defined as a dimensional score above a cut-off, the exact cut-off chosen can seldom be defined absolutely. It may have been validated against clinicians’
judgment, or by finding the level that best differentiates referred children from the ordinary population. It may vary with cultural expectations, so it is hard to give absolute or universal criteria. Accordingly, the presence of functional impairment usually needs to be added to a definition. A disorder is often defined as a “harmful dysfunction” – there needs to be both a perturbation of ordinary function, at behavioral or cognitive level, and evidence that it is indeed causing impairment to the mental and social development of the child. The idea of impairment and its assessment are taken further in chapter 4.

Multiple Taxons

Single vs. Multiple Entities

Categorical classifications can be based on allotting cases to the single category they best fit, or on multiple categorization – a case may be simultaneously classified in several ways. It can be a good discipline to try to fit multiple problems into a single pattern, but it is also important to detect a secondary condition even when it is masked by a more obvious one.

One kind of multiplicity is obviously necessary: different domains of problems need different classifications. It makes no sense to ask whether a child has asthma or intellectual disability. They constitute problems of different types, and are best considered on separate axes. Field trials of early versions of the ICD (Rutter, Lebovici, Eisenberg et al., 1969; Tarjan, Tizard, Rutter et al., 1972) indicated that many disagreements between clinicians were of this type, and correspondingly that reliability among diagnostic raters could be increased if they were not asked to choose between (say) autism and severe intellectual disability, but were allowed to choose both, one on an axis of psychiatric symptoms and the other on one of intellectual ability. This not only increases agreement, but provides a richer conceptualization and an opportunity to code and examine the extent to which (in this example) intellectual ability modifies the course and treatment response of autism. A multiaxial system embodies this conceptual refinement; it differs from a multicategory system in that every axis needs a coding (even if the coding is of “no abnormality”). Axes of psychiatric symptoms, somatic diseases, psychosocial stressors and severity of impairment have been incorporated in the multiaxial version of ICD-10 (WHO, 1996). Specific learning disabilities and intellectual impairments are dealt with in rather different ways by DSM-IV and ICD-10 (in which they are independent axes); the important feature is that both, in different ways, allow the clinician to record, systematically and separately, the extent to which both general and specific learning impairments are present.

Multiaxial systems of classification have become the norm in child/adolescent psychiatry for five main reasons. First, they avoid false dichotomies resulting from having to decide between two diagnoses that do not, in any meaningful sense, constitute alternatives. The example given of autism or intellectual disability illustrates the point. The first gives information on the clinical syndrome whereas the second describes the level of intellectual impairment. Second, because there has to be a coding on each and every axis, the classification provides information that is both more complete and less ambiguous. Thus, in a multiaxial system the absence of a coding of intellectual disability could mean that the child had normal intelligence, or that the child was cognitively impaired but the clinician did not consider that it was relevant to the referral problem, or that the diagnosis was omitted by error. Third, it avoids artifactual unreliability resulting from differing theoretical assumptions. Thus, psychosocial adversity would be coded and present by both the clinician who viewed it as the main cause and by the clinician who saw it as only a minor contributor. The same would apply to somatic conditions such as cerebral palsy or diabetes. Fourth, it provides a means by which to note systematically, not only the presenting clinical picture, but also possible causal factors (or factors likely to influence prognosis or response to treatment) and degree of overall psychosocial impairment. Fifth, because of these features it represents a style of thinking that is much closer to most clinicians’ preferred style of conceptualization than is the case with a system that forces everything into the Procrustean bed of a diagnosis based only on symptom pattern.

Hierarchical Classification Systems

Most classification schemes make some use of hierarchies, based on a view that some conditions are fundamental and that, if others are present, they are likely to derive from the fundamental condition. The implication is that the former includes and accounts for the latter. Foulds (1976), for example, presented rating scale data from adult psychiatric in-patients to argue that the symptoms of people with schizophrenia usually included depression and anxiety; that those of people with depression did not usually include those of schizophrenia but did include anxiety; whereas people with anxiety did not usually show either depression or schizophrenia and were therefore at the bottom of a hierarchy of schizophrenia–depression–anxiety. There are evident dangers of circular reasoning, but with care the predictions can be tested. Clearly, this type of prediction would be unlikely to give a complete account of child psychopathology as a whole, but could be practical within groups of children sharing risk factors (such as diffuse brain damage) or with problems in a particular domain such as hyperactivity.

In this way, DSM-IV excludes the diagnosis of generalized anxiety disorder if it occurs exclusively during a mood disorder, or a psychotic disorder (such as schizophrenia) or a pervasive developmental disorder (such as autism), and ICD-10 does so if the criteria for a panic disorder or an obsessive-compulsive disorder are met. Both DSM-IV and ICD-10 exclude the diagnosis of autism if Rett disorder is present, and exclude the diagnosis of reactive attachment disorder if a pervasive developmental disorder is present. The general assumption that severe and pervasive mental disorders often give rise to secondary symptom patterns is well based; the
CHAPTER 2

problem is that the evidence to justify hierarchies is generally rather thin, and neither DSM-IV nor ICD-10 is consistent in its approach.

Polythetic/Monothetic Classes
Almost all medical classifications are polythetic. That is, cases are defined on the basis of having many, but not all, of a list of specified attributes in common. That is because variability in manifestation is a general biological feature, even with diseases solely due to one major gene. In the neuropsychiatric arena, such variability is evident in marked degree with conditions such as tuberculous sclerosis or the Fragile X anomaly. There is similarly great variability in the manifestations of autism, even between monozygotic twins with the same genetic liability: the phenotype extends from severe handicap to quite subtle disturbances of social function. It would not therefore be reasonable to require that the disorder in any particular individual had to have all the diagnostic features. The trouble is that, in the absence of a diagnostic test of some kind, there are real difficulties in deciding both how varied the manifestations could be and where and how the boundaries should be drawn. Latent class analyses may help but what are really required are external validators (see below).

Prototype vs. Algorithm
In allotting cases to classes, most clinicians use a combination of two strategies. The first is a kind of pattern matching: the profile of problems presented in the case is compared with a “schema” or “prototype” in the clinician’s mind. The clinical guidelines of the ICD-10 provide a set of descriptions of problems, which act as prototypes in this sense. This does not exclude a dimensional approach: a case can fit more or less well to a prototype, can be more or less typical, and can be of greater or lesser severity. Furthermore, a case may fit one or more separate prototypes (see Multiaxial Classification Systems, below). The mental processes involved are what distinguish it from the second form of case identification: the algorithmic. The research diagnostic criteria of ICD-10 and the whole of the DSM-IV system are founded upon an algorithmic approach, in which a number of possible features are recognized as present or absent. The features are then combined (often by simple addition) to determine whether a cut-off point for the disorder has been reached. This has the advantages of transparency and fidelity to the rules that are applied in research. It also provides a ready means of resolving boundary problems about whether a case does or does not reach the requisite severity for a diagnosis. The disadvantages are that it tends to lead to a large number of diagnoses being made in a single case, which may not be truly independent; and that it is hard to apply in practice because it is simply not feasible to go through the process for every diagnosis that might apply to the individual case. The replicability of the algorithmic process makes it much the preferred method for research purposes. The needs of practice tend to lead clinicians to adopt a prototypic approach. Algorithms are often applied in the specialist assessment of complex cases and in cases presenting diagnostic difficulty. Legal processes sometimes apply algorithms in an overmechanical fashion.

Lumping vs. Splitting
Grouping disorders into superordinate categories can be helpful in drawing attention to features they may have in common. This applies, for instance, to the neurodevelopmental disorders (see chapter 3). Oppositional and conduct disorders are regarded by ICD-10 as being closely linked rather than as separate disorders, with oppositional disorders representing an earlier version of the condition. The kinds of research to test this approach are developmental, with most conduct-disordered children having been oppositional at an earlier stage; hierarchical, with most conduct-disordered children showing or having shown the features of oppositional disorder; and associational, with both conditions having strong links with environmental adversity in family and neighborhood (see chapter 35).

The coexistence of conduct disorder with hyperkinesis is dealt with by a mixed category of hyperkinetic conduct disorder that is a subcategory of hyperkinetic disorder. This decision is based on evidence such as the developmental course, with hyperactivity predicting antisocial behavior but not vice versa; and genetic and neurobiological evidence suggesting similarity between hyperkinesis simple and hyperkinesis in the presence of conduct problems (see chapter 34). However, the appearance of conduct disorder has massive implications for substance abuse and personality problems, so the distinction is important to retain in classification.

A subdivision may need to be made for a single symptom – blood phobia has such striking differences from other phobias, in associations with fainting and slowed heart rate on exposure, that it needs a separate place. It must be admitted that many fine subdivisions – for instance, among the disorders of anxiety – are unvalidated, but only if they are made can their implications be explored.

General vs. Child-Specific
Children present in very different ways at different developmental stages. However, there are practical and conceptual difficulties entailed in changing diagnosis simply because one ages. The difficulties have increasingly led to child psychiatrists using similar categories of emotional disorder to those of adult psychiatry. Sometimes this can be misleading. Differences between depressive disorders in children and those in adults are quite marked: in heritability, in presentation and in response to medication (see chapter 37). Tricyclic medicines are known to be ineffective in childhood, yet they are often prescribed. This poor practice may be maintained by the lack of clear distinction between childhood and adult forms.

The decision about whether or not to split can increasingly be based on evidence from prospective longitudinal studies, in which people are examined both in childhood and as adults. There is, for example, a change in pattern of ADHD towards an adult presentation more of disorganization than of overactivity (see chapter 34). At the same time, the adult
and childhood forms show similar cognitive changes and responses to medication. The concept resulting is of a continuity in disorder with age-related differences in presentation.

Transcultural Issues

In general, the idea of using a single classification for all countries has worked well, and many types of problem have proved to be essentially invariant across cultures (see chapter 15). Exceptions to the rule, however, need to be noted lest investigators and clinicians in non-Western cultures apply taxons and metrics uncritically.

Other differences may reflect variations in the blend of risk and protective factors. Strongly religious societies, for example, may create both supports for those with disabilities and occasions for spiritual anxieties. A high rate of obsessional symptoms focused on religion in some Muslim countries (Fontenelle, Mendelowicz, Marques et al., 2004) could reflect either the opportunity for religious scrupulosity to develop or the functional value of obsessionality in promoting religious observance.

Other differences again result from differences between societies in the significance attached to particular problems. Examples come from lower concern about anxiety and more about oppositional behavior in Thailand by comparison with the USA (Weisz, Suwanlert, Chaiyasit et al., 1993); and in the contrast between the low rates of ADHD in Hong Kong when identified objectively and the high rates when identified by parent and teacher concern and ratings (Luk, Leung & Ho, 2002).

Validation of Categories

The classification of child psychopathology started with the taxonomy of how behaviors correlate with each other, notably Hewitt and Jenkins’ (1946) factor analysis of symptoms. Sophisticated multivariate analyses then led to the derivation of a larger number of syndromes based on symptom profiles (Verhulst & Achenbach, 1995). It was increasingly recognized that groupings based on patterns of symptomatology needed to be tested by their ability to predict criteria that are external to the symptomatology and that have clinical meaning and utility (Feighner, Robins, Guze et al., 1972; Cantwell, 1975; Rutter, 1978).

Clinicians sometimes assume that an ideal classification should be based on etiology; however, that is not so. Most successful medical diagnoses that work well are based, instead, on the underlying pathophysiology that gives rise to the clinical syndrome. For instance, diabetes is defined in terms of the metabolic abnormality and not on which pattern of susceptibility genes is present. Most disorders are multifactorial, and elucidation of causal factors is important chiefly because it is likely to lead to an understanding of the basic pathophysiology. There is not, and cannot be, a classification according to a particular cause because there is no single cause. However, in internal medicine, there usually is a final common pathophysiological pathway that leads to the clinical disorder. The goal should be the identification of the underlying pathophysiology of mental disorders, rather than finding the single main cause. We are a long way from reaching that goal at the moment. For the same reason, there cannot be any one validating test against some hypothetical gold standard. Instead, there has to be recourse to multiple validating approaches with the hope, and expectation, that when most point in the same direction, it is likely that the diagnosis has some meaningful discriminative validity. Accordingly, we summarize such evidence briefly before seeking to draw conclusions on the current state of play on diagnostic validity.

Biological Findings

In many respects, the clearest biological distinction is between severe intellectual disability (IQ below 50), mild intellectual disability (IQ 50–69) and the range of normal intelligence (Simonoff, Bolton & Rutter, 1996; see chapter 49). Individuals who are severely cognitively impaired have a much reduced fecundity and life expectancy, most show gross neuropathological abnormalities of the brain, and most have either clinical brain disorders (such as cerebral palsy or epilepsy) or marked congenital abnormalities. Their social class background, on the other hand, is generally similar to that of the general population. By contrast with severe cognitive impairment, most people with mild impairment show a normal fertility pattern and a normal life expectancy, but to a marked extent they are disproportionately likely to come from a socially disadvantaged background. The genetic influences are more likely than in the case of severe intellectual disability to reflect many genes operating as part of a multifactorial liability, and thus constitute the end of a continuum on the dimension reflecting normal variations in intelligence. (Some individuals will nevertheless have the same major genetic mutations as those found with severe intellectual disability.)

Autism is differentiated from the broad run of other psychiatric disorders by its reduced life expectancy (mainly due to deaths associated with epilepsy; Isager, Mouridsen & Rich, 1999) and by the high rate of epilepsy (about 25%). It does not differ from intellectual disability in either respect but it does differ with respect to the age of onset of epilepsy (Rutter, 1970; Volkmar & Nelson, 1990). Neuropathological studies are few, but the findings do not reflect the gross pathology that is typical of intellectual disability (see chapter 46). Furthermore, a larger than normal head size is associated with autism, by contrast with the small head size that is more usually characteristic of intellectual disability (Fombonne, Wostear, Cooper et al., 2001; Woodhouse, Bailey, Rutter et al., 1996).

Biological findings are beginning to find some differentiation among other disorders. Abnormalities on both structural and functional imaging are found in many cases of hyperkinetic disorder and OCD and the findings provide a substantial case for a neural basis for the disorders (at least as a contributory factor in etiology; see chapters 34 and 43). Neurodevelopmental impairment is also more likely than in ordinary children. However, there are limitations in how far these findings can
be used for validation. There are a few pointers to possible diagnostic specificity: the structural and functional changes in frontal and striate regions in hyperkinetic disorders probably differ from the limbic changes in obsessional and post-traumatic disorders, and those with bipolar disorder have more extensive abnormalities (including amygdala) than either. It is too early in investigation to be clear how robust and how generalizable such findings will turn out to be.

To some extent, similar problems apply to the associations between neurodevelopmental impairment (as indexed by motor delay and language impairment) and schizophrenia (Tosato & Dazzan, 2005): association is present, but far from universal, and found in similar forms in other disorders too. Life-course-persistent antisocial behavior differs from that which is adolescence-limited in its association with neurodevelopmental impairment and this helps to make a developmentally important distinction.

More recently, evidence has suggested that the misuse of psychoactive substances may have a coherent pathophysiology. A low striatal density of D2 receptors predicts a much bigger subjective reaction when people are given either intravenous methylphenidate (a D2 dopamine transporter inhibitor) or other euphoriant drugs (Volkow, Wang, Fowler, et al., 2002). Furthermore, a variety of different drugs, including heroin, alcohol and nicotine, all engage mesolimbic dopamine projections to the nucleus accumbens (Hyman, Malenka & Nestler, 2006). Genetic analyses are compatible with this view (see below). Therefore, it may be that substance misuse itself may come to be regarded as a mental disorder, rather than a lifestyle choice that only merits a diagnosis if it causes harm or physical dependence.

Drug Response

It might be expected that drug responses would help greatly in diagnostic validation. In general, at a scientific level they do not. As a first consideration, most drugs target multiple neurotransmitters and have several distinct therapeutic actions. For example, tricyclics have independent effects on disorders as diverse as depression, ADHD and nocturnal enuresis. Second, in many cases, the therapeutic effects are neither specific nor dramatic. There are substantial benefits at the group level but these are not sufficiently consistent at the individual level to help much in diagnosis; if someone who is depressed does not return to a normal mood following administration of antidepressants, this by no means rules out the diagnosis of depression. Marked individual variations in drug response are common throughout medicine. Third, many drugs appear to affect behaviors rather than diagnosis-specific pathophysiology. Thus, the effects of stimulants on inattention and overactivity are qualitatively much the same (albeit quantitatively less marked) in individuals who do not have ADHD as in those who do. On the other hand, there are drugs that appear to have effects on disorders that differ from those on the healthy. Thus, lithium does not make euthymic individuals less “manic,” even though it does reduce the likelihood of manic episodes in those with bipolar disorder. There are sometimes strong predictors of drug action (e.g., the val/val form of the COMT gene is associated with a stronger enhancement of cognitive performance by stimulants than are other forms of the gene), but these are in the realm of genotypic rather than phenotypic prediction (Mattay, Goldberg, Fera, et al., 2003).

In practice, the treatability of a disorder can be a strong reason for diagnosing it. The acceptable indications for drugs are usually phrased in terms of the presence of disorder rather than the presence of a target behavior. It is often said, for instance, that stimulants should not be given unless a child meets diagnostic criteria for ADHD. The great variations between countries in the rate of diagnosis of ADHD seem likely to be influenced by the extent to which clinicians desire to use the medication. Treatment needs to be decided on the basis of assessment of risks and benefits and not on whether a particular set of diagnostic criteria is met.

Genetic/Family Study Findings

Findings from twin, adoptee and family studies have been crucial in establishing some very important differences among diagnostic groups (Kendler & Prescott, 2006). Schizophrenia tends to breed relatively true, with associations that extend to schizotypal and paranoid disorders but not much wider than that. However, there is some overlap in genetic influences with schizotypal and paranoid disorders but not much wider than that. Therefore, it may be that substance misuse itself may come to be regarded as a mental disorder, rather than a lifestyle choice that only merits a diagnosis if it causes harm or physical dependence.
Molecular genetics is increasingly being applied to the question of validating diagnostic categories. The clearest finding has been the validation of Rett syndrome by an association with a specific genetic mutation (see chapters 34 & 46). ADHD has been robustly associated with allelic variants in the genes coding for the dopamine (D1 and D3) receptors and the dopamine transporter; and more provisionally with a range of other DNA variants affecting synaptic transmission. Specificity to the diagnosis of ADHD is much less clear, however, and the same variants have been associated with a range of personality changes and with anxiety states. The loci found in genome scans of people with ADHD show a strong overlap with loci provisionally detected in studies of people with autism, suggesting either that some common genetic influences exist or that phenotypic differentiation still leaves much to be desired.

Molecular and behavioral genetics have both contributed to the idea that misuse of various psychoactive substances may have a common origin. Kendler, Jacobson, Prescott et al. (2003), using a large adult population-based sample of male twins, found that both the genetic and the shared environmental effects on the use and misuse of six classes of illicit substances were largely or entirely non-specific in their effect – the influences were not on the tendency to use one drug rather than another, but on the misuse of all the drugs considered. One DNA variant implicated (DRD2 gene minor Taq 1A (A1) allele) is more common in people misusing substances than in the general population (Young, Lawford, Nutting et al., 2004).

Unquestionably, genetic findings are informative on the differentiations among mental disorders but they should not determine classificatory distinctions. Thus, the genetic liability to blood phobia does not differ from that of other specific phobias, but it needs to be differentiated clinically because, unlike all the other phobias, it is associated with a fall (rather than rise) in blood pressure – leading to fainting. Generalized anxiety disorder and major depression share the same genetic liability but the implications for choice of medication are somewhat different.

Psychosocial Risk Factors
On the whole, there is relatively little diagnostic specificity with respect to the psychopathological risks associated with psychosocial stress and adversity. However, there are two important exceptions. First, severe institutional deprivation in the early years of life has a relatively specific association with syndromes involving disinhibited attachment (Rutter, Colvert, Kreppner et al., 2007; see also chapter 55). Second, severe and acute stress experiences of an exceptional kind are particularly likely to lead to PTSD phenomena (see chapter 42). There is also some tendency for psychological loss stresses to lead to depression, and danger-type stresses to lead to anxiety (see chapter 26). Family conflict, discord and hostility are also more likely to lead to antisocial behavior than to emotional disturbance; the same applies to social disadvantage. Within antisocial disorders, life-course-persistent varieties show a stronger association in serious family adversities than that found with adolescence-limited varieties (see chapter 35).

Cognitive Correlates
Autism stands out as different from other psychiatric disorders both because of its particularly strong association with general cognitive impairment and its relatively specific association with theory of mind and central coherence deficits (see chapter 46). ADHD, too, is relatively distinctive through its association not only with mild cognitive impairment (which would apply to many conditions), but also with impulsive responding, altered time perception and sensitivity to delay of reward (see chapter 34). Schizophrenia is associated with a slightly below average IQ before the onset of the psychosis; there is sometimes a marked drop in IQ around the time of onset; and established cases have a higher rate of particular problems such as those in working memory (Bowie & Harvey, 2005).

Epidemiology
Age of onset and sex ratio tend to go together. Thus, disorders involving neurodevelopmental impairment (such as developmental disorders of language, autism, and ADHD, and life-course-persistent antisocial behavior) characteristically begin early in life and are much more common in males (see chapter 3). Emotional disorders beginning in adolescence (such as depression and eating disorders), by contrast, tend to be much more common in females; even antisocial behavior beginning in adolescence differs from earlier onset varieties in having a much weaker male preponderance. Rett syndrome is unique in being confined (or almost confined) to females – because the mutation is lethal in males.

Course of Disorder
The long-term course of disorders also helps to sort out diagnostic distinctions (see chapter 13). The plateau of developmental progress and loss of purposive motor skills associated with Rett syndrome make it quite distinct. Adult outcome findings are relevant in showing the major continuities between depression in adolescence and recurrent depression in adult life. Similarly, strong continuities are to be found between antisocial behavior (including conduct and oppositional/defiant disorders) and personality disorders in adult life; there is a strong persistence of autism and a relatively strong persistence of schizophrenia, of obsessive-compulsive disorders and of tics/Tourette syndrome. There are fewer data on anxiety disorders but, although there is some overlap with depression, specific phobias seem somewhat distinct.

Summary of Validity Inferences
Putting together the evidence discussed above, it is possible to arrive at a three-fold division of disorders into those that are reasonably well-validated, those with pointers suggesting probable validity and those where the evidence indicates that the categorical subdivisions are probably invalid.
The first group clearly contains autism and autism spectrum disorders (considered together), schizophrenia and schizophrenic spectrum disorders (again as a grouping), depressive disorders, hyperkinetic behavior as a feature that differentiates it from other disorders of disruptive behavior, oppositional and conduct disorders (considered together) and Rett syndrome. A range of contrasting approaches all provide good evidence of discriminative validity. The same applies to the distinction between intellectual disability (usually severe) that is associated with gross neuropathology and that (usually mild) that is not.

The second cluster of probably valid syndromes includes OCD, eating disorders (pooling anorexia and bulimia nervosa), tics and Tourette syndrome, specific phobias, PTSD, disinhibited attachment disorder, bipolar affective disorders, and the distinction between life-course-persistent and adolescent-linked antisocial behavior. As briefly noted above, in each instance there is substantial evidence of discriminative validity but it is either less consistent or it spans fewer research approaches. From a practical point of view, these provide sufficient grounds for retaining the diagnostic category, even though there are important questions to be tackled.

The third cluster of probably invalid categories is less easy to deal with, if only because of the usual problem of knowing how much weight to attach to a lack of evidence of a meaningful difference, when new research could change that situation completely. Nevertheless, it is important to be aware that our usage of prevailing classifications means that we are making distinctions that, at least currently, lack substance. For example, that applies to most of the detailed subclassifications, such as those among anxiety disorders or those among pervasive developmental disorders (PDD), Rett syndrome apart. That definitely does not mean that we should necessarily switch to some broader category. Thus, although there is no good evidence that the distinction between, say, autism and Asperger syndrome or atypical autism means much, the evidence on discriminative validity applies to the narrower category of autism and not to the broader category of PDD. Also, up to now, it has proved quite difficult to provide either a clear conceptualization or precise operationalization of the criteria for the broader category. The issue is the one that pervades psychiatry: namely, uncertainty on the boundaries of a syndrome when the defining pathology is unknown. It should be added that this uncertainty applies in some (often major) degree to most of the conditions for which there is no evidence of validity.

A second group of probably invalid categories includes syndromes that are clinically striking but for which the external correlates provide little support for basic differences from other diagnostic categories. Selective mutism and conversion reactions fall into that group. In both cases the distinctiveness of the clinical picture and the particular therapeutic challenges it presents probably warrant the retention of the category. However, the same might have been said of school refusal (Hersov, 1977) and that no longer has a place in most classification schemes (Elliott, 1999). Then there are categories that derive from theoretical concepts but that lack satisfactory diagnostic criteria that would allow the testing of validity. Inhibited attachment disorder (see chapter 55) clearly is a diagnosis of that type and many would argue that borderline personality disorder is too (see chapter 50). Certainly, subdivisions among personality disorders remain rather unsatisfactory. It should be added that it is necessary to note that epidemiological findings indicate that there are quite a few children with psychosocial impairment but whose mental health problem does not fulfill any particular diagnostic category. Moreover, they have a mental health outcome, at least in the short term, that is as poor as those with a diagnosis (Angold, Costello, Farmer et al., 1999a). Evidently, there is a need for some sort of residual psychopathological category.

In practice, clinicians find it useful to recognize and name some types of presentation that they do not suppose to be coherent diagnoses. Deliberate self-harm, for instance, is a behavior that can characterize several diagnoses and can be seen in people with no other diagnosis at all. However, the pragmatic implications are strong – including the need for treatment guidelines to manage the emergency presentations and the assessments of risk that are required whatever the underlying cause (see chapter 40).

Finally, it is necessary to return to the uncertainties in deciding between categorical and dimensional approaches. ADHD well illustrates this dilemma. Most of the biological validity evidence (such as the neuroimaging findings and associations with motor and language problems) applies to a relatively narrow diagnostic category, but many of the genetic findings suggest (but do not prove) a dimensional liability (Banaschewski, Hollis, Oosterlaan et al., 2005). Furthermore, the risk over time for social impairment applies to the broader and milder form of ADHD as well as to a narrowly defined hyperkinetic disorder (Lahey, Pelham, Chronis et al., 2006). Of course, it may well be that there is both a qualitatively distinct disorder and a risk dimension, which look similar but which differ in their pathophysiology.

Agreement

Agreement on Clinical Psychiatric Diagnoses

Diagnostic ratings by experienced clinicians show at least a modest concordance. Limited agreement within panels of independent clinicians has been found over the years – for DSM-III (Mattison, Cantwell, Russell et al., 1979; Mezzich, Mezzich & Coffman, 1983; Prendergast, Taylor, Rapoport et al., 1988), and for ICD-9 (Gould, Shaffer, Rutter et al., 1988; Prendergast et al., 1988; Remschmidt, 1988). Field trials for DSM-IV reported better agreement, but on the basis of self-selected pairs of psychiatrists who made diagnoses on selected patients. The shortcomings of this strategy were pointed out by Rutter and Shaffer (1980), who noted that one would expect clinicians working together to have similar diagnostic practices. Further work needs to be carried out before the language of child psychiatry becomes sufficiently explicit to sustain scientific progress.
On the other hand, good diagnostic agreement can be achieved by independent research teams that have agreed supplementary criteria in advance (Prendergast et al., 1988). This satisfactory agreement is comparable with that obtained by studies in which two clinicians from the same center rated cases with fuller information (Stroeber, Green & Carlson, 1981; Werry, Methren, Fitzpatrick et al., 1983). The conclusion seems to be that training can improve diagnostic reliability to a satisfactory level, so the goal of an adequate system is not impossibly distant. The increased clarity of diagnostic rules in ICD-10 has been reported to increase inter-rater reliability, although the overall accuracy still leaves much to be desired (Steinhausen & Erdin, 1991). Other procedures that have been reported to enhance reliability are the use of a standard coding form after interview (Beitchman, Kruidenier, Clegg et al., 1989), and the use of a multiaxial system (Skovgaard, Isager & Jorgensen, 1988).

A good deal of the unreliability in routine practice can be seen therefore to stem, not from the ambiguities in classification as such, but from their application under the constraints of everyday work. In other branches of medicine, the pitfalls in diagnosis have been studied, and it seems likely that these will also apply to psychiatric diagnosis also. Chief among them is the tendency of the human mind to seek confirmation of a working hypothesis rather than to seek disproof of it. The initial perception of clinical problems often proceeds by matching to a prototype that is held in the mind, and there is a tendency to overestimate the similarity of the case to the phenotype. It is therefore easy to arrive at a premature categorization; and once it has been arrived at then the mind tends to overlook aspects that do not fit. This is often called “anchoring” of the first impression; and it will also be influenced by the prior conceptions of the probability of different classes that the diagnostician carries. These prior conceptions can also be prone to illusions – for instance, a clinician tends to overestimate associations between phenomena based on the frequency with which they see it, rather than the base rates of each problem in the population. The most practical way to avoid these kinds of errors is to be aware of them. The use of checklists in diagnostic practice is helpful, even to the experienced clinician, in making sure that comprehensiveness of assessment is achieved and that one does not ignore features of the case that are not a part of the key prototype being used. In training, and in reflecting on one’s clinical experience, it is important to instill a sense of the diversity of presentations as well as the most typical ones. Above all, one should be critical of one’s working ideas and be prepared to change formulations as assessment and treatment proceed.

The limited agreement between raters has had some impact on the way that diagnostic schemes have been formulated. The emphasis has been on clarity and simplicity of definitions rather than on subtleties of phenomenology. Descriptions such as overtalkativeness and overactivity are common to bipolar disorder and ADHD; they therefore cause confusion to clinicians as to how they should be placed; but remedies such as defining the qualitative differences between the goal-directed energies of mania and the desultory and disorganized qualities of ADHD have been hard to achieve in reliable fashion. Poor agreement between raters can also be due to systematic variability in the child’s response to different situations (such as home and school). Correspondingly, the criteria for ADHD and for hyperkinetic disorder require that the defining behaviors should be present and impairing across situations.

**Co-occurrence of Different Symptom Patterns**

Over the last few decades, a substantial literature on the topic of “comorbidity” has accumulated. The concept refers to the situation in which two or more separate and independent disorders are present in the same person. It is crucial to appreciate that this is by no means synonymous with the co-occurrence of different symptom patterns. It is not the same because the co-occurrence may have several other meanings. To begin with, statistical considerations deriving from referral patterns mean that clinic samples will always be likely to be misleading (Berkson, 1946). Nevertheless, even epidemiological samples show very high rates of co-occurrence of different symptom patterns (Angold, Costello & Erkanli, 1999b), so other explanations must be considered (Caron & Rutter, 1991; Rutter, 1997). First, as already noted in the section on hierarchical classifications, there is a general recognition that it is very common for many disorders to include a diverse mixture of symptoms. Even outside accepted exclusionary hierarchy rules, it must be expected that many co-occurrences are likely to reflect this diversity. Thus, it is very frequent for affective disorders to involve a mixture of anxiety and depression. Similarly, it is quite common for obsessive-compulsive features to arise only in the course of a depressive disorder, and remit with it.

Second, there are many symptoms of mental disorders that are both non-specific indications of psychopathology (the mental equivalent of fever in internal medicine) and also defining symptoms for specific disorders. Clearly, anxiety is a feature of this kind but so are depression, overactivity and inattention.

Third, the overlap may reflect imperfections in diagnostic criteria – such as the inclusion of the same symptom in two or more categories, as with overactivity in relation to both ADHD and mania. This is particularly likely to lead to artifactual overlap when using either questionnaires or structural interviews relying on respondents’ “yes” or “no” answers.

Fourth, the overlap may stem from misleading assumptions in diagnostic criteria. Thus, the high frequency of co-occurrence among anxiety disorders, or among personality disorders, probably arises for this reason. Similarly, co-occurrence may arise because one disorder represents an early manifestation of another. In these circumstances, at the point of transition from one pattern to the other, artifactual co-occurrence will occur. This probably accounts for much of the co-occurrence...
CHAPTER 2

between oppositional/defiant and conduct symptoms (see chapter 35).

Fifth, the overlap may reflect the fact that many risk factors provide risks for several disorders and from the sharing of multiple risk factors across disorders. As we have noted, few risk factors are diagnosis-specific. This non-specificity is by no means special to psychopathology; it applies to many multifactorial disorders in internal medicine (Rutter, 1997).

Sixth, the presence of one disorder may create a risk for another. Thus, someone with an autism spectrum disorder (Hutton, Goode, Murphy et al., in press) or an obsessive-compulsive disorder may become depressed as a response to their predicament. Alternatively, they may behave in ways that predispose to life situations that provide risks for another. The association between antisocial disorders and the shaping of stressful environments (Champion, Goodall & Rutter, 1995; Robins, 1966) that provide an increased risk for depression would be an example of this kind.

It is apparent from these contrasting possibilities that their investigation could throw an important light on causal processes. For example, multivariate analyses of adult twin data (Kendler & Prescott, 2006) have shown that although both social anxiety and depression show similar patterns of behavioral co-occurrence with alcohol abuse, the mechanisms are different. Social anxiety constitutes a statistical mediator for alcohol abuse (implying that the presence of social anxiety leads people to seek relief through alcohol consumption), the association between depression and alcohol abuse does not reflect mediation. Rather, it largely reflects a shared genetic liability. Findings, of course, may point to multiple mechanisms. Thus, for example, as we have noted, twin findings indicated that most of the genetic influence on drug taking applies to all drugs. The implication is that the genetically influenced propensity to take drugs concerns some aspect of risk-taking rather than response to particular chemical substances. On the other hand, twin data also suggest that using marijuana creates a “gateway” influence to using other drugs with more serious dependency properties and ill-effects on health (see chapters 13 & 36). Clearly, the scientific need is for more hypothesis-testing studies of the mechanisms underlying co-occurrence of different symptom patterns, rather than further documentation that it exists, with the unwarranted assumption that it means that there is comorbidity.

In the meanwhile, classification systems have to have rules on how to deal with the co-occurrence of different symptom patterns. Both ICD-10 and DSM-IV accept the need to be able to make multiple diagnoses if it is clear that the individual truly does have two or more separate conditions. After all, in most circumstances, it cannot be supposed that the presence of one disorder protects against others (although that can happen). Accordingly, someone with, say, autism or schizophrenia, can develop another mental disorder if they experience the risk factors for it. A strict single-category system would be unworkable and neither of the main systems have such a requirement.

Nevertheless, there is a dilemma on how to classify when there is uncertainty on whether or not the two conditions are truly separate and independent. ICD-10 and DSM-IV differ somewhat in their approach. Both provide for a hierarchical approach in a few instances (see above) and both provide a few mixed categories when there is good evidence that they both represent a single disorder (e.g., mixed episode of mania and depression). However, ICD-10 has rather more mixed categories (e.g., mixed anxiety and depressive disorder and depressive conduct disorder). The rationale is that the weight of evidence suggests either that there is something distinctive about the admixture (as compared with the situation when either condition occurs on its own) or that the same disorder commonly gives rise to this admixture of symptoms. It provides an economic way of communicating and it is a practice that is common in medicine. However, it has two possible disadvantages. First, the overall placement of the combination category in the classification system carries messages that may be misleading. Thus, in ICD-10, mixed anxiety and depression is classified as a variety of anxiety disorder, although the evidence suggests that it is more likely to represent a mood disorder (see chapter 37). Depressive conduct disorder is classified as a variety of conduct disorder and that does seem to be better justified in that research findings suggest that conduct disorder has much the same set of correlates and much the same outcome irrespective of the co-occurrence of depression – although there are some differences (Simic & Fombonne, 2001). On the other hand, it seems doubtful whether the presence of conduct disorder alters the meaning of the depression (Fombonne et al., 2001). Accordingly, the validity of the mixed category is called in question. Also, the mixed category limits finer distinctions (such as between the subvarieties of anxiety disorder that may be associated with either conduct disorder or major depression).

The availability of mixed categories in ICD-10 is quite limited, however, and the bigger difference from DSM-IV lies in the approach to mixed symptom patterns that are not covered by a combination category. ICD-10 is not entirely explicit in how they should be dealt with, but the implicit expectation is a profile recognition or prototypic approach. Thus, if the main picture is one of severe depression, but there are marked obsessive features that ebb and flow with fluctuations in the depression, the mood disorder only would be the expected diagnosis. By contrast, DSM-IV would code obsessive disorder in addition (if the criteria were met) unless the content was mood-specific (e.g., as with a guilty rumination). The ICD-10 prototypic approach probably closely approximates much ordinary clinical practice. The main problem is that it has proved difficult to make prototypes sufficiently explicit that they will always be used in the same way.

With DSM-IV the mixture of two or more symptom patterns leads to the coding of as many diagnoses as there are patterns. This has the advantage of not requiring hierarchical judgments about which pattern is primary when in reality it may be very hard to tell, and it also succeeds in retaining a good deal of information when many patterns are present and no single category would convey them all. On the other hand, there are practical drawbacks to such a scheme. It encourages
an unchallenged assumption that they are indeed independent patterns and that each can be dealt with in the same way as if there were no other problems. Alternatively, after multiple diagnoses are made, the clinician may then after all resort to a superordinate single-category way of thinking in which every possible profile has its own place. The coexistence of many diagnoses can be confusing and work against the key purpose of clarity and understanding how the research literature may apply to a particular child. It does not allow for the possibility of artifactual associations (see above). Furthermore, it is cumbersome, and perhaps impossible, for a clinician to review the presence or absence of every possible category, and clinicians usually vary a good deal in their willingness to record symptom patterns that are not the main presentation (Rutter, Shaffer & Shepherd, 1975).

Future Developments

Classification will develop as knowledge grows, and especially as we achieve more knowledge on the pathogenetic processes that lead to disorder. They have been considered under “validity” and will be taken up in more detail in following chapters. We may discover specific links between cause and presentation that will yield new “diseases” to join Lesch–Nyhan and Rett syndromes. At present, however, it seems clear that, with multifactorial disorders, it will be usual for there to be multiple causes of small effect, often involving an interplay between genetic susceptibility and environmental risk and protection (Rutter, Moffitt & Caspi, 2006). Given that most forms of psychopathology are multifactorial in origin, it would make little sense to classify on the assumption of a single basic cause, because there will not be one (Rutter, 2006). Rather, the future is likely to lie in the elucidation of the underlying neurophysiology (or neurotransmitter or neuropsychology or neural interconnectivity). Social scientists sometimes object on the grounds that this would ignore the importance of environmental risk mechanisms. Their objections involve a reversion to an unwarranted dualism between psyche and soma. The recognition of the importance of infectious agents in causing somatic disease led to research, and then better understanding, of the effects of such agents on the organism and on its functioning. Something closely comparable should happen with psychosocial risk factors. It may be that new knowledge will lead those working on classification systems to introduce yet more complexity, more categories and more axes. We hope that does not happen. The history of science is that an increased understanding of causal processes often leads to simplification, rather than an ever-expanding complexity. The same should occur with psychopathology.

Public Impact

The use of explicit diagnostic schemes has demystified some of mental health, and created a better public understanding of the processes involved. Nevertheless, substantial concerns remain. The enterprise of psychiatric diagnosis is often attacked.

Some attacks are essentially on the functions for which diagnoses are used. Educators may object to the concepts of specific learning disorder because they object to assumptions that the causes lie in the children rather than their social situations. Many European clinicians resist the use of the concept of ADHD because they reject the idea that it is a neurological disorder. These attitudes ask too much of a diagnosis; it does not usually explain a child’s condition, but only describes it. We may regard the diagnosis of ADHD as valid, in part because it predicts at a group level a range of neurobiological changes. However, there should be no expectation that the diagnosis means that the individual child arrived at the condition through those changes.

Other attacks on diagnosis are upon its consequences. The stigma of mental disorder is real, and can be unwelcome to children and their parents, who fear that normal means of education and socializing will be barred to those known to have a diagnosis. Evidence for this happening, however, is hard to find. Labeling a disorder can also have helpful consequences, in obtaining appropriate resources or in relieving confusion and guilt. The behaviors that evoke a diagnostic label may also evoke much crueller vernacular labels such as “stupidity,” “laziness” or “immorality.” The issue should be not so much that of whether to convey a diagnostic label as how to do so in a constructive fashion that encourages problem-solving and understanding.

Other attacks on diagnosis are on its abuses. Several of these have been referred to in this chapter. Clinicians should not allow their prototype of a disorder to become a stereotype and neglect other factors in the child, and they should not ignore factors beyond the individual; these are reasons for going beyond diagnosis to formulation. One should not start to regard diagnoses as things. Such “reification” is present in arguments such as “He does not really have a mental disorder; the cause lies in his family and society.” These are alternative and complementary descriptions, not contradictory explanations.

Classification schemes are an essential language for making sense of mental health. They allow the user to relate individual cases to others, to communicate, and therefore to learn. When a case is assigned to a powerful class, many predictions follow. The classifications of child and adolescent mental health are becoming increasingly powerful.

References

CHAPTER 2

From the beginnings of psychiatric classifications, there have been attempts to establish broad overarching groups (see chapter 2). Thus, for many years, mental disorders tended to be put into the two broad categories of “organic” and “functional” disorders. The rationale was that, with respect to causation, the disorders within each group had more in common with other disorders in the same group than with those in the alternative group. The implication was that it might be useful for research into causal processes to determine commonalities within these broad groups, rather than to assume that each diagnostic category would have a unique cause not shared by all other conditions.

One such broad grouping was the notion of “minimal brain dysfunction” (MBD), which was popular in the 1960s and 1970s (Wender, 1971). The concept has been discredited (Rutter, 1982) and is no longer in general use. The crucial flaws were that particular behaviors could not be used to infer brain pathology, and that organic brain dysfunction did not lead to a homogenous psychopathological pattern. In addition, it seemed to presuppose that all types of brain dysfunction would have similar consequences. It is clear that that is not so. The problem with this broad grouping is that it arose from a theoretical notion for which there was no good empirical support. The question that we consider in this chapter is whether the concept of neurodevelopmental disorders fares any better as a guide to the future. Our focus here is on conceptual issues in the characterization and classification of disorders, rather than on aspects of clinical management, which are dealt with in the chapters on individual disorders.

What Do We Mean by Neurodevelopmental Disorders?

Over the last two decades or so, there has been increasing use of this concept. However, there are at least four rather different ways in which the term has been used. The narrowest concept is provided by the second axis of the ICD-10 classification (World Health Organization, 1996), dealing with Specific Disorders of Psychological Development. They were placed on a separate axis because they differed from the general run of psychopathological conditions in three key respects:

1. An onset that is invariably during infancy or childhood;
2. An impairment or delay in the development of functions that are strongly related to biological maturation of the central nervous system; and
3. A steady course that does not involve the remissions and relapses that tend to be characteristic of many mental disorders.

The overall description of this group of disorders noted that there is impairment in some aspect of mental development, but the impairment tends to lessen as the children grow older; despite this, deficits tend to continue into adult life; most of the conditions are more common in males than females; and a family history of similar or related disorders is common, suggesting that genetic factors have an important role in the etiology. The subclassification within this axis comprised disorders involving language development, scholastic skills or motor function. DSM-IV (American Psychiatric Association, 2000) has a broadly comparable subclassification but the disorders are not placed on a separate axis and the overall conceptualization for grouping is not expressed so explicitly.

An alternative usage extends the term “neurodevelopmental disorders” much more broadly to include single-gene disorders such as Williams syndrome or Prader–Willi syndrome (Tager-Flusberg, 1999) or disorders deriving from prenatal insults or toxins, such as fetal alcohol syndrome (Harris, 1995). These conditions develop on the basis of neural impairment, involve cognitive deficits of various kinds, and, as with the specific disorders of psychological development, are characterized by a steady course without remissions or relapses. However, whereas the Axis 2 ICD-10 disorders are defined in terms of a profile of specific impairment of linguistic, scholastic or motor skills, these disorders are defined in terms of etiology. Although it can sometimes be fruitful to compare the deficits associated with a particular known etiology and those in a specific developmental disorder, it is potentially confusing to classify these different types of disorder together, and in this chapter we restrict consideration to those disorders with a putative multifactorial etiology. For similar reasons, we would argue against adopting a definition that includes intellectual disability, cerebral palsy, traumatic brain injury and epilepsy under the rubric of neurodevelopmental psychiatric disorders.
There are two more modest ways in which the concept of neurodevelopmental disorder can be broadened beyond specific disorders of psychological development. First, many people include both autism spectrum disorders (ASD) and attention deficit/hyperactivity disorders (ADHD) in the overall grouping of neurodevelopmental disorders. At first sight, it might be objected that there are several ways in which both of these are rather different. Thus, neither reflects a straightforward impairment in a development-based skill that is closely related to biological maturation. Also, both involve deviant functioning (i.e., that which is not normal at any age) as much as impaired functioning (i.e., that which is normal in form but impaired in level). Nevertheless, the reason why they have come to be grouped with neurodevelopmental disorders is that they share with the other disorders the facts that they are multifactorial in origin; are present from early life; tend to improve with increasing age but are also associated with disordered functioning that extends right into adult life; they involve a strong genetic influence; and both show a marked male preponderance. Furthermore, they are characterized by neuropsychological impairments, in aspects of executive function in ADHD (see chapter 34), and in social cognition, central coherence and executive function in ASD (see chapter 46). Strikingly, epidemiological and clinical studies have shown that these two disorders often co-occur with the ICD-10 Axis 2 disorders of psychological development, and genetic findings have similarly begun to point to a possible shared genetic liability (as well as a liability that is more syndrome specific). In addition, although autism may be associated with other forms of psychopathology that do show remission and relapses (Hutton, Goode, Murphy et al., in press) the basic disorder is persistent rather than recurrent. Much the same applies to ADHD (see chapter 34).

A further possible broadening of the concept of neurodevelopmental disorders brings in life-course-persistent antisocial behavior (Moffitt, 1993) and schizophrenia (Rapport, Addington, & Frangou, 2005). At one time, both of these would have been regarded as acquired disorders but there is now an abundance of evidence that schizophrenia is often associated with impairments in the development of both language and motor function and with cognitive impairments that precede the development of overt schizophrenia (see chapter 45). Similarly, unlike adolescence-limited antisocial behavior, the life-course-persistent variety of antisocial behavior begins in the preschool years and is associated with hyperactivity and impairments in information processing and social cognition (see chapter 35). For the purposes of this chapter we have not included either of these disorders under the rubric of neurodevelopmental disorders for two main reasons. First, both antisocial behavior and schizophrenia do show fluctuations in their manifestations that are more akin to the remissions and relapses associated with the broad run of mental disorders than with the relatively steady state of the specific disorders of psychological functions. Second, there is not the same evidence of a shared genetic liability. For these reasons, we prefer to conceptualize these as disorders that have their origins in a neurodevelopmental abnormality rather than as a neurodevelopmental disorder as such, and confine the term neurodevelopmental to those disorders traditionally regarded as specific developmental disorders, plus ASD and ADHD.

**Are the Neurodevelopmental Disorders Distinct Conditions?**

Both traditional medical, and traditional psychological, approaches have tended to operate with discrete diagnostic categories. Thus, reading disability continues to be conceptualized as “developmental dyslexia,” with the implication that it is a discrete neurological condition (Démonet, Taylor, & Chaix, 2004). For many years, specific language impairment was termed developmental dysphasia (Zangwill, 1978) with the same kind of implication. This terminology has now gone out of fashion because of the recognition that impairments in language development differ in important ways from acquired disorders of language. In psychiatric classifications, both ASD and ADHD are treated as if they are conditions that are entirely separate from other disorders of psychological development. In line with this conceptualization, cognitive psychologists have looked for a single specific underlying deficit that is responsible for each disorder, the nature of the deficit differing for each one (Morton & Frith, 1995).

There are two main reasons for challenging this view of neurodevelopmental disorders as a set of independent conditions. First, there is substantial co-occurrence among them. Second, both etiological and psychological studies indicate that multiple deficit models are more consistent with the multifactorial and probabilistic etiology of such disorders (Pennington, 2006), and that significant developmental impairment may arise only when there is more than one risk factor present (Bishop, 2006). As in internal medicine, the same pathological endpoint can arise through multiple, rather different, causal pathways (cf. Rutter, 1997). In the following sections, we present evidence to support the case that rather than looking for the cause of each type of neurodevelopmental disorder, we need to take account of the commonalities among them, and develop more complex models that can explain the patterns of association and dissociation among deficits.

**Commonalities Among Developmental Disorders**

Research findings across the whole of psychopathology, both in childhood and adult life, have been consistent in showing the high frequency with which individuals have multiple, supposedly separate, disorders (Angold, Costello, & Erkanli, 1999; Caron & Rutter, 1991). This is strikingly apparent for the neurodevelopmental disorders – indeed, it has been argued that a pure disorder is the exception rather than the rule (Gilger & Kaplan, 2001; Kaplan, Dewey, Crawford et al., 2001) – and is reflected in the ICD-10 category of mixed developmental...
CHAPTER 3

disorders. Thus, there is considerable overlap between specific reading disability (SRD) and specific language impairment (SLI) (Bishop & Snowling, 2004; Eisenmajer, Ross, & Pratt, 2005), between SRD and ADHD (Dykman & Ackerman, 1991; Willcutt & Pennington, 2000) and between SLI and ADHD (Beitchman, Brownlie, Inglis et al., 1996). Less work has been carried out on developmental coordination disorders (DCD), but there is evidence for an overlap between motor impairment and both SLI (Hill, 2001) and ADHD (Kadesjö & Gillberg, 1998). As far as autistic disorder is concerned, the defining criteria disallow a diagnosis of SLI in a child meeting criteria for autistic disorder, but it is clear that at the symptomatic level there is considerable overlap, with many affected children showing the kinds of structural language deficits that characterize SLI (Tager-Flusberg & Joseph, 2003). Furthermore, many children with SLI or ADHD show in milder form the kinds of social/pragmatic impairments that are characteristic of autistic disorder (Bishop & Norbury, 2002; Clark, Feehan, Tinline et al., 1999; Farmer, 2000; Geurts, Verté, Oosterlaan et al., 2004). SRD co-occurs with mathematical difficulties at a higher level than predicted from the prevalence of either disorder on its own (Lewis, Hitch, & Walker, 1994).

It has become accepted to refer to these patterns of co-occurrence as “comorbidity,” but this is misleading because it ignores the possibility that much of the supposed comorbidity is simply a function of the invalid, and artificial, diagnostic subdivisions in classification systems (see chapter 2). Thus, for example, it seems likely that much of the co-occurrence of supposedly different anxiety disorders is simply a consequence of these disorders being slightly different manifestations of the same underlying condition (see chapter 39). Might the same apply to neurodevelopmental disorders? Clearly it could.

Thus, SLI and reading disability both comprise disorders of language – the former with respect to spoken language and the latter with respect to written language. It would be rather surprising if there was no co-occurrence between the two. That is not to argue that all cases of reading disability derive from oral language impairment, because manifestly they do not (Bishop & Snowling, 2004); but it is to suggest that co-occurrence to some degree is to be expected.

However, the co-occurrence of neurodevelopmental disorders does not apply only to language-related disorders; as noted above, there are also overlaps between language and motor impairments, attention deficit and social deficits, and these cannot readily be explained as different manifestations of a common cognitive disability. To some extent, overlaps could reflect referral bias in clinical samples: for instance, a child whose reading or language disability is accompanied by social impairment or attentional deficit would be more likely to be referred to a psychiatrist than one who had an isolated impairment. However, this cannot be the whole explanation, because overlaps are seen in epidemiological samples (e.g., Beitchman et al., 1996), and second, the rates of co-occurrence are higher than would be predicted from knowledge of the frequency of individual disorders.

A “Syndrome” of Neurodevelopmental Disorder?

One might try to wonder if, rather than differentiating between neurodevelopmental disorders, it would make more sense to group them all together into an overarching category, treating them as variant forms of a common underlying disorder. However, there are sufficient differences among the neurodevelopmental disorders to preclude such a conceptualization. First, molecular genetic studies have been successful in identifying chromosomal regions associated with risk for reading disability, SLI, ADHD and ASD, but there has been little or no overlap between the linkages reported for these different disorders. For instance, Fisher (2006) noted that whereas linkages to dyslexia have been found on chromosomes 1, 2, 3, 6, 15 and 18, those to SLI have been found on chromosomes 13, 16 and 19. Fisher pointed out that we need to be careful in interpreting such findings: it would be dangerous to assume that there are highly specific pathways from genotype to phenotype, especially because few studies have used multivariate methods to look at more than one disorder at a time. Undoubtedly there are some genes whose effects are common to more than one neurodevelopmental disorder (e.g., Willcutt, Pennington, Smith et al., 2002), but behavior genetic studies also usually find evidence for specific as well as common genetic influences on co-occurring disorders (e.g., Martin, Piek, & Hay, 2006). Second, there are differences among disorders in drug response. It is striking, for example, that whereas ADHD shows a marked beneficial response to stimulant medication (see chapter 34), no drugs have other than a slight inconsistent effect on the basic problems associated with ASD (see chapter 46). Similarly, although medication may provide some symptomatic improvement with the other neurodevelopmental disorders, there are not the marked benefits that are seen with ADHD. Third, although it is difficult to compare across imaging studies because of variations in the ways in which they have been conducted (Peterson, 2003), patterns in the various neurodevelopmental disorders do not seem at all closely similar: for instance, fronto-striatal systems are implicated in ADHD (see chapter 34), whereas in dyslexia there is reduced activation in left temporo-parietal cortex (see chapter 48). Fourth, at a behavioral level, there are differences among neurodevelopmental disorders in short and long-term course (Rutter, Kim-Cohen, & Maughan, 2006a). Finally, although most neurodevelopmental disorders are characterized by a preponderance of males, sex ratios vary across disorders, with the male excess being far more striking for ASD than for other neurodevelopmental disorders (Rutter, Caspi, & Moffitt, 2003). Arithmetical difficulties stand out from the rest, with boys and girls equally likely to be affected (Lewis et al., 1994; Rourke, 1989; Shaley, Auerbach, Manor et al., 2000).

Clearly, it is not feasible to treat the whole gamut of neurodevelopmental disorders as a single condition, but can we nevertheless identify distinct syndromes within this category, in which a pattern of deficits arises from a common
neurobiological cause? Rourke’s (1989) account of “non-verbal learning disability” (NLD) is such a model: a distinctive pattern of strengths and weaknesses in sensorimotor skill, scholastic achievement, and socioemotional development are seen as all originating from destruction or dysfunction of white matter in the right cerebral hemisphere. The deficits seen as characterizing NLD encompass specific arithmetical disorder, DCD and Asperger syndrome. The construct of NLD explains the co-occurrence of these deficits in terms of a specific neurobiological basis. However, the validity of the category is questionable. The different deficits certainly can and do co-occur, and the association of the symptomatology of Asperger syndrome with the neuropsychological manifestations of NLD has been empirically demonstrated (Klin, Volkmar, Sparrow et al., 1995). However, the association appears too weak to justify treating it as a syndrome: this is demonstrated in studies showing that a high proportion of children with a clinical picture of NLD do not show specific deficits thought to characterize this disorder (Drummond, Ahmad, & Rourke, 2005; Pelletier, Ahmad, & Rourke, 2001). If we embrace the construct of NLD, we end up by excluding numerous cases because they do not show the anticipated combination of deficits, meaning that either we have to dilute the “syndrome” to be too general to be useful, or we have to devise additional categories to encompass the cases that do not fit. Similar problems arise if we try to fit language, literacy and speech disorders into a broader syndrome; we can find many children who show this constellation of impairments, but there are also many who do not (Bishop & Snowling, 2004; Pennington, 2006).

Neurodevelopmental disorders thus pose a considerable challenge for a classification system. On the one hand, we need to explain why there is common co-occurrence of different deficits, while at the same time allowing for dissociations between different types of deficit, and variable patterns of associated features. The causal model shown in Fig. 3.1 provides a framework for conceptualizing these questions. In this model, first put forward in the context of SLI and dyslexia, a neurodevelopmental disorder is identified on the basis of a constellation of behaviors; these result from specific cognitive deficits, which have particular neurobiological bases, which are in turn affected by genetic or environmental factors. When extending the model to cover the whole gamut of neurodevelopmental disorder, the “cognitive” level is taken to include a wide range of underlying mental operations that cannot be directly observed, but are inferred from behavior, including perceptual-motor skills, language, memory, social cognition, reasoning and executive functions. Relationships among the different levels of functioning are not one-to-one, but involve complex multifactorial influences going from etiology to neurobiology, from neurobiology to cognition, and from cognition to behavior. Viewed from this perspective, it is clear that overlaps between observed behavioral impairments may arise from shared cognitive deficits, shared neurobiological origins and/or shared etiology. We now turn to consider evidence for these different causal mechanisms.

**Causal Models of Neurodevelopmental Disorders**

**Cognitive Deficits**

One goal of developmental neuropsychology is to uncover the underlying nature of deficits seen in neurodevelopmental disorders. As shown in Fig. 3.1, the same behavioral deficit may arise for different reasons, and one would hope that as our conceptual understanding advances, we might be able to categorize disorders not in terms of surface behavior, but in terms of underlying cognitive deficits. For instance, most children with reading disability have difficulties with phonological analysis which are evident even when they are tested using methods that do not require any reading or writing (see chapter 48). Other poor readers have visual difficulties, problems learning specific spellings of irregular words or poor comprehension of written texts. A focus on underlying cognitive deficits thus could help identify new subgroups. It also suggests that some of the existing distinctions among disorders may be unrealistic; for instance, increasingly speech, language and literacy problems are regarded as different manifestations of a common phonological impairment, whose behavioral correlates would vary depending on the age at which the child was observed and the severity of the impairment (Bishop & Snowling, 2004). Nevertheless, if we try to categorize disorders in terms of underlying deficit rather than observed behavior, this does not necessarily simplify our nosology, because multiple deficits are the rule rather than the exception, at the cognitive as well as the behavioral level. Thus, although one can identify children who fit the picture of “phonological dyslexia” or “surface dyslexia,” most poor readers present a mixed picture (Snowling & Nation, 1997).
CHAPTER 3

Even if one looks at impairments in very different domains, associated disorders are common.

Pennington (2006) conducted a series of studies comparing children with pure dyslexia, pure ADHD, and comorbid dyslexia and ADHD. He was interested in the possibility that comorbidity among these disorders might reflect the influence of one behavior on another (e.g., attentional difficulties might arise because the child who could not read well became bored and distractible; or conversely, the child’s difficulty in attending could lead to scholastic deficits). If the first account were true, then the comorbid children should resemble the pure dyslexic cases in terms of underlying impairment. If the second account applied, then the comorbid children should resemble the pure ADHD cases. In fact, the pure dyslexia group had phonological deficits, the ADHD group had inhibition deficits, but the comorbid group had evidence of both phonological and inhibition deficits. These results are consistent with conventional wisdom that links dyslexia to poor phonology and ADHD to weak inhibition, but it leaves unexplained the co-occurrence of these two impairments.

We can summarize by saying that it was hoped that, by studying underlying impairments, we would obtain clearer distinctions between disorders and find that apparent comorbidity was a consequence of poor specification of disorders. In fact, studies such as this show that comorbidity is just as apparent at the level of cognitive impairment as it was at the level of observed behavior. This suggests that we need to seek an explanation for the associations among neurodevelopmental disorders at a different causal level.

Neurobiological Bases

Neuropsychological studies of adults highlight how fairly specific impairments in functions such as language, reading, arithmetic or motor programming can arise as a consequence of a focal brain lesion (McCarthy & Warrington, 1990). When one sees analogous impairments in children, it is tempting to assume a similar etiology via underlying brain damage, with the precise pattern of observed impairment depending on the extent, location and severity of the damage. This kind of model was put forward in the 1950s by Pasamanick and colleagues, who proposed a “continuum of reproductive casualty,” suggesting that whereas major neurological insult resulting from birth trauma, intracranial hemorrhage or anoxia can lead to clear signs of neurological damage such as cerebral palsy or epilepsy, milder damage may lead to more subtle learning difficulties. However, this conceptualization of the etiology of neurodevelopmental disorders has not received much empirical support. There is good evidence that such damage often gives rise to behavioral and cognitive sequelae (Pasamanick & Knobloch, 1966), but the suggestion that neurodevelopmental disorders often arise from damage during the obstetric process has not proved to be the case. Nichols and Chen (1980) found only weak associations among neurological soft signs, hyperactivity and learning disorders, and even weaker associations between these variables and perinatal complications.

Furthermore, the notion that “birth injury” was the main risk factor fell into disrepute in view of the evidence that many of the risks supposedly associated with obstetric complications actually derived from prenatal problems. A genetically abnormal fetus is more likely to have a low birth weight and to be born following premature gestation. That probably accounts for the somewhat inconsistent association between obstetric complications and ASD (Bolton, Murphy, Macdonald et al., 1997). Undoubtedly, extremely low birth weight does lead to an increased rate of motor, language, scholastic and attentional difficulties (Marlow, 2004; Marlow, Wolke, Bracey et al., 2005). However, the association is not strong when assessed in the opposite direction (i.e., by starting with children with neurodevelopmental disorders and studying their perinatal history).

With the possible exception of developmental co-ordination disorder (for review see Cermak, Gubbay, & Larkin, 2002), obstetric complications do not have a particularly important association with any of the neurodevelopmental disorders. It is family history that provides the key differentiator.

The Concept of Maturational Lag

Given that neurodevelopmental disorders are, on the one hand, familial, and on the other hand, not caused by acquired brain lesions, we need to seek another causal mechanism at the neurobiological level. There is often an implicit assumption that genetic or other prenatal influences have led to some failure of neurodevelopment that leads to abnormality that is functionally equivalent to a focal brain lesion – hence the analogous syndromes seen in neurodevelopmental disorders and adult acquired disorders (Temple, 1997). According to this view, the brain of a child with a neurodevelopmental disorder has an underlying abnormality that persists through childhood. An alternative possibility is that these disorders are no more than an extreme of the normal variation in the timing of development. We know that there are huge differences in the timing of puberty in both males and females, and marked differences, too, in the timing of the eruption of teeth. In similar fashion, there is marked individual variation in the timing of speech acquisition. When such a delay is followed by later normal functioning it may be regarded as a maturational lag of some kind. The implication is that the problem involves a normal variation in the development of certain brain systems responsible for cognitive functioning, rather than in some abnormal difference in brain systems, and that there can be a highly selective delay in the maturation of just one brain system. Associations between neurodevelopmental disorders would then arise in cases where the maturational lag extended to encompass several brain regions, or where there is pluripotentiality (i.e., a given brain structure is involved in a range of cognitive functions; Noppeney, Friston, & Price, 2004).

A key prediction from the “lag” hypothesis is that not only should the pattern of functioning resemble that of a normal younger child but also, as children with a neurodevelopmental disorder get older, the main difference from normal functioning should be found for later-maturing functions and not for early-maturing functions (Bishop & Edmundson,
The limited available evidence is in keeping with that expectation and runs against the outmoded static lesion notion. However, for most neurodevelopmental disorders, although there is a general tendency for gains in function with increasing age, delayed early development is not followed by later normal functioning (Rutter, Kim-Cohen, & Maughan, 2006a). Can a maturational lag account have any explanatory value in such cases?

Two main possible explanations, both speculative, have been proposed for why children with a neurodevelopmental disorder do not ultimately catch up. First, the persistence could derive from what Stanovich (1986) termed a “Matthew effect,” whereby the poor (poor readers) get poorer (make slow progress), while the rich (good readers) get richer (make good progress) as a result of literacy experience boosting further language and literacy development. Furthermore, a poor reader may lack the necessary experiences later (i.e., reading is not usually taught in secondary schools, and such books as are available are likely to be too advanced to be intelligible). There could also be more indirect effects whereby early impairments create a negative spiral affecting other skills (e.g., the effects on intimate social relationships of communication difficulties in early childhood). Because of the importance of experiences in the development of psychological functions, there is little doubt that something of this kind could have a contributory role. What is much less certain is whether it could account for the severe problems in intimate social relationships in adult life found for many individuals with a severe receptive SLI in adult life reported by Clegg, Hollis, Mawhood et al. (2005) – because the relationship deficits were not a function of the severity of the earlier language deficits (at least in terms of those measured), and because the nature of the deficits appeared so different from those usually associated with social rejection. It is also noteworthy that persistence of disorder is often seen in young people with SLI who have been enrolled in special education throughout the secondary as well as primary school years (Conti-Ramsden, Botting, Simkin et al., 2001; Haynes & Naidoo, 1991). Perhaps the key empirical finding is provided by Francis, Shaywitz, Stuebing et al.’s (1996) individual growth curves comparison of 69 children with a reading disability and 334 children with no reading problem. Nine yearly longitudinal assessments showed that both groups tended to plateau at about 13 years of age, with no narrowing or expansion of the gap between the groups. They differed in level but not in trajectory. The finding rather runs counter to the Stanovich (1986) proposition.

A second kind of explanation for persistence of disorder was proposed in the context of language and literacy deficits by Wright and Zecker (2004). They invoked a decline in neuroplasticity as a limiting factor, and suggested that neurobiological events at age 10 years associated with the onset of puberty halted auditory development at whatever level it has reached, so that the adolescent was left with a lasting residue of deficit. This viewpoint is consistent with evidence that there are sensitive periods for aspects of language acquisition, so that it is difficult to become fully competent in the phonology and syntax of a second language acquired after puberty (Mayberry & Lock, 2003; Oyama, 1976). However, critical periods for auditory development have not been demonstrated, and there is electrophysiological evidence that development of the auditory system (Albrecht, von Suchodoletz, & Uwer, 2000) as well as of some other cortical systems continues right up into adulthood (see chapter 12). Longitudinal studies using magnetic resonance imaging (MRI) have confirmed that brain development continues well after the onset of puberty, with higher-order association areas maturing only after lower-order somatosensory and visual areas (Gogtay, Giedd, Lusk et al., 2004; see also chapter 12), and that such changes – especially in the frontal cortex – are associated with intellectual functions (Shaw, Greenstein, Lerch et al., 2006a). There is considerable variation from one cortical region to another, with some showing radical changes at puberty and others unaffected (Nelson, Bloom, Cameron et al., 2002). Clearly, further research is required in order to provide an understanding of both brain development (and its functional consequences) in typically developing individuals and in those with neurodevelopmental disorders. As the evidence currently stands, the postulate that the relevant brain systems lose plasticity around the time of puberty remains highly speculative, and to test it we would need studies that compare the impact of training on brain and behavior in pre- and postpubertal individuals. The trajectory findings of Francis et al. (1996) are compatible with the suggestion of a change in brain plasticity in adolescence but they provide no direct support.

We may sum up by concluding that there is little hard evidence in support of a maturational lag account. We need more longitudinal and neurobiological studies to evaluate this idea. In its favor, this kind of explanation has the potential to highlight parallels between causal mechanisms in normal and impaired development, and to account for changing profiles seen in neurodevelopmental disorders. It provides the impetus for studies that track neurodevelopment over time: for instance, Shaw, Lerch, Greenstein et al. (2006b) documented changes in cortical thickness over time in children with ADHD, with evidence of normalization in children who had a good outcome. However, a maturational account seems more plausible as an explanation for transient delays early in development than for severe and persistent neurodevelopmental disorders.

A final point to note is that it is important not to confuse the hypothesis of a developmental delay with the entirely different hypothesis that the causation of disorders of psychological development, together with ASD and ADHD (as well as numerous forms of other psychopathology), are based on dimensional genetic and environmental risk factors (Rutter, Moffitt, & Caspi, 2006b). With multifactorial disorders, dimensional liability is the rule rather than the exception. The question of whether or not the dimensional risks are the same ones that apply within the normal distribution is a separate issue and it is one that has been very little investigated up to now, although there has been some relevant research in relation to ADHD (see chapters 23 and 34).
Furthermore, relatives of comorbid cases should show increased risk for disorder B (with or without disorder A, see chapter 12). Klein and Riso (1993) noted that evidence for overlapping etiology of disorders indicate a shared liability. Klein and Riso (1993) emphasized interactions between different neural systems, and to that extent would predict the existence of disorders affecting more than one domain of functioning. However, this theoretical perspective is still very young; its main contribution to date has been to question the simple parallels that are sometimes drawn between developmental and acquired disorders, and to emphasize the need to put development center stage. In order to make more specific predictions about neurodevelopmental disorders and their co-occurrence, we need to develop specific computational models of normal development, which then allow us to identify which perturbations could result in a particular profile of deficit (Thomas & Karmiloff-Smith, 2003).

**Etiological Influences**

For those conditions where genetically informative designs have been applied (SRD, SLI, ADHD, ASD), there is evidence of substantial genetic influences on the liability to disorder (see chapter 23). With respect to neurodevelopmental disorders (together with other multifactorial disorders), these probably usually reflect the actions of normal variants of multiple genes of small effect operating together with multiple environmental influences (Gilger & Kaplan, 2001; Rutter, Moffitt, & Caspi, 2006b) rather than the deterministic effect of major mutant genes. This view of etiology is reflected in the causal model in Fig. 3.1, in that there is no one-to-one relationship between genes and neurobiology. Rather, a specific neurological system is likely to be influenced by a range of etiological influences and the given etiology will impact on a range of brain regions. Such a model allows for both co-occurrence of deficits and the existence of pure disorder. Particular patterns of variation may reflect the influence of either specific combinations of genetic or environmental factors, or the operation of chance influences (Wolff, 1997).

This raises the question of whether patterns of co-occurrence between disorders indicate a shared liability. Klein and Riso (1993) noted that evidence for overlapping etiology of disorders can be found by looking at the familiality of disorders in pure and comorbid cases. In essence, they note that if shared etiology is implicated in causing disorders A and B, then we should see an increased risk for disorder B (with or without A) in relatives of a person with disorder A, and vice versa. Furthermore, relatives of comorbid cases should show increased risk for the single disorders A and B, as well as for the A + B combination. Note that these predictions are not made by other models of comorbidity: for instance, if the A + B combination represented a separate subtype of disorder with distinct causes, then it should “breed true,” and there should be no increase in rates of disorder A in relatives of those with disorder B (or vice versa). Furthermore, the predictions hold up for any disorder that shows familiality, regardless of whether genes or shared environmental factors are more important.

If the disorders are significantly heritable, it is possible to go further using either quantitative genetic methodologies (such as twin studies) or molecular genetic studies (focusing on individual identified genes) to determine how far there is a shared genetic influence between the two disorders. Few researchers to date have adopted this approach; an exception is Pennington (2006), who studied comorbidity of SRD and ADHD in a twin sample and concluded that there was evidence for shared genetic influence on the two disorders. In a similar vein, Bishop (2002) found evidence for overlapping genetic influences on language impairment and motor immaturity in a sample selected for SLI. Molecular genetic findings also suggest that susceptibility extends beyond traditional diagnostic boundaries (Rutter, Moffitt, & Caspi, 2006b).

**Research Implications of the Neurodevelopmental Disorder Concept**

Probably the single most crucial research implication is that investigators need to consider the possibility that the causal influences on key features may extend across the range of neurodevelopmental disorders, rather than being specific to just one. Thus, it is striking that, with the exception of arithmetical difficulties, all the neurodevelopmental disorders show a marked male preponderance (Rutter, Caspi, Fergusson et al., 2004). That stands in marked contrast to the finding that disorders with a marked female preponderance all concern syndromes typically beginning in adolescence and that involve emotional disturbance, rather than neurodevelopmental impairment, as the key feature. Baron-Cohen and Hammer (1997) have hypothesized that ASDs represent an “extreme male brain.” There is a lack of good supporting evidence but, in addition, it is necessary to ask whether that same explanation should be held to apply to ADHD or SRD or SLI. It does not seem particularly likely that the causes of the male preponderance are entirely different in the case of each of the syndromes, although there may be syndrome-specific factors as part of the explanation.

A further question for research is whether studies should continue to be focused on “pure” disorders given that they do not appear to be at all typical. The answer will depend on the question that is being asked. Pure groups can be useful in identifying correlates of a specific kind of deficit without additional confounds. For instance, suppose one wants to test the hypothesis that reading disability is caused by a low-level auditory perceptual deficit. The goal is to compare a group...
of children with SRD and a control group on a task in which they have to listen for small differences between sounds, and make a manual response to indicate what they have heard. If the sample includes children who have substantial difficulties with language comprehension, motor dexterity or attentional control, then it may be hard to disentangle the influence of these impairments on task performance. Careful sample selection to exclude such cases may give cleaner results. Having said that, it is worth noting that those who claim to study pure cases may be including large numbers of children with additional deficits which are missed because they are not assessed. For instance, many studies of SRD fail to assess children’s language or attentional skills. If a sufficiently detailed assessment battery is used, covering the whole range of neurodevelopmental disorders, the numbers of pure cases available for study may become vanishingly small. If so, it may be better to assess associated deficits, so that one can establish how far they are associated with the dependent variable of interest, rather than try to control for their effects by exclusion of comorbid cases (cf. Breier, Gray, Fletcher et al., 2001).

In many research contexts, focus on pure groups is not just hard to achieve, it can be seriously misguided. In etiological studies, restricting the phenotype to those with a pure disorder may be misleading, if risk factors in fact operate across a range of neurodevelopmental disorders. As noted above, inclusion of comorbid cases can provide a rich source of evidence about the reasons for co-occurrence of disorders, both when studying underlying impairments and when the focus is on etiology. Another instance where it may be unhelpful to restrict attention to pure cases is when conducting research on intervention. For instance, a remedial package that is effective for children with a pure reading disability may not work well if there is co-occurring ADHD. Given the common overlap between disorders, we need more research that considers how the presence of a comorbid disorder affects treatment outcome, rather than simply ignoring or excluding such cases.

Implications for Clinical Practice

Perhaps the most important point to stress is the need for clinicians to be aware of the complexity of neurodevelopmental disorders. Multidisciplinary assessment is key for identifying each child’s pattern of strengths and weaknesses. We are aware of cases where a child has received a diagnosis of SLI from a speech and language therapist, dyslexia from an educational psychologist, ADHD from a pediatrician, ASD from a child psychiatrist and developmental dyspraxia from an occupational therapist! In part this may be because of the different perspectives and expertise brought to the assessment by different professionals, and in part by genuine changes in the clinical presentation over time. For instance, a child whose main problem in the preschool years is unintelligible speech may become intelligible but subsequently be diagnosed as having developmental dyslexia (Bishop & Snowling, 2004). Another child who initially seems to be a case of specific receptive language disorder may subsequently merit a diagnosis of ASD (Conti-Ramsden, Simkin, & Botting, 2006). Most parents will be thoroughly confused by such multiple diagnoses, and conclude that somebody has “got it wrong.” It is essential that professionals work together to ensure that the child receives a diagnosis that provides access to the most appropriate services, while at the same time assessing the whole range of areas of function that may be impaired. Intervention will need to be individually tailored to take into account the child’s specific strengths and weaknesses.

It is also important that both clinicians and parents recognize that diagnostic labels are shorthand descriptors that do two things: they summarize the child’s major area of deficit; and they indicate that the problem is neither part of another syndrome nor attributable to a known organic etiology. All too often, those interpreting the labels assume they imply more than this, and treat terms such as “developmental dyslexia” and “developmental dyspraxia” as if they referred to syndromes with distinctive features and clear boundaries that are distinct from normality and have a known biological basis. In practice, these diagnoses are made on the basis of quantitative difference from normality. A statement such as “My child can’t read because he’s dyslexic” is not an explanation, rather it is a circular redescription of the problem. Furthermore, the use of a single diagnostic label can oversimplify the complex and multifaceted nature of many neurodevelopmental disorders.

CHAPTER 3

Initial Questions Regarding Referral

Clinical appointments are initiated by someone making a referral, usually with some form of focused question, although the extent to which this is made explicit varies. In the case of children, it would be rather unusual for the young people themselves to have initiated referral, but that may sometimes be the case. Although the clinician is likely to wish to organize the initial assessment around the question as to whether the child has a clinically significant disorder and, if there is such a disorder, what its nature is, that may or may not be the question that is uppermost in the mind of the person making the referral. Rather, the main issue may be what the family or school should do about a particular behavior that is causing concern in that setting. Alternatively, there may be questions over particular administrative decisions such as whether the school the child is attending is most appropriate, whether there is a need for exclusion from school, or whether the child should be removed from the family. In other cases, the referral may be to request an opinion that is relevant to some court case involving either child care or the child’s responsibility for some criminal act or possible need to respond to such an act with some form of therapeutic intervention. In yet other cases, there may be an implicit query as to the meaning of the child’s behavior – perhaps as to whether or not it represents an early manifestation of some serious mental disorder (such as schizophrenia or autism) that is thought to run in the family. Another possibility is that the main problem concerns disturbed family function that happens to have involved the children in some way (Shepherd, Oppenheim, & Mitchell, 1971). If so, there is the need to understand why this child has been referred at this time in this way. It is quite common, too, for different people to have quite discrepant views as to what is the problem and what needs to be done about it. Thus, the father and mother may be at loggerheads over this, their view may be different from that of the child, and all of these may differ from the perspectives of the school, the social services or the family doctor.

Because of all of these uncertainties, and the wide range of possibilities, it is crucial for any assessment to begin with some procedures designed to clarify questions about the referral (Kanner, 1957; Rutter, 1975). Who initiated the referral? Why was the referral made? Why was the referral made now? Whose problem is it? What are the key concerns or questions to which people want a response? Are there administrative decisions that hang on the assessment and, if there are, what are they?

To some extent, these questions can be clarified through obtaining relevant reports in advance of the interview for diagnostic assessment. Clearly, this needs to be carried out through discussion with the family and with their approval. Ordinarily, however, at the time of the first interview it is desirable to have available relevant reports from the school, from any social agencies that have been involved, from previous medical assessments, and from psychological and educational evaluations. Chapter 20 considers the circumstances under which it may be desirable to have structured questionnaires completed in advance of the first interview, as well as the use of more open-ended questionnaires regarding what the family wants from the referral.

As well as clarifying the reasons for referral, the initial assessment needs to be planned in such a way as to provide information on how family members interact with one another and how they deal with each other’s concerns. The aim is to identify possible strengths and limitations in the family and to understand their ways of functioning in order that this may be taken into account in planning therapeutic interventions. The establishment of a relevant form of therapeutic alliance needs to be a key consideration right from the beginning of the diagnostic assessment (Green, 2006; Kazdin, Whitley, & Marciano, 2006).

Observations of the Family

Observations need to begin with the ways in which the communications (either by letter or telephone call) were dealt with prior to the first interview (Cox & Rutter, 1985). Who took the lead? What was the style used? What implications might there be for either the parents’ attitudes towards their children or towards professionals? Similar questions need to be considered in relation to observations in the waiting room. If the availability of chairs provided open choice, how did the family choose to sit? What was the style of interactions among family members while waiting to be seen and how did
they respond to meeting the clinicians? How did they spend their time in waiting and what were they doing when the clinician went to collect them for interview?

Regardless of how later stages of the assessment are to be undertaken, it is usually informative to have a brief meeting with the family all together in order to clarify these sort of issues and also to explain how the assessment will be organized and who will be seeing whom for what purpose. Similar queries to those posed in relation to the waiting room arise with respect to the seating in the interview room. If the aim is to assess family interaction, it is crucial that the interview questions be addressed to the family as a whole, rather than singling out individual family members for their views. Often it may be better to put the query in the form of a questioning statement of a general kind, rather than a specific enquiry. Thus, the clinician may say something like: “I wonder how much you talked together about coming to see me today?” or there could be a general question such as “Have you had a family discussion about the reasons for coming here today?” Many parents are likely to have the cultural expectation that they (rather than the child) should answer the clinician’s questions and, in interpreting how they respond, it is important to take that into account. Nevertheless, direct questions to the child in this initial family session may make him or her feel put on the spot and, thereby, uncomfortable. Again, a more general style of bringing the whole family into the interview may be preferable (for a fuller discussion of family interviewing see chapter 63). For example, if someone has responded with a firm answer on expectations or the reasons for coming, the interviewer might say something like: “I wonder whether everyone in the family sees things in this way?” It is helpful to note how much the parents provide the child with “space” to express his or her own views. How do the parents react if the child puts things in oppositional or confrontational ways? How do members of the family react when someone is expressing feelings of distress, anger or resentment? What are the patterns of eye-to-eye gaze among family members? What are their facial expressions and body gestures? Although it is usually a mistake to move quickly into interpretations, it may be helpful to make observations or express reactions as a means of getting the family to talk about the situation. Thus, the clinician may say things such as “That appears to be a very difficult situation” or “It feels as if that was awkward for you to talk about” or “It sounds as if that came as a bit of a surprise to you.”

Depending on how the interview progresses, it may be appropriate to move on to direct questions about some aspect of the referral. For example, if the school or social services initiated the referral, the family may be asked how they felt about whatever it was that precipitated the referral. Was that something that they, too, were concerned about or did they see it rather differently? Similarly, if the parents have initiated referral because they were worried about some aspect of the child’s behavior or emotional state, it may be important to ask the child directly whether this was something he or she was concerned about.

Younger children should not be expected to sit still during the interview and the interviewer needs to decide in advance what toys or play materials will be made available for the children. The interview provides the opportunity for seeing what the children decide to do and also whom they talk to or whom they turn to during the interview. How do the parents respond if the child seems distressed or is behaving in a disruptive way? Again, it is necessary to recognize that there may be culturally influenced expectations as to how the parents should behave. If the clinician wants the parents to be able to respond to the children it may be appropriate to say that directly by indicating “It’s okay if you want to respond to (child’s name) while we’re talking” or “By all means go to (child’s name) if you’d feel more comfortable doing that.”

Elements in the Diagnostic Clinical Assessment

Interview with the Child

Interviews with older children and adolescents can follow rather similar approaches to those used with adults, but various adaptations are needed with young children. Nevertheless, in all cases, it is essential to have an individual assessment of the child. Several points warrant emphasis (see chapter 19). First, it is usually helpful to be able to assess children’s behavior, styles of social interaction and ways of talking in several contrasting situations. Thus, it is usually desirable to have an opportunity of seeing the child with the rest of the family. Psychological testing will provide the quite different stimulus of a series of structured tasks requiring the child’s engagement and attention. Psychological testing should always include a careful description of the child’s behavior and social interactions, as well as test performance (see chapter 21). The interview with the child will be different yet again in providing a dyadic interaction opportunity but of a much less structured kind. Particularly at the beginning of the interview, the style needs to be such as to encourage children to express their own concerns (after setting the child at ease through talking about neutral topics that interest the child) and this needs to proceed to a more systematic approach to specific behaviors and feelings. Chapter 7 notes some of the considerations that apply particularly to the interviewing of young children. On the whole, free descriptions in answer to open questions provide accounts of behavior that are most accurate and least prone to distortion. On the other hand, these tend to be very lacking in detail and, almost always, it will be necessary to follow with more specific questions. It is important that this be carried out in a way that does not provide a lead to specific answers. People of all ages are open to the influence of suggestion but this is particularly the case with younger children (see chapter 7).

Variations in the style of child interview and observation are needed both when the children may be handicapped in their communication and social skills, and when the clinical issues require a focus on particular forms of behavior that may not
be tapped adequately in an ordinary interview (see chapter 19). The Autism Diagnostic Observation Schedule (ADOS) provides relevant social presses (Lord, Risi, Lambrecht et al., 2000). It was initially developed primarily for research purposes but specialized clinics are now increasingly using it for clinical assessments. Even if the standardized half-hour assessment is not used clinically, the principles are certainly relevant to any form of clinical diagnostic interview with children or adults for whom the diagnosis of some form of pervasive developmental disorder (autism spectrum disorder) has been raised (see chapter 46). There is a similar need to adapt interview approaches for children with seriously impaired hearing or vision, or with limited language (see chapter 59).

The need to consider how assessments should be adapted for particular purposes is exemplified by the approaches needed for the assessment of possible attachment disorders (see chapter 55). The concept of these disorders is that they are characterized by pervasive problems in selective attachment. The disinhibited variety of attachment disorder might be thought to comprise a relative lack of selective attachments and the inhibited variety both a lack of security provided by established selective attachments and by various abnormal features. So far as the disinhibited variety is concerned, there are two features that particularly require attention. The first concerns the child’s reaction to a stranger and the degree to which this lacks the normal wariness plus the extent to which there is an inadequate appreciation of social boundaries and an unusual degree of physical closeness or contact before a relationship has been established. In addition, there may be a lack of selectivity in going to the principal caregivers for security or comfort and it is important that the children’s response to family members be observed, as well as the response to a stranger. What is needed clinically is a form of assessment that provides the opportunity to assess the child’s reaction to strangers (the clinicians fill that role); responses to separations from and reunions with the parents (taking the child to be seen on his or her own and returning later serves that purpose); and the child’s use of the parents as a secure basis (a joint family interview is useful in that connection).

Whatever the age of the child, and whatever the clinical issue, it is important that the interview combine an appropriate degree of structure and standardization (which are essential for comparability across children) and sensitivity to the unexpected and to the individual issue. The latter have been most studied in relation to the interviewing of parents in a clinical setting (Cox, Rutter, & Holbrook, 1981; Rutter, Cox, Egert et al., 1981) in which one of the most striking findings was the very high frequency of clinically significant information of an unusual kind which would be most unlikely to have been picked up by confining questioning only to predetermined topics. The same consideration certainly applies to interviews with children. It is very important for clinicians to be sensitive to the cues provided by children and these will need to be followed through in whatever way seems most appropriate to the individual situation. This need applies even more to what children say about their psychosocial circumstances than it does to what they say about psychopathology (see below).

Parental Interview

The parental interview will be particularly concerned with the assessment of psychopathology but, in planning therapeutic interventions, several other features need to be considered. To begin with, it is essential to determine what it is about the child’s behavior, feelings or social interactions that is of the greatest concern to the parents. That may not necessarily be the feature that the clinician considers of the greatest psychopathological importance but, ordinarily, it is sensible that early therapeutic interventions be recognized by the parents as addressing their concerns. In addition, it will be important to find out how the parents (and other people) have tried to deal with the concern. How have they tried to respond and what success or otherwise have their approaches achieved? If adequate use is to be made of this in therapeutic planning, it will be essential to move beyond a general answer (such as admonish the child, comfort him or her, or try to be understanding) and, instead, obtain a more detailed sequential account of how this has been done. What did they do and what was the child’s response? If certain approaches did not work, did they persist (and if so, for how long and under what circumstances) or did they keep changing? A closely related issue is the impact that the child’s disturbance has had on them and on the rest of the family.

In dealing with the development of the disorder, attention will need to be paid to possible predisposing factors in life circumstances or physical state. Before proceeding with specific questioning, it is usually better to elicit the parents’ views on what might have been important. There is then the somewhat different matter of the functional analysis of the behavior that is causing concern (see chapter 62). In other words, what are the features that seem to make the behaviors of concern more or less likely to occur? What circumstances seem to improve the situation? Questions regarding the degree to which behaviors are situation-specific or pervasive are important, not only for their implications with respect to severity, but also in terms of features in the environment that may act as a risk or protective factor.

There are important advantages in making sure that children are seen with their parents for part of the diagnostic assessment. However, people do not behave, or talk, in the same way when seen on their own and when seen as part of a family group. Moreover, it may be unhelpfully embarrassing for children to have to hear their problems discussed with a professional. Accordingly, it is usually desirable for part of the assessment time to be spent in seeing the child on their own and for the parents similarly to be seen separately. Not only may this provide information that would not be obtained quite so readily in a family setting, but it also makes explicit a concern to pay attention to family members as individuals as well as with them as part of a group. Some clinicians prefer to conduct the whole of the diagnostic assessment interview in a conjoint family setting but, in our view, this has disadvantages.
with respect to information gathering. A somewhat similar
decision needs to be made as to whether both parents should
be seen together or whether there should be some time with
each separately. Our usual practice is to follow parental
preferences in the first instance but to be alert to cues that
suggest that it may be necessary to see parents on their own
for a brief period in addition. In that connection, however, it
should be noted that one study (Cox, Hemsley, & Dare, 1995)
showed that families did not respond well to a change of style
from family to individual or vice versa, when making the transi-
tion from diagnostic assessment to therapeutic intervention.

School Reports
It is always desirable to obtain a school report, preferably
in advance of the first interview with the family (but after
obtaining their agreement that the school may be contacted).
Children may well behave differently at school from the way
they do at home and it is important to obtain an account of
scholastic functioning (educational difficulties are frequently
associated with psychopathology). There are some advan-
tages in using a standard questionnaire as part of the report-
ing from school (see chapter 20). However, a questionnaire
is never adequate on its own because it is crucial for teachers
to be able to express their own concerns (and that may in-
volve features that are outside the coverage of the question-
naire), because it is important to consider changes over time
and not just present behavior, and because it is important
to find out how school has dealt with difficulties and how
the child has responded to whatever actions were taken. Some-
times, there may be specific queries that arise out of the
diagnostic assessment and, when that is the case, it may be
useful for a member of the clinical team to contact the school
directly in order to discuss the points that have arisen. Particu-
larly when there seems to be a major discrepancy between
the accounts of the child’s behavior at home and at school,
visits to both settings to observe what is happening may be
informative.

Psychological Testing
Chapter 21 considers the approach that needs to be taken
to psychological testing and its role in the overall diagnostic
assessment. A key part of the psychological evaluation con-
cerns the psychologist’s observation of the child’s behavior in
relation to the tasks that have been given and in relation to
the social encounter with the psychologist. This is important
because of the information that it provides about the child’s
psychological functioning generally, and not just because of
its importance in relation to the interpretation of the psy-
chological test findings.

So far as the latter are concerned, it is essential in all
cases to consider whether the scores are consistent with the
account of the child’s performance given by the parents and
by the school, and in keeping with the clinician’s observations
of the child. Of course, it is to be expected that there will
not be perfect agreement across all assessments but, if there
are major discrepancies, that always has to be a matter for

further study. If the child’s performance during standardized
testing was markedly better or markedly worse than that
expected on the basis of other people’s reports, what is the
explanation? Does it reflect differences in the cognitive
demands in the several situations, or does it reflect social
features of the situation? What are the implications for the
situational factors that seem to facilitate better performance?

A crucial part of any psychological assessment concerns
the evaluation of the likely validity of the findings. Attention
needs to be paid to the extent to which it was possible to
engage the child in the relevant tasks, noting whether dis-
turbed behavior may have interfered with task performance.
Particularly in the case of young children for whom there
is a query regarding possible severe intellectual disability, it
is important to note how the child dealt with the situation
as a whole, and with the task presented. A clear enquiring
curiosity about the environment, a systematic problem-
solving approach, and initiative combined with imagination
in dealing with test materials would all cause questioning of
the validity of a very low test score. Obviously, too, it will
be necessary to consider whether overall task performance has
been constrained because of specific difficulties in functions
such as language, motor coordination or vision. In terms of
the predictive validity of scores, consideration will also need
to be given to the possibility that current cognitive function-
ing has been impaired as a result of severely disadvantageous
rearing experiences that no longer apply. In short, test scores
provide invaluable information but they need to be interpreted
in relation to the assessment as a whole.

Medical Examination and Testing
Physical illnesses are common in the population and can
cause mental disturbance, so a child mental health assessment
needs to be competent to detect illness (see chapter 22).
The most fundamental requirement is that a thoughtful and
systematic history-taking should be used as a guide to the
possibility that somatic problems might be relevant with
respect to the psychopathology that has been the focus of the
referral. General medical problems, as well as neurological ones,
should be borne in mind – such as deafness in attention prob-
lems and endocrine dysfunction in eating problems. When there
is nothing in the history to suggest the presence of a possibly
relevant somatic condition, it will probably be sufficient to
ensure that previous health screening has been competent, to
measure the child’s height and weight, and to undertake a
screening neurodevelopmental examination that does not
require the child to undress fully. Questions should have been
asked to determine pubertal status but, unless it appears
likely to be specifically relevant, there is no need to undertake
a physical examination for this purpose.

When the child has a possible global or specific develop-
mental delay, or a disorder such as autism (see chapter 46)
or hyperkinetic disorder (see chapter 34), a rather fuller
assessment is necessary (see chapters 22 & 49). Appropriate
medical assessments will be essential when there are symptoms
affecting somatic functions, because this could result from
somatic disease. Early studies of so-called hysterical conversion reactions in both children (Caplan, 1970) and adults (Slater, 1965) showed the relatively high frequency with which these were wrongly diagnosed as psychogenic in origin, as indicated by the clear emergence of underlying physical disease of a directly pertinent kind during the course of follow-up. With proper clinical assessment, such misdiagnoses nowadays should be much less common, but clinicians need to be aware of the possibility (see chapter 57).

**Standardization of Clinical Assessment**

A key question concerns the merits and demerits of standardizing how clinical assessments are undertaken. In the past, some clinicians used methods that assumed that a particular form of treatment would invariably be required. At one time, this often concerned psychoanalytically oriented psychotherapy and somewhat later it often concerned conjoint family therapy of one kind or another. Exactly the same issues, however, apply to the assumption that the treatment will always involve use of diagnosis-specific medication (whether this be for depression or attention deficit/hyperactivity disorder [ADHD]). This approach to clinical assessment should no longer be acceptable. To begin with, single-therapy clinical practice is bad practice and any form of adequate clinical assessment must take on board the possibility of a range of appropriate therapeutic interventions. Systematic studies of interviewing (Cox & Rutter, 1985) have made it clear that systematic focused questioning is essential to obtain the relevant data for clinical diagnosis. In that connection, there is much to be said for the use of standardized interviews and standardized observations (see chapter 19). On the other hand, there are also dangers in the restriction of assessment to such diagnostic instruments.

The dangers arise from several different considerations. First, systematic studies of interviewing have shown the very high frequency with which idiosyncratic items of clinically significant importance are present (Cox & Rutter, 1985). These will be missed if assessments are constrained by predetermined areas of interest. Second, it cannot be assumed that current diagnostic concepts cover the full range of psychopathology. As Kanner aptly put it in the title of one of his papers on differential diagnosis, “The children haven’t read those books” (Kanner, 1969). The point that he was making is that there is a most imperfect match between the neat diagnostic description given in textbooks and the clinical presentations seen in referred patients. The usual explanation will be that the person has a somewhat atypical variety of a well-recognized, well-validated disorder. Nevertheless, the last half-century has seen the recognition for the first time of several disorders of considerable importance that had not been noticed before. Kanner’s (1943) identification of autism is the most striking example but it is closely followed by the identification of Rett syndrome (Hagberg, Aicardi, Dias et al., 1983; Rett, 1966). Both Asperger syndrome (Asperger, 1944) and Wolff’s concept of schizoid disorder in childhood (Wolff, 1995) constitute other variants within the realm of what might be regarded as autism spectrum disorders. “New” conditions are, however, by no means restricted to this group. Russell’s (1979) identification of bulimia nervosa constitutes another example, as does that of attachment disorders (see chapter 55). More recent, and therefore less well validated, examples are also provided by the quasi-autistic pattern seen in some children who have experienced profound institutional deprivation (Rutter, Andersen-Wood, Beckett et al., 1999); the social abnormalities that have been found to be associated with severe developmental disorders in receptive language (Clegg, Hollis, Mawhood et al., 2005); and the autistic-like patterns seen with some cases of congenital blindness (Brown, Hobson, & Lee, 1997). Sometimes, too, the clinical recognition of a new pattern concerns a risk factor (as with the fetal alcohol syndrome; Jones & Smith, 1973) or a feature that had not been appreciated before (as with pragmatic language disorders; see chapter 47). Not all of these patterns of psychopathology constitute well-validated syndromes but the general point remains; clinicians must always be on the alert for unusual patterns that do not fit existing diagnostic conventions.

Third, the initial diagnostic assessment cannot be confined to the topic of diagnosis. It must also concern reasons for referral, factors that might be important in either the causation or course of the disorder or which influence the planning of treatment; and the assessment of factors that may be relevant for prognosis. In the remainder of this chapter, we consider the range of issues that should be covered in any adequate clinical assessment. Standardized approaches constitute an important part of such assessment but they are only one part. In other words, there is much to be said for well-articulated clinical standards but there are dangers in translating these into a rigid and restricted predetermined diagnostic protocol.

Finally, the initial diagnostic assessment must go on to provide a formulation that provides a basis for therapeutic planning. That must include not only what the pattern of symptomatology has in common with those seen in other individuals, but also the aspects that are particular to this individual and this individual family. Formulations need to include a hypothesis of what seem to be the most important factors that are going to influence response to treatment; an articulation of what evidence will be needed to determine whether that hypothesis was, or was not, correct; and the development of a therapeutic plan as to how best the therapeutic goals may be achieved.

**Presence/Absence of Clinically Significant Psychopathology**

Because most psychiatric disorders do not include pathognomonic qualitatively abnormal features that cannot be found in normal children or adolescents, a key basic question has to be whether the severity or nature of psychopathology is such as to be clinically significant. Necessarily, that query comprises...
two somewhat different issues. First, there is the question of whether the problems being considered are causing significant suffering for the individual or significant distress for others. Second, there is the question of whether the psychopathology falls outside the normal range of behavior, or which carries with it a significant likelihood of recurrent or chronic malfunction. Clinical intervention will sometimes be indicated when the answer to one of the questions is in the affirmative but in the negative to the other. Thus, a serious grief reaction following the death of a loved one is quite common in normal individuals but it may warrant offering appropriate counseling (see chapter 26), even though it may not be a psychiatric disorder in the normal sense of the word. Similarly, many parents present at health clinics with their children’s difficulties in eating or sleeping – these are essentially normal, yet are causing major family disruption. Appropriate guidance and help may well be needed in such circumstances (see chapters 53 & 54).

The issue is an important one in relation to emotional disorders because anxiety, depression and fears are a normal part of the human condition that most people experience at some time. The considerations to be taken into account include: whether there has been a substantial change from the person’s usual mental state, whether the intensity of the emotions goes beyond the range of normal variation, whether the person is able to control the unpleasant emotions by means of distraction or engagement in pleasurable activities, whether the emotions intrude into and interfere with normal life functioning, and whether the emotions are pervasive across situations. Somewhat similar criteria apply to overactivity/inattention but with the difference that, because these are usually first manifest in the preschool years, there will not usually be a recognizable change from any previous normal pattern. The assessment of disruptive behavior is rather less straightforward because the child may not perceive that there is a need to control such behavior.

Assessment of Impairment

From the time of the Isle of Wight studies onwards (Rutter, Tizard, & Whitmore, 1970), the degree to which psychopathology gives rise to impairment of psychosocial functioning has been a key consideration in the assessment of clinical significance. There was a further impetus to use such a criterion from the epidemiological evidence that some forms of symptomatology, particularly specific phobias, were present in what seemed to be an absurdly high proportion of the population if impairment was not taken into account (Bird, 1999; Bird, Yager, Staghezza et al., 1990). That has seemed a reasonable approach because, if psychopathology is not impairing function, there would not seem to be much need for intervention. Epidemiological findings have been consistent in showing that there are substantial differences among different forms of psychopathology in the extent to which there is associated impairment. To begin with, quite a few children show psychosocial impairment associated with psychopathology but without the required number of symptoms to fulfill the criteria for a specific diagnosis (Angold, Costello, Farmer et al., 1999). When this is the case, intervention may well be justified. The presence of marked symptoms in the absence of impairment is most frequently seen in relation to specific phobias (Simonoff, Pickles, Meyer et al., 1997). Conversely, it is rather unusual for there to be multiple symptoms of depression without there being any impairment (Pickles, Rowe, Simonoff et al., 2001). However, the diagnosis here is made, not just on the severity of negative mood, but on associated phenomena such as self-depreciation, feelings of guilt, feelings of hopelessness about the future and suicidal thoughts or actions. The need to consider associated symptomatology constitutes a key element in diagnosis.

 Clinically significant developmental disorders of language (see chapter 47) need to be differentiated from normal variations in language development on the basis of the breadth of affected language functions (e.g., including understanding as well as use of spoken language), impaired use of language-related skills in make-believe play, difficulties in the control of motor movements associated with spoken language (as with drooling) and associated socioemotional or behavioral problems (Rutter, 1987). Although impairment is certainly a useful criterion to employ, there are both logical and practical problems associated with giving it too high a priority. First, from a medical perspective, it would seem foolish to say that a person did not have a disorder because they were not impaired if there were signs or symptoms (or test findings) indicating an obviously pathological condition. Thus, someone with diabetes, whose condition has been shown by the appropriate laboratory tests, would still be diagnosed as having diabetes even if functioning was unimpaired. Similarly, a person whose condition has been shown by the appropriate laboratory tests, would still be diagnosed as having diabetes even if functioning was unimpaired because symptoms were well controlled by diet or the use of insulin. The same would clearly apply in the case of schizophrenia that was well controlled by appropriate medication. In these instances, however, the abnormality is evident in terms of qualitatively abnormal findings, as evidenced either by history or present status, or both. The second concern is that a person may cope successfully with their disorder to the extent that symptoms are not manifest because the situations that elicit them have been avoided. There will not be psychosocial impairment if the person’s life is so organized that the issues do not arise. This most obviously applies in the case of certain phobias. Third, the degree to which there is psychosocial impairment will inevitably be influenced by social circumstances. Many decades ago Wootton (1959) pointed to the absurdity, for example, of rates of disorders going up and down according to fluctuations in the employment rate. She noted too the major difficulties in basing a diagnosis of psychiatric disorder on the extent to which it caused problems for other people. This has been a problematic issue in deciding whether conduct disorders should be regarded as psychiatric conditions (Hill & Maughan, 2001). In this case, what is a persuasive argument in favor of regarding it as a disorder is the extensive evidence of impaired personal functioning in both childhood and adult life, including an increased risk of suicide and of other forms of psychopathology.
CHAPTER 4

Although qualitative abnormalities are not a feature of the majority of psychiatric disorders in childhood or adolescence, they are present in some. For example, the pattern of socioemotional deficits shown by individuals with autism is one that would be abnormal at any age (see chapter 46). The same applies to the thought disorder, negative symptoms and delusions/hallucinations found in schizophrenia (see chapter 45). The situation is not quite so clear cut with obsessive-compulsive phenomena but, although ruminations and minor checking behavior may be regarded as falling within the normal range of variation, that is not the case with overt compulsive rituals of a marked kind (see chapter 43). Somewhat similar considerations apply to Tourette syndrome and chronic multiple tics (see chapter 44). Particular care needs to be taken in eliciting detailed descriptions of such qualitatively abnormal features because, if people have not experienced these phenomena, they may interpret the questions as referring to the more normal features that were within their experience.

The existence of firm diagnostic criteria for different psychiatric disorders in the official classification systems is sometimes thought to imply that there cannot be a disorder if it does not fit into one of the specified diagnoses. Manifestly, that is not the case, as both clinical and epidemiological studies show (Angold et al., 1999; Pickles et al., 2001). Of course, the presence of social impairment does not in itself mean that there is a psychiatric disorder. It does suggest that something is wrong but one key diagnostic question is whether or not this is attributable to some form of physical disease. Nevertheless, even when such disease appears to be ruled out, the diagnosis of psychiatric disorder needs to be based on clear evidence of psychopathological dysfunction, even if the number and pattern of symptoms do not fit the rules of any single specified disorder.

Duration and Timing of Disorder

Classification systems have often used duration of disorder as a key criterion by which to determine whether or not psychopathology is clinically significant. For example, DSM-IV (American Psychiatric Association, 2000) has specified a minimum duration of 2 weeks for a major depressive disorder, 6 months for a conduct disorder or a generalized anxiety disorder, 2 years for a dysthymic disorder in adults and 1 year in childhood, no duration for anorexia nervosa but 3 months for bulimia nervosa. It is immediately obvious that the choice of these time periods is essentially arbitrary. Thus, most clinicians would regard 2 weeks as a rather short period of time for a major depressive disorder, and it is noteworthy that the research diagnostic criteria specify 4 weeks, rather than 2 (Mazure & Gershon, 1979). Also, a year seems a long time to require a dysthymic disorder to last in order to regard it as meeting criterion. A further problem is that, even with high-quality research interviewing that involves a specific focus on personalized timing, the reliability of the timing of onset of disorder has proved rather poor (Angold, Erkanlis, Costello et al., 1996). In all probability, this is not because people find it difficult to remember some clearly identifiable time when a disorder began, but rather because many disorders do not have a clear-cut onset. Frequently, symptomatology builds up over time, with several points at which new symptoms become apparent and/or when psychosocial impairment first becomes evident (Rutter & Sandberg, 1992; Sandberg, Rutter, Pickles et al., 2001). Clearly, it is important for clinicians to obtain as good an account as possible of how psychopathology developed over time and to seek to identify times that might be conceptualized as either an onset of disorder or a clear worsening of disorder. From a clinical perspective, however, it is less appropriate to follow DSM-IV rules about duration in a slavish fashion than it is to decide that the symptoms constitute something that manifestly falls outside the range of normal variation for that person and which either involves qualitative abnormalities or has interfered with psychosocial functioning to a substantial extent.

Nature of the Mental Disorder

In chapter 2 we consider some of the conceptual and practical issues concerned with varying concepts of comorbidity. Here, we need to emphasize that, regardless of which classificatory principle is followed, it is essential in clinical assessment to obtain an adequate assessment of the mix of symptomatology. That is because, irrespective of whether or not the mixture is conceptualized as comorbidity or mixed symptomatology in a single disorder, it is likely to have implications for treatment strategies. The day may come when there are drugs that are specific to particular diagnoses but that day is a long way off at the moment. Both psychological and pharmacological treatments need to focus on particular patterns of symptomatology rather than the diagnosis as such.

If the assessment has indicated that there is a significant psychopathological disorder, the next questions are what form it takes, and what diagnosis or diagnoses may be applied to it. ICD-10 (World Health Organization, 1996) and DSM-IV (American Psychiatric Association, 2000) adopt different approaches to this issue (see chapter 2). There are pros and cons with respect to how co-occurrence is handled in both these classification systems. However, the clinical need is to assess the overall mixture of psychopathology because this is likely to influence treatment decisions and prognosis, and because it may help in sorting out the meaning of the symptom patterns and the causal mechanisms that might be involved.

Also, a basic hypothesis-testing approach to diagnostic assessment is fundamental to the diagnostic enterprise. For example, although not well reflected in either of the two main classification systems, it is important to differentiate among the various causes of fecal soiling (Rutter, 1975). This may arise, for example, because the child has failed to gain bowel control. Alternatively, control may well have been achieved and maintained, with the disorder lying in the deposition of feces in inappropriate places rather than in any lack of or loss of control. A third possibility is that there has been fecal retention leading to gross distension of the bowel and partial
blockage. In these circumstances, fecal soiling may arise because there has been an overflow of feces stemming from the prior distension. In order to differentiate between these possibilities, careful assessment is needed of whether or not the feces are normal in form and consistency, whether there is a history of previous normal bowel control, whether the soiling has been preceded by patterns of retention or other abnormalities in bowel functioning, and whether the deposition of feces is essentially random (according to where the child happens to be at the time that the bowels are opened) rather than selectively placed in situations having psychological meaning. Clearly, the therapeutic interventions need to be chosen on the basis of the type of disorder represented by the soiling (see chapter 56).

A decision-tree approach may also be very useful in the assessment of developmental disorders of language. When the diagnostic issue concerns some pattern of psychopathology associated with the language delay, it is helpful to tackle the decision-making in stepwise fashion (Rutter, 1985). Thus, it is usually best to begin by determining the child’s overall level of cognitive functioning, going on to consider whether language skills are significantly below those of other aspects of cognitive functioning. The question then is whether the psychopathology shown is outside the range of normal behavior expected in relation to the child’s overall mental age and level of language functioning. If it is outside that range, rather than move straight away to consider the complete list of possible psychiatric diagnoses, it is generally helpful to ask the question of whether the behaviors are of a kind that might be found in any child (that is, the usual run of emotional problems and disorders of disruptive behavior) or whether the pattern is qualitatively different in a way that is associated with pervasive developmental disorders. Having made that decision, it is then somewhat easier to move on to a consideration of which particular diagnostic concept best fits the picture in whichever direction the prior decision has taken.

In some cases, the clinical question may concern social usage of a skill. Thus, selective mutism (see chapter 47) is characterized by a high degree of selectivity in circumstances of talking. As in experimental studies more generally, the need is to design a situation in which children can and do succeed but do so in ways that are informative on the mechanisms involved. With selective mutism, the need is to be able to demonstrate that the children can use spoken language in particular circumstances, just as much as showing that they do not use spoken language in other situations.

**Psychosocial Assessment**

Psychosocial risks are important in the development of psychopathology (see chapters 25 & 26). It is important therefore that the diagnostic assessment provides an efficient, reliable and valid means of assessing the presence of psychosocial risk factors. However, the need should not be seen as exclusively related to questions of causation. In planning psychological interventions (when they are indicated), it is important to identify possible protective mechanisms as well as risk features. Moreover, it is necessary to assess risk and protective factors, not only in terms of what is happening within the family, but also what is happening within the peer group, school and community (Rutter, Giller, & Hagell, 1998; Shonkoff & Phillips, 2000). Furthermore, the psychosocial assessment needs to include both past experiences and current circumstances. On the whole, most early experiences do not have enduring effects that are independent of later psychosocial circumstances (Clarke & Clarke, 2000). Nevertheless, profoundly depriving experiences can have major sequelae that persist long after children have ceased to suffer deprivation and have had good rearing experiences in a well-functioning family (Rutter, Kreppner, O’Connor et al., 2001). Similarly, there may be enduring effects of seriously abusive experiences (see chapters 28 & 29) or unusual severely traumatic experiences (see chapter 42).

A key consideration with respect to all these experiences, risk and protective, is the need to appreciate that the experiences cannot be thought of as impinging on a passive organism. Children, and adults, think and feel about what they experience and the cognitive/affective sets that they develop (or internal working models) may be very important in determining the consequences of such experiences. What this means is that the assessment needs to determine both how children have coped with their experiences (see chapter 65) and what they have thought about what has happened to them and how they view their current experiences.

Research over recent decades has made it abundantly clear that genetic factors have an important role in the origins and persistence of all forms of behavior, including all forms of psychopathology (see chapter 23). The findings are of major clinical importance for several rather different reasons. First, they show the importance of recognizing the influence of genetic susceptibilities with respect to individual differences in the liability to psychopathology. That means, amongst other things, that any adequate diagnostic assessment will need to include systematic questioning with respect to a family history of psychopathology.

Particular attention needs to be paid to disorders in parents and in siblings, not just because they are the closest relatives with respect to genetic inheritance, but also because mental disorders in the immediate family will involve environmentally mediated, as well as genetically mediated, psychosocial risks (Rutter, 1989). Thus, parental mental disorder is associated with a substantially increased risk of family discord and family breakdown, and also focused hostility on individual children (Rutter, Maughan, Meyer et al., 1997). This means that it is important to assess the ways in which parental mental disorder impinges on the family and not just to be content with recognizing its presence. The risks may also involve physical risk factors in relation to substances that cross the placental barrier during pregnancy. Thus, high levels of alcohol ingestion in the early months of pregnancy may lead to the neurodevelopmental abnormalities associated with fetal alcohol syndrome (Spohr & Steinhausen, 1996; Stratton, Howe, & Battaglia, 1996). There may also be effects from taking...
CHAPTER 4

recreational drugs or prescribed medications (Delaney-Black, Covington, Templin et al., 2000; Singer, Arendt, Farkes et al., 1997). The extent to which there is enquiry about mental disorders occurring in second- and third-degree relatives needs to be guided by the particular clinical problem. However, it should be routine to ask about the occurrence of major mental disorders or developmental problems on both sides of the family. Genetic testing (using cytogenetic and molecular genetic methods) is not part of routine assessment but it is important in some circumstances (see chapter 24) and could become more generally applicable in the future.

Research methods that provide systematic standardized assessments of psychosocial features are too time-consuming for use in most clinics. Nevertheless, they do provide helpful guides on how such routine clinical assessments should be undertaken. As with the assessment of psychopathology, the agreement between the reports of parents and children tends to be modest to moderate at best (Achenbach, McConaughy, & Howell, 1987; Borge, Samuelsen, & Rutter, 2001; Rutter, Tizard, & Whitmore, 1970; Simonoff et al., 1997). That is partly because parents will not know about the full range of children’s experiences outside the home, partly because their perspectives may not be the same and partly because some disorders may be relatively situation-specific (Cox & Rutter, 1985). The implication is that some assessment of psychosocial risk and protective experiences needs to be obtained from both parents and children. The classification of psychosocial experiences developed by the World Health Organization (van Goor Lambo, Orley, Poustka et al., 1990) provides some guidance on the range of experiences that need to be considered and there are standardized interviews that cover most of the relevant experiences (Sandberg, Rutter, Giles et al., 1993). However, the research findings from studies that have used designs that can separate environmental from genetic mediation (Rutter et al., 2001; Rutter, 2007) suggest that the experiences carrying the greatest psychopathological risk mainly concern marked negativity in close personal relationships, a lack of continuity in personalized caregiving, a lack of appropriate learning experiences and participation in social groups with a deviant ethos, attitudes or styles of behavior (Rutter, 2000a). Although not much investigated in genetically sensitive designs, it is likely that parental monitoring and supervision of children’s behavior are also important in relation to antisocial problems (Rutter, Giller, & Hagell, 1998; but see Stattin & Kerr, 2000, with respect to the role of children’s disclosures). In relation to all these experiences, it is necessary to determine the ways in which such experiences impinge on individual children, and are responded to, and not just the experiences as they affect the family as a whole. Although excessive claims have been made about the preponderant importance of child-specific experiences (Reiss, Neiderhiser, Hetherington et al., 2000; Rutter, 1999), it is the risks as they affect the individual child that are important, even if they impinge similarly on other children in the same family.

In that connection, the research evidence suggests that it is often useful to make direct comparisons among children in the family with respect to features such as whether one is more likely to be criticized than others, more frequently favored, or more likely to be involved in relevant risk or protective experiences in the family (Carbonneau, Eaves, Silberg et al., 2002a, Carbonneau, Rutter, Simonoff et al., 2002b). In addition, research has shown how much can be inferred from the ways in which a parent talks about the children. This was first demonstrated in the Camberwell Family Interview (Brown & Rutter, 1966; Rutter & Brown, 1966) but has been developed as a much briefer assessment in relation to the 5-minute speech sample (Magaña, Goldstein, Karno et al., 1986). The implication is that it is important to have a time during the assessment when parents are asked neutral questions about their children, not just questions focusing on problems. Thus, it is helpful to get parents to talk about what their children are like as individuals, how easy they are to be friendly and affectionate with, what is their most striking individual characteristic, etc. The same, of course, applies to the ways in which children talk about their parents and about their siblings.

**Diagnostic Formulation**

Diagnoses serve the important role of providing a succinct summary of the key clinical features that are held in common with disorders experienced by others (see chapter 2). This is a most important purpose and one that is central to communication among clinicians, just as much as among researchers. Multiaxial systems of classification (World Health Organization, 1996) can go somewhat further because they can serve to classify relevant psychosocial situations that may have played a part in causation or that may be pertinent with respect to therapeutic planning, as well as intellectual level and level of adaptive functioning. By considering the information included across a complete range of axes, a lot of clinically relevant information can be summarized succinctly.

Nevertheless, that is not quite the same thing as developing hypotheses about causal processes and hypotheses about therapeutic interventions. For example, suppose it has been found that the child has cerebral palsy. As outlined in chapter 30, there is good epidemiological evidence that this is associated with a substantial increase in psychopathological risk in groups of children with this condition. However, the risk could come about through several different routes, each of which has different implications for intervention. Thus, in some instances, the main risk may derive from the electrophysiological disturbance associated with frequent, poorly controlled epileptic attacks. In other cases, the risk may stem from impaired cognitive skills and from the educational difficulties to which they may give rise. In some cases there may be relatively direct neural effects of brain dysfunction, as exemplified in so-called frontal lobe syndromes exhibiting social disinhibition that sometimes occur after severe head injuries (Rutter,
Chadwick, & Shaffer, 1983). In yet other cases, the psychopathological risk may derive from the child’s negative self-image as a result of his or her physical limitations, or perhaps from parental overprotection that came about as a way of dealing with a physically handicapped child. In yet other cases, the cerebral palsy may be a relatively incidental finding that has no particular relevance with respect to the mental disorder. Of course, when dealing with a single case, it is difficult to have hard evidence that enables a choice between these alternatives, but it is important for the clinician to have a view on the likely importance of different mechanisms.

Closely comparable issues arise with respect to psychosocial risk factors. If the mother is alcoholic, did the psychopathological risk derive from the child’s in utero exposure to high levels of alcohol, from the genetic susceptibility, or from the family disruption and poor parenting to which the alcoholism may have given rise? In considering causal processes, too, crucial distinctions need to be drawn between distal and proximal risk processes (Rutter, Giller, & Hagell, 1998) and also between influences on the initiation of the child psychopathology and the processes that are currently maintaining it. Thus, poverty and social disadvantage are associated with an increased risk of mental disorders in childhood, but most of the risks seem to be indirectly mediated. That is, the overall disadvantageous social circumstances do not, in themselves, cause psychopathology but they do make good parenting more difficult and the main risks stem from the parenting problems (see e.g. Conger, Conger, Elder et al., 1992, 1993). In the same sort of way, parental loss and parent–child separations are associated with an increased risk of antisocial behavior but, again, this seems to be largely because of the associated family discord and conflict (Fergusson, Horwood, & Lynskey, 1992; Rutter, 1971). Furthermore, although family conflict is associated with an increased risk of psychopathology, it seems that this largely comes about when the conflict leads to negativity that is focused on that particular child (Reiss, Hetherington, Plomin et al., 1995). Also, it is important to appreciate that the child’s disorder may predispose to problems in parenting or to family conflict. In these examples, the global family situation needs to be thought of as a risk indicator, rather than an immediate risk mechanism. It is implicated in the causal processes but largely because it predisposes to other psychosocial features that constitute a more direct psychopathological risk. It is by no means easy to make these distinctions in individual cases (or even at a group level) but it is important when trying to decide how best to intervene.

The distinction between initiatory or provoking risk factors and factors concerned with the maintenance of a disorder is somewhat different. For example, an extremely traumatic experience may precipitate a post-traumatic stress disorder (see chapter 42) but some individuals recover quite quickly whereas others are affected for several years afterwards. In most cases, the difference between recovery and persistence is likely to lie less in the severity of the initial experience than in how the person thinks about that experience and how they have dealt with it. The original traumatic experience cannot be taken away but the person may be helped to deal better with both the thought patterns and emotional reactions to which the experience gave rise. In other cases, it may be helpful to differentiate between the factors that had a major role in the timing of the onset of the disorder and those that were responsible for the increased liability that led to the disorder occurring at all (see chapter 26). Thus, severely threatening life events (such as psychological loss or humiliation) may precipitate the onset of a depressive reaction or the initiation of a particular behavior such as a suicidal act (see chapter 40). On the other hand, the overall susceptibility to disorder may have more to do with the associated chronic psychosocial adversity than with the time-limited acute event itself. One of the important findings in life-events research is the high frequency with which seriously negative events derive out of chronic psychosocial adversity. Both are important but they may serve a somewhat different risk role.

**Treatment Planning**

In recent years, systematic literature review and consensus development conferences have led to official and unofficial guidelines for treatment planning. They are usually organized around a diagnosis, so the diagnosis given will in itself suggest treatment possibilities. Indeed, purchasers or managers of health care may insist on clinicians following the guidelines for a particular condition.

The clarification of the evidence base is very welcome, but we see dangers in the mechanical following of protocols. The current state of knowledge seldom allows the diagnosis by itself, or even several simultaneous diagnoses, to dictate intervention. Major benefits of treatment protocols include the indication to services of what methods of assessment and treatment should be made available. However, it is the individual formulation rather than the diagnostic category that should guide the treatment plan.

Clearly, the proximal risk mechanisms involved with the maintenance of the disorder must play a major part in determining the therapeutic hypotheses that constitute the basis for planning treatment. However, several other matters have to be taken into account. To begin with, it is necessary to consider possible protective mechanisms, as well as risk processes (Rutter, 1990). As in the broader consideration of features associated with resilience (Rutter 1999, 2000b, 2006), such possible protective processes may reflect a quite diverse range of features. Thus, the strengths may lie in the child’s temperamental qualities and/or coping skills (Sandler, Tein, Mehta et al., 2000), in the presence of a particularly good close relationship in or outside the family, of compensating good experiences at school or in the peer group, or in a possible change of pattern in family functioning. Thus, if one parent is particularly under stress, the other parent may be encouraged to take a greater role in parenting. The point is that the clinician needs to think broadly about the child’s psychosocial situation in order to identify possible strengths and protective possibilities.
CHAPTER 4

In planning any intervention, it is as necessary to decide which features are modifiable as it is to determine which are the risk and causal mechanisms. Thus, it is necessary to decide whether the intervention should focus primarily on working with the child, with the parents, with the family as a whole, with the school or trying to change other aspects of the broader environment. Of course, the treatment strategy may involve more than one of these avenues. One aspect of deciding about openness to modifiability concerns different perceptions of the child and of what needs to be done. Part of the same issue concerns a decision on what are realistic goals. The aim must be to provide relief for the child’s suffering in the first instance, but restoration of full normality may not be a realistic goal (e.g., only rarely would it be so in the case of autism; see chapter 46). Similarly, the intervention may not necessarily focus on the hypothesized basic causal process. Again, to use the example of autism, there would be general acceptance that this is a neurodevelopmental disorder but, equally, the evidence suggests that behavioral and/or educational interventions working with parents and teachers currently provide the best opportunities for reducing handicaps, even though autism has clearly not been caused by the lack of such experiences.

Yet another decision concerns whether or not to use medication and, if medication is used, how it should be employed and when it should be introduced. There are no drugs that are curative for child psychiatric disorders but there are several conditions for which medication has been shown to produce worthwhile benefits. These include depressive disorders (see chapter 37), obsessive-compulsive disorders (see chapter 43), tics and Tourette syndrome (see chapter 44), schizophrenia (see chapter 45) and hyperkinetic disorders (see chapter 34). They may also provide symptomatic benefits in other disorders. Decisions on drug usage will be influenced, among other things, by the severity of overall impairment and the particular pattern of symptomatology. Thus, the advantage of stimulants over behavioral approaches is much less marked, or even absent, when ADHD symptomatology is mild (see chapter 34), and antidepressants are probably more likely to be effective when the depression is accompanied by vegetative symptoms such as sleep and appetite disturbance, and psychomotor retardation (see chapter 37). In most cases, medication will need to be combined with some form of psychological or educational intervention. That is because, in most cases, although medication brings marked benefits, it does not restore normality and steps may be needed to help the child and/or family cope more effectively and deal with any life situations or circumstances that provide psychopathological risk. Such steps may involve guidance or counseling of some kind but, in other cases, more intensive psychological intervention may be indicated. Decisions will need to be guided by what seem to be risk features either in the psychosocial situation or the child’s style of thinking, or perhaps of behavior. It should be added, however, that the use of medication will carry psychological messages and that, unless carefully handled, these can undermine the psychological intervention (for an example in relation to dieting see Craighead, Stunkard, & O’Brien, 1981). The implication is not that different forms of intervention should not be combined but rather that the clinician needs to be concerned to present the combination in an appropriate way.

However, it should not be thought that drugs will influence only somatic features and not cognitions. The use of antidepressants in adult depression makes it clear that that is not the case (see chapter 37). Equally, it should not be supposed that psychological treatments cannot influence somatic functioning. The effects of psychological treatments in obsessive-compulsive disorder, in terms of their effects on functional imaging findings, negate that expectation (Baxter, Schwartz, Bergman et al., 1992). However, recent research indicates that the effects of treatments on the brain may vary according to whether or not the treatment has been psychological or pharmacological, or whether a placebo has been used (Goldapple, Segal, Garson et al., 2004). At present, it is not clear quite how these findings should be used in thinking about the diagnostic formulation, but what they do indicate is the fallacy of assuming that psychological interventions operate only on the mind and pharmacological ones only on the brain. In fact, both do both, albeit in slightly different ways. Nevertheless, in relation to hypotheses about maintaining factors, the clinician will wish to take decisions on the appropriate choice, and mixture, of therapeutic interventions. It is important that this is done in a way that carries with it predictions as to how it will be clear whether the therapeutic hypothesis is correct or needs modification as a result of the response to intervention.

A good treatment plan will include an indication of how one can tell whether it is meeting its goals. This may be an expectation of what symptoms on a rating scale will change, or a less tangible prediction for a change in family or peer relationships. Whatever the intended outcome, it should be clear enough that one can check whether it is being achieved. The spirit of hypothesis-testing, which we have emphasized throughout this chapter, implies that formulations must be able to shift in the light of review. One example would be that of a child who presented with marked inattentiveness at school, who was sleepy in the daytime and markedly sleepless at night. The initial formulation was unified: the lack of sleep was thought to cause both drowsiness and poor attention. Successful treatment of the insomnia, however, did nothing to help the tendency to fall asleep in the daytime and it became clear that the two sleep problems were in fact independent and needed different interventions.

As Hoch (1964) pointed out many decades ago, one of the key challenges in the whole of treatment, not only in psychiatry but right across medicine, is why treatments work for some individuals yet not for others. Similarly, side-effects can be really problematic in some people yet of minor importance in others. The field of pharmacogenetics (see chapter 23) carries with it the promise that genetic findings may help in this connection because of the evidence that genetic factors influence people’s susceptibility to drugs and probably also their susceptibility to psychological interventions. At the moment, pharmacogenetics
is a field with promise but one with, as yet, few direct clinical implications for the care of individual patients.

Research findings are not as helpful as one might wish in the choice of which particular kind of psychological treatment to use, when that is the approach that is being adopted. Although the evidence is reasonably consistent that focused goal-oriented interventions work better than open-ended, more general ones (Rutter, 1982), that would seem to suggest that the specifics of the treatment are important and that general support is not enough. On the other hand, although the range of comparisons remains more limited than one would like, the evidence does not indicate that, for any disorder, one particular style of psychological treatment is clearly generally better than others. Moreover, even when treatment is given by experienced clinicians, with an investment in more intensive treatments, studies with both young people (Le Grange, Eisler, Dare et al., 1992) and adults (Wallerstein, 1986) have often shown that skilled counseling may be as effective as more intensive psychological interventions that are designed to get more into the heart of the psychological problem. Although it should certainly not be supposed that simple treatments are always to be preferred, the findings do indicate that the more complicated and intensive ones are not necessarily better. Decisions on the particular form of psychological intervention probably need to be guided by the nature of the psychological difficulties, the personal characteristics and preferences of the individual child and family, and the preferences of the clinician in terms of skills, experience and preferred mode of working. Nevertheless, cost–benefit considerations are important and the choice of a more prolonged treatment over a shorter one will always need to be justified.

Standards for Practice
Clinical practice must be performed under a variety of administrative and financial constraints. We have outlined what is needed in psychiatric assessment; health services may often wish to make some assessments of mental function that fall short of psychiatric assessment. This is often justified, and problems such as uncomplicated bedwetting, or parental discomfort at coping with young children’s oppositional behavior, may well need no more than a simple screen as to whether problems are present that indicate a psychiatric assessment.

However, when problems are big enough and persistent enough to require referral, then information is needed about all the above domains – the nature of the disorder based on several sources of information, coexistent problems, impairment, course of disorder and psychosocial experiences, together with a professional judgment to synthesize them.

Assessment for Court Reports and Other Comparable Situations
Clinical assessment and diagnostic formulations tend ordinarily to be thought of in terms of what should be done with respect to a young person who is referred to a clinic because somebody feels that there is a problem and that something needs to be done to help. However, in addition, there are a variety of situations in which the clinician (whether psychiatrist, psychologist, pediatrician or social worker) is expected to serve as an expert witness in relation to some dispute that has come before the courts or some other decision-making body (see chapter 8). The assessment, rules and principles are, in essence, closely comparable to those that apply in the clinic situation (although the reporting and responsibilities are different) but there are several particular considerations that require emphasis.

To begin with, it is absolutely essential to be explicit about the expertise that one does, and does not, have. For example, the case might be one where there is litigation over whether or not a child has developed autism (or some other condition) as a result of immunization, head injury or an infection. The clinical expert can usually express well-informed views on the nature of the child’s disorder, on whether its onset and course are atypical in any way that casts light on the nature of the disorder, and on what is known about the causes of the condition in question. On the other hand, psychiatrists and psychologists are not likely to be expert on particular detailed laboratory findings and the report needs to be careful to avoid straying on to conclusions based on types of evidence on which the person is not expert.

Similarly, dispute may focus on the statistical likelihood of a particular association between some postulated causal factor and the specified outcome, or on the likelihood that, when two or more children in the same family have died or suffered from a particular injury, this implies malevolent action on the part of the parent. Particular care needs to be taken on interpreting the meaning of any particular statistical likelihood, as well as the strength of the particular likelihood. As always in clinical diagnosis and assessment, it is crucial to consider competing possibilities. For example, if the occurrence of two cases of autism arising in the same family is being alleged to be a result of parental mishandling, the report would need to draw attention to the likelihood that genetic factors may have played a part. Alternatively, if the outcome is tuberculosis, it would be important to bear in mind the likelihood that multiple cases in the same family may stem from the spread of infection. Those are obvious circumstances and the dispute usually arises when causation is nowhere near so obvious. Nevertheless, the same need arises to consider the possibility that genetic factors or shared environmental factors (other than those involving parental abuse) may be responsible. Where relevant, attention needs to be drawn to what possible investigations might be undertaken that could help in resolving the issue. A further consideration is that the clinician needs to consider what is the appropriate comparison to be made. The issue will very rarely be one of simply whether multiple cases of the condition could have arisen by chance, but rather what is the relative likelihood of its having arisen through some genetic or shared environmental factor rather than parental abuse. Clinicians would need to ask themselves whether there is research evidence that has shown the likelihood of particular
answers when the starting point is uncertainty of a comparable kind to the case in question. In short, the court may be asking the expert whether some particular outcome is a result of some alleged cause, but, just as in the situation where a child is referred with the question as to whether the behavior is caused by, say, schizophrenia, the duty of the clinician is to look much more broadly at the issues and not confine attention to the one alleged possibility.

A further need is to ensure that attention is drawn to findings (whether clinical or laboratory) that raise doubts about the particular opinion the expert is putting forward. In other words, it is the obligation of the clinician to make explicit the evidence for and against, and not simply come up with some ex cathedra assertion. When expert opinions have proved potentially misleading it is usually because either expertise has been claimed when the person does not have the relevant expertise, or attention has not been paid to possible competing explanations, or the statistical comparisons have been made against a too limiting set of alternatives, or possibly relevant evidence has been omitted from the report despite the fact that the expert knew about the evidence.

A further need is to pay careful attention to the relevant research evidence, as well as the findings in the particular case, and to make explicit the logic and reasoning that constitute the basis of the opinion being expressed. Particularly in criminal courts, the lawyers on either side are likely to press the expert for a definitive statement as to whether something did or did not occur. If such a definitive opinion is possible, that is fine, and it should be stated, but in most instances the valid conclusion is likely to be probabilistic rather than categorically determinative and that should be made explicit, regardless of pressures to come down on one side or the other.

Perhaps most frequently of all, clinicians are likely to be called upon to give evidence when there is disagreement as to whether, following the break-up of a marriage or break-up of a family, a particular child should be placed with one parent or the other, or should have this amount or that amount of time with each parent, or indeed whether it is safe for the child to have unsupervised contact with a particular parent when the evidence suggests that abuse may have taken place. In almost all circumstances that come to court, there is no ideal solution. In these circumstances, the obligation of the expert is to consider carefully the pluses and the minuses of the various alternatives and to put forward a carefully considered opinion as to what is the most desirable (or least undesirable) course to take. It is also quite common for it to be necessary to express opinions on the basis of some contingency as to how things are managed or how something is dealt with. It is the sort of thinking that ought to constitute the basis of any clinical assessment but it is a very healthy challenge for clinicians to have to be as explicit as they need to be in making overt the reasoning for their opinions and the balance of evidence on which they are having to rely.

In recent high-profile cases, senior figures in the profession have expressed grave worries about the dangers that professionals face in giving evidence in cases that involve disputes over child protection. In our view, these concerns are misplaced. It is true that there have been ill-judged and unreasonable campaigns against the opinions of some expert in particular cases. It is also, of course, not unknown for even the most careful, skilled and thoughtful assessments to be sometimes in error. We all make mistakes. What is required is that we take the greatest care in coming to decisions, to be fully honest in the way we express opinions (including doubts and uncertainties where these are present) and to be willing to change our opinion if it is made evident that either there is evidence that we did not know about or, alternatively, that there are facts or findings either in the literature or in a particular case that indicate that we have been in error.

In the British judicial system, it is explicit that the expert’s duty is to the court, and not to whoever has called them to give evidence (or who has paid their fees). That is not so in all countries but, in our view, there is much to be said for having it explicit that where the expertise is being sought in relation to the needs of a particular child, the expert’s loyalties are to do the best for that child and that is most easily accomplished if the expert is called by the court, rather than by one or other of the parties in dispute. At the moment, that is the exception rather than the rule and it is to be hoped that this may change in the future.

In other circumstances, the expert may be asked to give an opinion in relation to some specific skill or capacity. For example, this often arises with respect to decisions on whether or not a child can be held responsible for their actions in relation to some alleged criminal activity. In these circumstances, the clinician will need to think carefully on how to assess such responsibility and to recognize that it cannot be carried out purely on the basis of age or IQ. There are marked individual differences in children’s ability to understand, even when the children are all of the same age or IQ. Moreover, understanding is likely to be influenced by children’s particular experiences in relation to relevant circumstances, and the ability to understand may also be influenced by the nature and gravity of the alleged offence (Royal College of Psychiatrists, 2006).

Precisely similar issues arise with respect to decisions on whether children are, or are not, competent to give permission, or refuse permission, for particular forms of treatment (or on whether or not to participate in research – Royal College of Psychiatrists Working Party, 2001). These are not easy decisions to make and there are no entirely satisfactory tests that may be employed. On the other hand, there are some reasonable guidelines that have been put forward (British Medical Association, 2000). A rather more specific example of a related issue has concerned cases in the past where it has been alleged that children have made statements about being abused or about their wishes for some particular family arrangement and have done so through what has been called “facilitated communication.” This is a circumstance in which the child is supposed to convey what they want to say through some technical device that involves the cooperation
of another person. The whole topic of “facilitated communication” has proved to be a controversial one but, from an expert witness point of view, the key issue is to find a means of determining whether the statements derive from the child or from the adult who was assisting. The usual solution to this dilemma has been to set up a procedure in which the answer is influenced by what is known to the facilitator but not to the child (Rutter & Yule, 2002).

**Conclusions**

In this chapter we have sought to bring together some of the main considerations that need to guide the approach to diagnostic assessment and the planning of treatment. Research findings have been informative in providing guidance on some of the methods of assessment that work better than others and have undoubtedly indicated the value of a systematic approach to the degree of standardization. However, it is always necessary to be responsive to the individual needs and circumstances of each patient, to pick up cues and to adapt assessment procedures accordingly. With respect to both diagnosis and the planning of treatment, it is also important to adopt a problem-solving, hypothesis-generating, and hypothesis-testing, style. The gathering of factual data on psychopathological signs and symptoms and on risk and protective circumstances constitutes the essential basis. On that basis, it is important to seek to tell a “story” about causal processes and to use that “story” to plan a treatment strategy and to do so in a way in which the response to treatment may indicate whether or not the therapeutic hypothesis was correct.

This chapter reviews what epidemiological and longitudinal research can tell us about the causes of child and adolescent mental illness. The job of epidemiology is to understand patterns of distribution of disease in time and space, so that those patterns can provide a guide to preventing disease (Kleinbaum, Kupper, & Morganstern, 1982). Not all epidemiological studies are longitudinal, and cross-sectional studies can also provide useful clues to the causes of illness. However, many epidemiological studies have studied longitudinal patterns of disease distribution over time as a test of causality; for example, to see whether smokers die younger than non-smokers (Doll & Hill, 1966). In this chapter, the main focus is on studies that are both epidemiological and longitudinal; that is, they make use of patterns in both space and time to develop and test ideas about what might be causing disorders.

Using Epidemiological Studies to Answer Causal Questions

Observation, categorization, pattern recognition, hypothesis testing, causal thinking – these are the stages through which a science tends to progress as it advances in knowledge and rigor (Feist, 2006). People tend to think of epidemiology as primarily a descriptive discipline, stuck at a fairly primitive level in its development as a science, somewhere between categorization and pattern recognition (Maldonado & Greenland, 2002). However, pattern recognition in the study of disease (how the distribution of disease deviates from random) can serve more than one purpose. Of course, descriptions of the prevalence and burden of disease in various places and at various times are critical for planning services and warning of epidemics, but studying these patterns can also generate hypotheses about what might be causing a disease or encouraging its spread. Observing the spread of a disease from one person to another across a city, a country or a continent may provide clues about its mode of transmission (by touch? sneezing? sexual contact?) and thus about what causes it, while the length of time between cases can give hints about the necessary incubation period, and hence the type of mechanism driving the disease process. In the case of psychiatric disorders, we can also use observations of the distribution of disorders across both space (why is the prevalence of schizophrenia so high in immigrants from the Caribbean to England? Eagles, 1991) and time (why is there an increase in depression in girls at puberty? Angold, Costello, & Worthman, 1999) to explore possible causes. Thus, epidemiology can be descriptive and analytic at the same time, concerned with both observation and causation.

Causation and Counterfactuals

Scientists, including epidemiologists, are taught never to equate correlation with causation without better evidence than a statistically significant association. But how do we get beyond association? How can we know that something was the effect of a certain cause? We think we know clearly enough in everyday life, but people have argued for centuries about the true definitions of cause and effect. Attempts to define them can easily become circular.

An approach that has gained popularity since the 1960s is based on an idea of the 18th century philosopher David Hume: “We may define a cause to be an object followed by another, . . . where, if the first object had not been, the second never had existed” (Hume, 2000). A 20th century reformulation of the proposition states: “Where c and e are two distinct possible events, e causally depends on c if and only
We can assume some sort of relationship between cause and effect. The relationship becomes more likely if:

1. more practical approach, which states that a causal relation is demonstrated by Robins and others (Maldonado & Greenland, 2002; Robins, 1997), the counterfactual approach to causal reasoning about cause and effect. Of course, this is an impossible research model because we cannot both expose and not expose the same child to the same stimulus, at the same time. “A counterfactual is something that is contrary to fact” (Shadish, Cook, & Campbell, 2002). However, the counterfactual metaphor is a useful one, because it sets a standard against which to judge the experimental and quasi-experimental designs that we discuss in this chapter.

In the real world, we generally follow John Stuart Mill’s more practical approach, which states that a causal relationship becomes more likely if:

1. The cause preceded the effect;
2. We can assume some sort of relationship between cause and effect; and
3. Our identified cause is the only logical explanation we can find for the effect (Mill, 1856).

As researchers we try to create (or observe) a situation where these three principles hold. As our knowledge of an area increases, it may be possible to strengthen the causal argument by elaborating some parts of the relationship. For example, the famous Henle–Koch principles (Koch, 1882) elaborated by Hill (1965), Susser (1991) and for psychiatry by Robins and Guze (1970), impose additional requirements that broaden their applicability beyond infectious diseases. Hill’s nine conditions comprise strength of association between “cause” and disease; consistency of the association; temporal precedence of cause over outcome; biological gradient (e.g., a dose–response curve); biological plausibility; coherence (i.e., the explanation does not conflict with current knowledge about the natural history of the disease); experimental evidence; and analogy with similar “causes.” It is important to note that Hill did not refer to these conditions as necessary “criteria,” but rather as “viewpoints from all of which we should study association before we cry causation” (Hill, 1965).

Two Kinds of Causality

There are two kinds of causal inference that epidemiological studies of causality seek to establish: specific causal inference, the ability to infer that the observed relationship is a causal one, not merely post hoc ergo propter hoc (“after this, therefore because of this”); and generalized causal inference, the ability to infer that whatever causal relationship was observed or tested in a given study applies more generally, outside the confines of the specific samples used. A useful study of causality will permit both kinds of inference to be made: the predicted causal factor did indeed cause the observed outcome, and the relationship between the two applies beyond this study.

Specific Causal Inference

Random assignment to treatment conditions is an excellent tool in the effort to infer that an observed relationship really is a causal one. Randomization is the nearest we can come to unbiased assignment to intervention and non-intervention groups. It simplifies controlling extraneous variables that might confuse the picture, and measuring the dose of the factor expected to be causal. However, in epidemiological studies, random allocation to “treatment” and “no treatment” groups is rarely possible (we discuss later some ways in which researchers have tried to create unbiased assignment in other ways). Other threats to internal validity (i.e., the validity of a specific causal inference) are problems for clinical as well as epidemiological research, and are discussed in the next section. For example, selection criteria for the study must not create the risk of regression artifacts (e.g., selecting participants because they score at the top of the range on a behavior problem scale, so that they are likely to score lower next time, irrespective of the treatment), and attrition must not occur at different rates or for different reasons from different groups in the study.

Generalized Causal Inference

Establishing that a causal inference is generalizable beyond a specific experiment is also a problem for both clinical and epidemiological studies. Establishing generalizability involves two tasks: matching the “surface characteristics of an operation to those that are prototypical of a construct” (Shadish, Cook, & Campbell, 2002), known more informally as establishing “construct validity”; and establishing “the extent to which causal relationships generalize over variations in persons, settings, treatments, and outcomes (external validity)”. (Shadish, Cook, & Campbell, 2002). However clearly a causal relationship may be established in a laboratory experiment, this is of little practical value until it is clear that:

1. The relationship shown in the experiment applies to the construct that the experiment was designed to model; and
2. The relationship holds outside the specific subjects, laboratory and methods used in the experiment.
CHAPTER 5

To quote Shadish, Cook, & Campbell (2002) again, it is necessary to specify “(a) which parts of the treatment (b) affect which parts of the outcome (c) through which causal mediating processes in order to accurately describe the components that need to be transferred to other situations to reproduce the effect.” Where internal validity refers to the validity of inferences about whether an observed covariation between (a) and (b) reflects a causal relationship, construct validity refers to the validity of inferences about the higher order constructs that the procedures of the study instantiate.

Causal Inference in Epidemiology

General causal validity is one area in which quasi-experimental epidemiological studies may have the edge on laboratory experiments. The reason for this is an extension of external validity that has been labeled “ecological validity” (Bronfenbrenner, 1977). Each experiment takes place in a specific setting, at a specific time. There may be characteristics of that setting or time that interfere with the simple logic of the experiment. For example, it is notoriously difficult to study blood pressure in laboratory settings because of the “white coat” phenomenon that plays havoc with people’s “resting” blood pressure in the presence of nurses and doctors. Even when a causal hypothesis is supported in laboratory studies, its effect size needs to be estimated in the real world.

Does Correlation Mean Causation or Doesn’t it?

Many research papers infer causation from a simple correlational observation. Later we discuss some better research strategies, here we point out some questions that have to be answered before a causal inference can safely be drawn. More details and further examples can be found in Rutter (2007) and Shadish, Cook, & Campbell (2002).

Which Variable Came First?

Does a lack of exercise cause weight gain, or is weight gain caused by a high fat diet, which is more common in people who do not exercise? A variant on this theme occurs when what looks like the outcome turns out to be the cause. For example, 40 years ago Richard Bell argued that “Current literature on socialization, based largely on correlations between parent and child behavior, can be re-interpreted plausibly as indicating effects of children on parents” (Bell & Harper, 1977).

Is There an Alternative Explanation for the Correlation?

Does a lack of exercise cause weight gain, or is weight gain caused by a high fat diet, which is more common in people who do not exercise? A variant on this occurs when the putative causal variable is associated with the true cause. For example, in unpublished analyses of a longitudinal community study of children and adolescents we compared the effects of growing up with a range of family structures (e.g., single, adopted or step-parent) with the effects of a disrupted family structure, via death or divorce or a new parental figure, controlling for family structure. We found that it was disruption, not family structure itself, that “caused” children’s behavioral problems. However, some family structures, such as having a single parent, were much more likely to be disrupted than others, such as having two biological parents, so the “true” cause was correlated with the putative cause.

Conclusions

We have argued that proving a causal relationship is difficult whatever research design is used. Balancing specific causality against general causality can require trade-offs in research design. In the next section we consider how longitudinal designs can help.

Using Longitudinal Data to Test Causal Hypotheses

Epidemiologists will often carry out repeated surveys to estimate whether some phenomenon (e.g., smoking) has increased or decreased. The essence of using repeated measures of the same subjects for testing causal hypotheses is that the subjects serve as their own controls. This eliminates some of the uncertainty about whether differences between measurements taken before and after an event are the result of using different subjects.

The passage of time can be interpreted in different ways that have different implications for causality. For example, age at first exposure to a risk, length of time since first exposure, and duration of exposure to risk are all interrelated aspects of timing of risk that may have different implications for causality and thus for prevention.

Duration of Exposure

Sometimes, the length of exposure to a risk factor may be a key to its harmful effects. For example, Duncan, Yeung, Brooks-Gunn et al. (1998) and Duncan, Brooks-Gunn, & Klebanov (1994) have made use of several longitudinal data sets containing information on family income to compare the relative importance of age at exposure to poverty and duration of exposure. They found a major effect of the persistence of poverty on emotional symptoms such as “dependence, anxiety, and unhappiness” (Brooks-Gunn & Duncan, 1997), whereas current but not persistent poverty was associated with higher levels of hyperactivity and peer conflict. However, effects of duration of poverty on conduct problems were seen in two other longitudinal studies (Moffitt, 1990; Offord, Boyle, Racine et al., 1992), so the picture is far from clear.

A series of papers from the English and Romanian Adoption Study Team addresses the impact of duration of risk exposure on cognition and affect some years after the risk was removed. Romanian children who had been in institutional care and were adopted before age 4 by families in the UK were compared with children born and adopted within the UK (Croft, O’Connor, Keaveney et al., 2001). The key exposure was neglect by caregivers, the outcome variable was parent–child relationship, and the hypothesis tested was that developmental and/or cognitive delay, a known consequence of severe early
deprivation, would mediate the relationship between early deprivation and parent–child relations. Duration of exposure to adversity was associated with more negative and less positive parent–child relations at age 4. By age 6, however, an effect was only seen in those who entered the UK after the age of 2, and who presumably suffered the most protracted exposure.

**Age at Onset of Exposure**
The importance of age at first exposure has been studied most intensively of all the aspects of risk over time in child psychopathology, because of the theoretical importance attached to early experiences in psychodynamic models of development. For example, researchers investigating the role of attachment in children’s development have concentrated on the very early months and years of life as the crucial period during which the inability to form one or more such relationships may have damaging effects that last into adulthood and perhaps even into adulthood (Rutter, 1988). In this case the critical date of onset of risk appears to occur after 6 months, but the duration of the risk period is not yet clear.

**Timing of Exposure**
Sometimes, longitudinal studies can clarify the difference between age at exposure and the developmental stage that a child is going through. For example, Rutter has pointed out that once children have achieved urinary continence at around age 2, there is a period of risk for relapse into incontinence that appears to coincide with starting school (Rutter, 1983). Once this period of risk is over, the chance of developing enuresis is very slight. In this case, developmental stage at exposure is clearly the critical developmental risk factor, because no parallel increase in functional enuresis occurs at later times of stress, such as moving to middle or high school, and there is no delay between the stress and the symptoms.

The difference between timing of exposure and length of exposure can also yield clues about causation. For example, a study of insulation workers exposed to asbestos found a cumulative risk of dying of mesothelioma over a 20-year period (controlling for other causes of death) that was the same irrespective of age at first exposure (Peto, Seidman, & Selikoff, 1982). Here, length of exposure was the critical aspect of risk. In contrast, the risk of breast cancer following irradiation appears to be highest in girls exposed at ages 0–9, falling with age until there is little excess risk for breast cancer associated with exposure to radiation after age 40 (Howe, 1982). Cases of breast cancer attributable to irradiation begin to occur roughly constant level, suggesting that the absolute excess risk increases with time since exposure. In this case, timing rather than duration is the critical aspect of the risk exposure.

**Using Longitudinal Data to Create Comparison Groups**
An important recent development in causal research is the use of longitudinal data to create groups that are comparable on a wide range of potential “confounders” of the causal relationship. In one example, Haviland and Nagin (2005) combined two recent statistical developments — trajectory modeling and propensity score modeling — to come closer to creating valid comparison groups to test the effect of an intervention. They were interested in whether joining a gang increases violence. Because youths who join gangs are known to be more violent than others before they join (Ireland, Thornberry, & Loeber, 2003; Lacourse, Nagin, Tremblay et al., 2003), some way had to be found to account for this in order to be able to examine the effect of joining a gang. Haviland and Nagin first divided the sample of boys into three trajectory groups based on their self-reports of violent delinquency at ages 11, 12 and 13 (the few boys who had already joined gangs by this age were excluded from the analyses). They then used the data from age 14 to divide each trajectory group into those who did, and did not, join a gang, and compared them on a range of measures (e.g., peer and teacher ratings of aggression at age 11, percent falling behind in school at age 10) that can be expected to be correlated both with the trajectory group and with gang membership. Although there were, as expected, large differences among the three trajectory groups, there were very few differences within each group between those who later became gang members and those who did not. This suggested that the trajectory grouping had created a balance on prior violent delinquency. The authors were then able to look at the effect of joining a gang at age 14 on violent delinquency within each trajectory group. First-time gang membership at 14 was associated with a significant increase in violence in each trajectory group, especially in the trajectory group that was persistently violent before joining a gang. These analyses help to direct the causal arrow from joining a gang to increased violence, rather than in the opposite direction.

**Research Designs for Studying Causal Relationships in Epidemiological Research**
In this section we describe three types of research design whose goal is to test for causality: the randomized experiment, in which subjects are assigned at random to experimental groups; the natural experiment, in which subjects are randomly assigned to groups, but not by the experimenter; and the quasi-experiment, in which the groups are not randomly assigned.

Before exploring in more detail the use of longitudinal studies to test causal hypotheses, it is important to recognize that there are important structural limitations to what can be done to test causality using longitudinal data.

**Age, Period and Cohort Effects**
As time goes by, people grow older, the world changes and new generations grow up. The passage of time in relation to a disorder can be examined in terms of age (e.g., subject’s age at onset of the disorder), period (the year or period of history when the disorder was assessed) and cohort (the year of birth...
of the sample or samples being assessed). Because of the linear dependency among these three time-related variables, if any two are fixed then the third is also fixed.

In practice, most longitudinal epidemiological studies recruit only a single cohort, so they cannot compare, for example, the effect on rates of depression of being aged 10 in 1980 and 10 in 2000 (a cohort effect). This is unfortunate, because changes from one cohort to another can give valuable suggestions about what might be driving behavior (e.g., Collishaw, Maughan, Goodman et al., 2004). Period effects also appear rarely in epidemiological studies of child psychopathology, although we will present some examples. This means that most longitudinal studies of causation deal with age effects (either on exposure to risk or on the development of a disorder given risk exposure), and they rarely acknowledge the potential effects of period or cohort.

**The Randomized Controlled Experiment: Why is it the Gold Standard for Causal Research Even in Epidemiology?**

The randomized controlled experiment is widely accepted as the highest standard of comparison for research that aims to establish causality (Shadish, Cook, & Campbell et al., 2002). Underlying the value placed on randomization is a concern that risk is not randomly distributed among comparison groups. If we want to know whether, for example, poverty predicts depression, we have to deal with the problem that poverty tends to go along with many other factors, such as medical illness, that might also predict depression. In a randomized experiment, the subject’s assignment to one research condition or another (e.g., treatment or no treatment) is based on chance. This procedure makes it easier to ascribe causality to an intervention because (given a reasonable number of study subjects) it:

1. Distributes threats to validity randomly across treatment conditions;
2. Permits the assumption that at pretest the expected value of all variables (measured or not) will be the same across treatment conditions; and
3. Allows the researcher to compute a valid estimate of error variance.

Thus, the great strength of the randomized design is that it provides an unbiased estimate of the average of the experimental variable or treatment effect (Shadish, Cook, & Campbell 2002).

Two distinct characteristics of the relationship between risk and outcome can influence the probability of disease: confounding and effect modification (Miettinen, 1974).

**Confounding**

Confounding distorts the impact of a risk factor on the risk of disease, because of the presence of some extraneous variable. A factor may act as a confounder in one study but not in another. Consider, for example, two groups at high and low levels of genetic risk for a disease that is also affected by poverty. If everyone in one group was at high genetic risk, a “real” relationship between poverty and disease might be obscured in that community; almost everyone who was poor would also be at genetic risk, so it would not be possible to say which factor was causing the disorder. In the second community, where not all the poor were at high genetic risk and not all those at high genetic risk were poor, it would be possible to look separately at the rates of disorder in four groups (poor non-affected, rich non-affected, poor affected, rich affected), and figure the risk associated with poverty.

**Effect Modification**

Effect modification or synergy refers to the different impacts of a risk factor at different levels of another variable (Rothman, 1976). This relationship is not specific to any particular study or community; it is a “real” relationship among two or more risk factors. For example, if both the gene for phenylketonuria (PKU) and a diet high in phenylalanine are necessary for PKU to occur, rates of the disorder will vary in different communities, depending on how many people inherit the gene and how many eat a high phenylalanine diet. The relationship between gene and disease remains constant across sites, but diet will act as an effect modifier, controlling the phenotypic consequences of the gene. Another example is the relationship among peak height velocity (PHV: the “growth spurt” of early adolescence), change of school and depressive symptoms. The period of PHV may be a time when youngsters are particularly vulnerable to symptoms of depression (Simmons & Blyth, 1987), particularly when they have to deal with stressful events. For example, it happens that in the American school system most children move from middle school to high school between eighth and ninth grades (ages 13–14). This coincides with the time when many girls, but few boys, are at PHV. School change could thus be acting as an effect modifier, increasing the risk of depression in girls but not in boys. Both confounding and effect modification can be dealt with by randomization.

**Randomized Experiments in Epidemiology**

Although it is rarely possible to use random assignment at the individual level in the “real world” settings of epidemiological research, it is sometimes possible to allocate classrooms, schools, towns or other communities to treatment and control conditions using the toss of a coin or a random number table, making the assumption that the estimate of the average treatment effect will be relatively unbiased by site differences. For example, recently there has been a flurry of research on methods to improve outcomes for the children of very poor families by supplementing family income on condition that parents ensure that their children get vaccinations and attend school. Incentive-based welfare programs like this, for example, the PROGRESA (Programa de Educación, Salud y Alimentación) intervention which has been running in Mexico since 1997 (recently renamed “Oportunidades”), are “site randomized experiments,” where whole communities, in this case 506 villages, are randomized to receive the intervention or not. The researchers plausibly argue that it makes sense to assign a community-wide intervention at the level of the community, rather than that of the individual.
Problems With Random Assignment in the Real World

There are many situations in which randomization is either impossible or unethical. Little of astronomy, geology, climatology or evolutionary science is amenable to randomized controlled experiments (but we have learned a lot about causation in spite of that). Frequently in medical research the barrier to assignment without bias is an institution – a school board, an ethics committee, a panel of judges – whose members believe that it would be “unethical” to assign a treatment randomly, when some patients or clients “need” it more than others. In effect, these situations pit the cold logic of science against the hot logic of human compassion, and the hot logic usually wins, even when (because this is an experiment) the intervention may not work, or may even be harmful (Dishion, McCord, & Poulin, 1999). The research community has done a poor job of educating the world of educators, social workers, judges, even doctors, and others at the battlefront of human services that a rigorous experiment may in the long run be more humane than a less rigorous one that cannot yield clear findings. Furthermore, if a non-randomized experiment shows an effect, the next step is a properly randomized experiment to be quite sure, so two sets of participants will be subjected to the research protocol instead of one.

However, there are situations in which a causal question simply cannot be answered using unbiased assignment. We cannot ethically assign children to have a parent with or without HIV/AIDS (Rotheram-Borus, Lee, Lin et al., 2004), or to witness a horrendous fire in order to study the effect on their use of mental health care (Dorn, Yzermans, Kerssens et al., 2006), or to have a major disaster such as 9/11 occur in the middle of their adolescence (Costello, Erkanli, Keeler et al., 2004) in order to test whether predisaster psychiatric disorder makes children more vulnerable to a traumatic event. If we want to ask causal questions in such situations, then we have to use other methods. Here we describe two alternatives: quasi-experiments and natural experiments.

Quasi-experiments

What distinguishes quasi-experiments from randomized experiments is that in the former case we cannot be sure that group assignment is free of bias. In other respects – the selection of the intervention, the measures administered, the timing of measurement – the two designs may be close to identical. But the difference – inability to use random assignment – can threaten the validity of causal conclusions based on the results, for reasons discussed earlier.

There are many variants on true randomization that have taken advantage of a situation where randomization was not possible but some approximation was. We describe three such strategies that epidemiologists have used to test causal hypotheses about risk factors or risk moderators. In the diagrams O = observation, X = event, T = time.

Sample Compared Post-event to a Population Norm

If data have already been collected before the event or intervention, it may be possible to set up a pre–post, exposed–not exposed design that comes close to random assignment.

This is the most common form of quasi-experiment following an unexpected catastrophe, because usually there has been no opportunity to collect “before” measures on those to whom the event will occur. Researchers try to use measures with known population norms, and compare the affected group with these. For example, Hoven, Dnarte, Lucas et al. (2005) compared children living in New York during the 9/11 attack on the Twin Towers with a representative population sample from nearby Stamford, CT, who had been assessed with the same instruments just before 9/11, as well as with other community samples. The New York children assessed 6 months after 9/11 had higher rates of most diagnoses.

This design is critically dependent on the comparability of the post-event sample and the sample on which the measures were normed, because otherwise the differences found might be the result of pre-existing differences rather than the event. So this tends to be the weakest of the various quasi-experiments, but it is often the only one available.

Dose–Response Measures of Exposure to an Event

Sometimes it is possible to use a dose–response strategy to test hypotheses about whether an exposure causes an outcome. The same researchers (Hoven et al., 2005) divided New York city into three areas at different geographical distances from the site of the World Trade Center and sampled children attending schools in each area, to test the hypothesis that, if physical distance from the event reduced the risk of psychiatric disorder, then the event was causally related to the disorder. They found high rates of mental disorder throughout the study area, but significantly lower rates in children who went to school in the area closest to the site of the attack. This took the researchers by surprise; their post hoc explanation was that the extent of social support and mental health care poured out after 9/11 prevented the harm that the event might have caused.

Second, they measured personal and family exposure to the attack, and compared children who had family members involved in the attack with those who were geographically close but had no personal involvement. They found, as predicted, that both personal and family involvement increased the risk of a mental disorder, but involvement of a family member was stronger than risk factor, even when the children were physically distant from the site.
CHAPTER 5

These aspects of the design of this study carry more weight than the one described earlier, because they incorporate stronger and more theory-based design characteristics. However, they still lack a pretest, and cannot rule out the possibility that these groups were different before the event.

In a study that combined a dose–response measure with a comparison to national norms, Glynn, Wadhwa, Dunkel-Schetter et al. (2001) used a group of women who were at different stages of pregnancy, or up to 6 weeks postpartum, on the day of the Northridge, CA, earthquake in 1994 to test two ideas:

1. Women become increasingly stress-resistant across the course of pregnancy; and

Across the three trimesters, women became progressively less responsive to the stressor, but were back to normal (same as first trimester) at 6 weeks postpartum (by which time the hypothalamic-pituitary-adrenal (HPA) axis response system is back to normal). Babies had 1.2, 0.6 and 0.6 weeks’ shorter gestation than predicted from national norms (adjusted for age, race and socioeconomic status, and obstetric risk), as a function of the trimester of pregnancy in which the earthquake occurred. As there was absolutely no reason for babies at different gestational stages at the time of the earthquake to be different in any systematic way connected to the event, this was a good example of a randomly assigned intervention. However, the study lacked pre-earthquake measures of maternal stress.

Different Groups Exposed and Not Exposed, Both Tested Before and After Exposure

This design has the potential to come closest to a randomized design, because the same subjects are studied both before and after the event that happened to one but not to the other. However, if sample a and sample b were not randomly assigned from the same subject pool, the researcher must convince the reader that there were no differences between the two before the event on potential confounders of the causal relationship.

For example, in a longitudinal study of development across the transition to adulthood, we had been interviewing a representative sample of young people every 1–2 years since 1993. Subjects were interviewed each year on a date as close as possible to their birthday. Thus, in 2001, when the participants were aged 19–21, about two-thirds of them had been interviewed when, on 9/11, the Twin Towers and the Pentagon were struck. We continued to interview the remaining subjects until the end of the year (Costello et al., 2004), but the world facing these young people was a very different one from that in which we had interviewed the first group of participants; for example, there was talk of a national draft, which would directly affect this age group.

The strength of this design is critically dependent on the comparability of the groups interviewed before and after the event. In this case we had 8 years of interviews with the participants before 2001. We compared the before and after 9/11 groups on a wide range of factors, and could demonstrate that each was a random subsample of the main sample. Thus, we had a quasi-experiment that was equivalent to randomly assigning subjects to experience vs. not to experience 9/11. We predicted that even though the participants were living 500 miles away from where the events occurred, this “distant trauma” (Terr, Bloch, Michel et al., 1999) would increase levels of anxiety and, possibly, in this age group, of alcohol and drug abuse. We also thought that the potential for military conscription, which would mainly affect the boys, might further increase the young men’s anxiety levels. We were wrong on both counts. There was no increase in levels of anxiety. Women interviewed after 9/11 reported higher levels of drug use in general, and cannabis in particular, with rates of reported use approaching twice the pre-9/11 level. However, men interviewed after 9/11 were less likely to report substance abuse, and use of all drugs was lower. There was an effect of time, such that in women the rate of drug use and abuse increased with each month following 9/11, while in men it fell each month.

We interpreted these findings in the light of evidence that when nations are at war rates of suicide and psychiatric hospitalization in the civilian population may go down (Lyons, 1979), suggesting that some people see the state of war as a challenge rather than a stressor. Perhaps the possibility of military service (or even of being subjected to drug tests) inspired the young men to get their act together, whereas it had the opposite effect on young women.

Conclusions About Quasi-experimental Designs to Test Causal Hypotheses in Epidemiology

A wide range of poor to excellent designs can be encompassed under the label “quasi-experimental,” from ones that lack either pretest or control group, to designs using interrupted time series or regression discontinuity approaches (neither of which is to be found yet in child psychiatric epidemiology) that combine ecological validity with logical rigor. The examples of quasi-experimental studies described here suggest that such designs can be quite effective at discounting previously held beliefs, but are open to the risk of post hoc interpretations (as in the Costello and Hovens examples). Also, as Shadish, Cook, & Campbell (2002) point out, “they can undermine the likelihood of even better studies.”

Natural Experiments in Epidemiology

Natural experiments are gifts to the researcher; situations that could not have been planned or proposed, but which do what a randomized experiment does: assign participants to one
exposure or another without bias, and hold all other variables constant while manipulating the risk factor of interest. Sometimes, the unbiased assignment is created by events, as when one group of families in our longitudinal study received an income supplement while others did not, where race (Native American vs. Anglo) was the sole criterion (Costello et al., 2003). In this case we had 4 years of assessments of children’s psychiatric status before and after the introduction of the income supplement, and so could compare the children’s behavior before and after the intervention in both groups. The years of measurement before the event enabled us to rule out the potential confounding of ethnicity with the children’s emotional and behavioral symptoms.

A tremendously important possibility for natural experimentation occurs when genes and environment can be separated (see chapter 21). Such naturally occurring situations provided the foundation for the rise of genetic epidemiology, which “focuses on the familial, and in particular genetic, determinants of disease and the joint effects of genes and non-genetic determinants” (Burton, Tobin, & Hopper, 2005). Genetic epidemiology also has the power to contribute in important ways to our understanding of environmental causes of disease:

“One serious problem facing mainstream epidemiology is that residual confounding by unobserved covariates could be strong enough to swamp the small aetiological effects now being sought. The distribution of alleles at any given locus tends not to be correlated either with environmental exposures or with the distribution of alleles at other loci (except those few in tight linkage disequilibrium). Therefore, the biology underpinning genetic epidemiology offers a potentially useful way to study environmental determinants in disease without residual confounding. This approach is called mendelian randomization” (Burton, Tobin, & Hopper, 2005).

Mendelian Randomization
The argument is based on Mendel’s second law, which states that the inheritance of any one trait is independent of the inheritance of any other trait. If it is possible to find a genetic polymorphism that influences exposure to a putative risk factor, then by Mendel’s second law those who carry the polymorphism and those who do not are randomly distributed with respect to other genes influencing the disease of interest. To use an example provided by Katan, suppose that a researcher wants to know whether low serum cholesterol increases the risk of cancer by favoring tumor growth. It is known that a gradient in the apolipoprotein E (APOE) genotype is associated with a gradient in serum cholesterol levels in the population. There have been suggestions that low cholesterol increases cancer risk (Katan, 2004). If serum cholesterol level does affect cancer, we would logically expect an association between APOE and cancer. In the absence of an APOE–cancer association, the cholesterol–cancer association may well be the result of other factors, or reverse association (i.e., cancer reduces cholesterol). In effect, this is a variant of the classic mediational model, using the argument that because the gene is known to affect the “mediator” (here cholesterol), if the gene does not influence disease frequency then the “mediator” cannot be causally related to the disease. Davey Smith and Ebrahim (2005) extended this work to show that the size of the effect of an intermediate phenotype on a disease can be estimated from the ratio of the coefficients for the regression of the disease on the gene and of the intermediate phenotype on the gene. As Burton, Tobin & Hopper (2005) point out, the same logic can be applied to genetic and environmental determinants of disease.

As the number of identified associations between genotype and disease increases, this approach will be increasingly useful. However, there are still problems (Chen, Akula, Detra-Wadleigh et al., 2004; Davey Smith & Ebrahim, 2005; Nitsch, Molokhia, Smeeth et al., 2006). First, as Tobin, Minelli, Burton et al. (2004) note, “Almost all current genetic studies are statistically underpowered to detect the relatively small effects of the frequent gene variants that underlie common, complex diseases.” Second, there is sometimes a risk of population stratification (i.e., confounding of genotype–disease associations by factors related to subpopulation group membership within the overall population in a study). Third, a genetic variant expressed during fetal development may influence development in such a way as to buffer against the effect of the variant, a form of developmental compensation introduced as “canalization” by Waddington (1957). Fourth, publication bias is a problem for meta-analyses of findings, because non-confirmatory studies tend not to get published. And, of course, most disorders that are fairly common in the population have complex etiologies involving multiple genes of small effect as well as multiple environmental exposures. If this were not the case, natural selection would have long since eliminated those with the disadvantageous polymorphism, unless, as appears to be the case of the hemoglobin beta (HBB) gene, which gives rise to thalassemia, some mutations may confer resistance to other disease (in this case, malaria).

Using Natural Experiments to Examine Genetic and Environmental Causes
As several papers have recently pointed out (Burton, Tobin, & Hopper et al., 2005; Davey Smith & Ebrahim, 2005), genetic epidemiology and standard observational epidemiology are rapidly merging. As Burton, Tobin, & Hopper et al. (2005) put it, “Once it is known which of two versions of a potentially causative gene an individual possesses, looking for an association between variants in that gene and the disease of interest is fundamentally no different from an exploration of a disease–exposure association in traditional epidemiology.” Genetic research in psychiatry began with the hypothesis that genes “cause” mental illness. More recently, genetic approaches are being used to map out the role of environmental factors in the etiology of mental illness in people with different genetic profiles. The first approach privileged genes as the
causal factors; in one sense rightly so, because psychiatric disorders involve behavior, and behavior comes about as a result of activity at the level of the genes. So for several decades causal research in genetic epidemiology took as its focus measuring the extent to which specific disorders were under genetic control by using genetically informative samples to partition the variance among genetic and environmental causes, primarily in order to estimate the extent of genetic involvement. But, in the words of the epidemiologists Kenneth Rothman and Sander Greenland: “Since ‘environment’ can be thought of as an all-embracing category that represents non-genetic causes, it is clear on a priori grounds that 100% of any disease is environmentally caused... Similarly, one can show that 100% of any disease is inherited.” (Rothman & Greenland, 1998). Although geneticists have historically focused on establishing or measuring the genetic contribution to a given disorder, genetic designs can also be used to examine the causal role of environmental factors, controlling for genetic liability (Rutter, Pickles, Murray et al., 2001).

Examples of Designs for Causal Research in Genetic Epidemiology

One thing that kept the two disciplines apart for a long time was the selection of samples. Genetic epidemiologists have used a range of research designs to get around the fact that the most direct experiment, which would modify a gene in some individuals and then compare their outcome to that of controls, is unethical in humans. Animal models of this kind have been very helpful in some areas of psychopathology, but are outside the scope of this chapter. Until recently, genetic epidemiology tended to make use of natural experiments affecting family structure – twins, children of twins, twins reared apart, adopted children, and so on – or else place of residence, as in migrant samples, to “pull apart” the aspects of the family that contribute genes and environment. Recently, direct study of individual gene variants in relation to disease outcomes has become easier and cheaper, so that singleton epidemiological samples can be used. Here we briefly review some traditional study designs for genetic epidemiology, and then look to the future.

Adoption Studies

Adoption studies separate genes from environment by separating a child from its biological parents, to be brought up by unrelated parents who provide the environment but not the genes. This avoids the passive gene–environment correlation (rGE) that is inherent in studies of children brought up by their biological parents, who pass on not only genes but also the structure – twins, children of twins, twins reared apart, adopted children, and so on – or else place of residence, as in migrant samples, to pull apart the aspects of the family that contribute genes and environment. Recently, direct study of individual gene variants in relation to disease outcomes has become easier and cheaper, so that singleton epidemiological samples can be used. Here we briefly review some traditional study designs for genetic epidemiology, and then look to the future.

Adoption studies separate genes from environment by separating a child from its biological parents, to be brought up by unrelated parents who provide the environment but not the genes. This avoids the passive gene–environment correlation (rGE) that is inherent in studies of children brought up by their biological parents, who pass on not only genes but also the environment in which the child grows up (Plomin, 1995). In one of the earliest of such studies, Cunningham, Cadoret, Loftus et al. (1975) compared two groups of adoptees, one group whose biological parents were “psychiatrically disturbed” and one whose biological parents were not. More than twice as many of the former group had psychiatric conditions requiring professional care. Because there were no differences between the adopting parent groups in levels of psychiatric disorder, this was taken as prima facie evidence that there was a genetic cause for the difference. Variants on this design include comparisons between adoptees and children raised by their biological parents (Plomin, DeFries, & Fulker, 1988), including studies of twin pairs of which one was adopted and one was not (Bergeman, Chipuer, Plomin et al., 1993), and mixed families of twins, singletons and adoptees (Neiderhiser, Reiss, & Hetherington, 1996).

Adoption studies have provided evidence for a genetic component in antisocial behavior, hyperactivity, drug abuse and schizophrenia (Cadoret, 1992; Cadoret & Stewart, 1991; Cadoret, Troughton, Bagford et al., 1990; Tienari, Lahti, Sorri et al., 1990), but perhaps not for childhood depression (Eley, Deater-Deckard, Fombonne et al., 1998). They have also been used to illuminate the causal role of environmental factors. For example, Duyme, Dumaret, & Tomkiewicz (1999) compared the IQ scores before adoption at age 4–6 and in adolescence, in groups of children adopted by families of low, medium and high socio-economic status (SES). The IQ scores of the three groups, which were similar before adoption, improved by significantly different amounts, from 7.7 points in the group adopted into low SES families to 19.5 points in those adopted into high SES families. These differences in improvement between groups with similar IQ scores a decade earlier argue for an environmental effect on an area of functioning that previous studies have shown to be under strong genetic influence (Plomin & Spinath, 2004).

Adoption studies have made tremendously important contributions to our understanding of the role of genes and environments in the development of psychopathology. However, they face serious problems (Maughan & Pickles, 1990). The meaning of adoption has changed dramatically over time, and has very different meaning in different cultures. Adoptive parents are in most societies carefully scrutinized, and as a group are low in high-risk behaviors. The amount known about birth mothers is often limited, and about birth fathers frequently nothing. In today’s open adoptions the birth parent may become a part of the rearing environment, which undermines the “pulling apart” of genes and rearing environment.

Migration Studies

If people move from one country to another, bringing their genes with them, it is potentially possible to compare their history of illness with:

1. Those from the same gene pool whom they left behind; and
2. Those with whom they share a new environment.

The latter strategy was used, for example, by Dohrenwend, Levav, Shrout et al. (1992) to test whether the high rates of mental illness seen in impoverished Israeli immigrants was more likely to be caused by the environment or by their genetic heritage of mental illness. Dohrenwend, Levav, Shrout et al. used the terms “social causation” for discrimination and hardship as causes of mental illness, and “social selection” to refer to the fact that those who came from mentally ill families were more likely to move down the SES gradient. Comparing more recent immigrants from North Africa, who were struggling with discrimination as well as poverty, and European immigrants
of low SES who had lived much longer in Israel, they found that schizophrenia was more common in the latter, while the North African immigrant men had more antisocial personality and substance use disorders, and the North African immigrant women had more depression. The authors argue for gender-specific modes of responding to environmental stress, while the “sorting and sifting” process had “left behind a residue of severely ill persons of advantaged European background” (Dohrenwend, Levav, Shrout et al., 1992) (i.e., people with a genetic liability to schizophrenia).

Janssen, Verhulst, Bengi-Arslan et al. (2004) compared self-reported psychiatric symptoms of Turkish youth whose families had migrated to the Netherlands with those of two comparison groups: Native-born Dutch youth and Turkish youth living in Turkey. A genetic causal argument would predict that areas in which the two Turkish samples were the same, but different from the Dutch youth, would be areas more affected by genetics than environment. This was true of scores on anxious/depressed, withdrawn, and thought problem scales. Areas in which the two Turkish samples differed could be affected by the stress of immigration. The immigrant Turkish youth reported more delinquency, aggression and attention problems than the Turkish youth living in Turkey.

Although migrants may be more representative of the general population than adoptees, there are still problems with generalizing from such samples (Hobcraft, 2006). Different groups migrate for different reasons; sometimes they are healthier than the population they left behind, sometimes they emigrate under extreme stress. It is quite rare to have “before” measures, especially of mental health, and migration itself may impose significant stress.

Twin Studies
Since the 1920s, geneticists have used the idea of comparing the correlation between monozygotic (MZ) and dizygotic (DZ) twins as a way to estimate the heritability of disease (Bukowski, Sippola, & Brender, 1993). MZ twins, with their identical genes, provide a wonderful opportunity for research into environmental causes of disease, because differences between them must be brought about by factors other than inherited genes, whereas DZ twins brought up together share a rearing environment but only half their genes.

Before genetic risk could easily be measured directly at the molecular level, comparing the correlations of MZ and DZ twins was an important technique for measuring the extent to which a given disease or trait was heritable (Plomin, DeFries, & McClearn, 1990). Several decades of work using this approach have made it clear that there is a substantial genetic component to many psychiatric disorders as well as to most personality traits. This was a major shift in thinking about the causes of disease. By extension, it was possible to use twins to construct a scale of genetic risk by examining the disease status of the cotwin, and to use this to test for gene–environment interactions. “A child’s genetic risk is highest if his or her co-twin has a diagnosis of disorder and the pair are MZ and a child’s genetic risk is lowest if his or her co-twin does not have a diagnosis of disorder and the pair are MZ. DZ twins’ genetic risk falls intermediate to these two groups” (Jaffee, Caspi, Moffitt et al., 2005). That is, risk was highest if an MZ cotwin had a diagnosis of conduct disorder, somewhat high if a DZ cotwin had a diagnosis, lower if a DZ cotwin had no diagnosis, and lowest if an MZ cotwin had no diagnosis. In a study of the impact of parental maltreatment on later conduct problems, the researchers had to establish, first, that there was no difference between MZ and DZ twins in their concordance for maltreatment; second, that the severity of maltreatment among children who were physically maltreated was similar across high and low genetic risk; and third, that MZ and DZ twins were equally likely to have conduct problems. They then compared the level of conduct problems in the four groups of twins. There was a clear increase in conduct problems from the lowest to the highest genetic risk group, and a significant interaction with maltreatment, such that the number of conduct problems was similar in maltreated and non-maltreated low-risk groups, but rose faster with increasing genetic risk in the maltreated group. This study could not identify which genes were involved in the increased vulnerability to maltreatment in some children, but it provides an excellent example of the use of twin samples to move beyond simple heritability studies toward identifying gene–environment interaction.

Children of twins provide another interesting variant on the twin design. Children of twins are as genetically related as siblings (if the twin parents are MZ) or cousins (if the twin parents are DZ), but are reared by different mothers. D’Onofrio, Turkheimer, Emery et al. (2006) compared the children of twin mothers who had divorced with the children of the non-divorced cotwins. The results were consistent with a causal role of divorce in earlier sexual intercourse and emotional difficulties, and increased risk of educational problems, depressed mood and suicidal ideation. No such effect of divorce was found for early drug use. The main drawback to this ingenious design is the large sample size needed.

Twin Studies
Since the 1920s, geneticists have used the idea of comparing the correlation between monozygotic (MZ) and dizygotic (DZ) twins as a way to estimate the heritability of disease (Bukowski, Sippola, & Brender, 1993). MZ twins, with their identical genes, provide a wonderful opportunity for research into environmental causes of disease, because differences between them must be brought about by factors other than inherited genes, whereas DZ twins brought up together share a rearing environment but only half their genes.

Before genetic risk could easily be measured directly at the molecular level, comparing the correlations of MZ and DZ twins was an important technique for measuring the extent to which a given disease or trait was heritable (Plomin, DeFries, & McClearn, 1990). Several decades of work using this approach have made it clear that there is a substantial genetic component to many psychiatric disorders as well as to most personality traits. This was a major shift in thinking about the causes of disease. By extension, it was possible to use twins to construct a scale of genetic risk by examining the disease status of the cotwin, and to use this to test for gene–environment interactions. “A child’s genetic risk is highest if his or her co-twin has a diagnosis of disorder and the pair are MZ and a child’s genetic risk is lowest if his or her co-twin does not have a diagnosis of disorder and the pair are MZ. DZ twins’ genetic risk falls intermediate to these two groups” (Jaffee, Caspi, Moffitt et al., 2005). That is, risk was highest if an MZ cotwin had a diagnosis of conduct disorder, somewhat high if a DZ cotwin had a diagnosis, lower if a DZ cotwin had no diagnosis, and lowest if an MZ cotwin had no diagnosis. In a study of the impact of parental maltreatment on later conduct problems, the researchers had to establish, first, that there was no difference between MZ and DZ twins in their concordance for maltreatment; second, that the severity of maltreatment among children who were physically maltreated was similar across high and low genetic risk; and third, that MZ and DZ twins were equally likely to have conduct problems. They then compared the level of conduct problems in the four groups of twins. There was a clear increase in conduct problems from the lowest to the highest genetic risk group, and a significant interaction with maltreatment, such that the number of conduct problems was similar in maltreated and non-maltreated low-risk groups, but rose faster with increasing genetic risk in the maltreated group. This study could not identify which genes were involved in the increased vulnerability to maltreatment in some children, but it provides an excellent example of the use of twin samples to move beyond simple heritability studies toward identifying gene–environment interaction.

Children of twins provide another interesting variant on the twin design. Children of twins are as genetically related as siblings (if the twin parents are MZ) or cousins (if the twin parents are DZ), but are reared by different mothers. D’Onofrio, Turkheimer, Emery et al. Before genetic risk could easily be measured directly at the molecular level, comparing the correlations of MZ and DZ twins was an important technique for measuring the extent to which a given disease or trait was heritable (Plomin, DeFries, & McClearn, 1990). Several decades of work using this approach have made it clear that there is a substantial genetic component to many psychiatric disorders as well as to most personality traits. This was a major shift in thinking about the causes of disease. By extension, it was possible to use twins to construct a scale of genetic risk by examining the disease status of the cotwin, and to use this to test for gene–environment interactions. “A child’s genetic risk is highest if his or her co-twin has a diagnosis of disorder and the pair are MZ and a child’s genetic risk is lowest if his or
environmental influences provided by another individual to whom they are genetically related; for example, an intelligent parent may also provide a more than usually stimulating environment (passive rGE). These types of rGE have the effect of making what is in fact an effect of environmental factors look like a genetic effect in analyses to partition the variance, unless they are specified and measured.

Conclusions

There has been a great deal of argument in epidemiological journals recently about whether observational epidemiology can ever establish causality (e.g., Kaufman & Cooper, 1999; Krieger & Smith, 2000; Maldonado & Greenland, 2002; Parascandola & Weed, 2001; Susser, 1991). The argument could more properly be framed within a wider question: can research ever establish causality? As the earlier discussion of randomized experiments pointed out, even the gold standard of clinical research, the randomized controlled trial, is only an approximation to the un-doable “counterfactual” experiment. The various designs described in this chapter are examples of ways in which researchers have used their ingenuity to get closer to their goal, either by clever design, for example by including overlapping cohorts of subjects, or by capitalizing on chance, as in natural experiments, or by incorporating a whole new body of knowledge, as in molecular genetic epidemiology. The genomics revolution in particular has the potential to revitalize psychiatric epidemiology, adding tremendously to the value of the longitudinal studies that have been building up over time, directing the search for causality, and providing important new links with clinical psychiatry.

For the reader of academic and professional journals the challenge of sorting valid causal research from invalid claims may seem overwhelming. It is often helpful to go back to the progress of scientific maturity listed at the beginning of the chapter: observation, categorization, pattern recognition, hypothesis testing and causal explanation, and ask of a given paper where it should be placed along the pathway to causality. Much epidemiological literature is somewhere between categorization and pattern recognition. The hard task is to observe a correlational pattern, develop a hypothesis about why it should exist and develop a valid way of testing the hypothesis. This chapter describes and presents examples of several such methods, from longitudinal studies to taking advantage of natural experiments such as twins.

For policy-makers it can be very difficult to know when the scientific evidence is strong enough to warrant a new intervention. The inference to be drawn from the work reviewed here is that it is probably dangerous to initiate new programs simply on the basis of correlational data. However, policy decisions have to be based not only on scientific evidence about causality, but also on the costs and benefits of both intervening and not intervening. This is too big a topic to deal with here, but methods are available (Kraemer, 1992).

For researchers trying to “learn the causes of things,” epidemiological and laboratory studies can support one another, with laboratory experiments, whether on humans or on animals, generally stronger on “specific causation” and population-based epidemiological studies stronger on “general causation.” Longitudinal studies are particularly useful (subject to the cautions discussed earlier) as we struggle to find the causes of complex chronic diseases, a class that includes most psychiatric disorders. Here the key risk exposures, and their interplay with genes, are likely to vary across development (Vinceis & Kriebel, 2006).

CHAPTER 5

Using Epidemiology to Plan Services: A Conceptual Approach

Michael Rutter and Jim Stevenson

As Earls (1979) noted in relation to child psychiatry, epidemiology is a basic science with two rather distinct functions: first, it documents the patterns of disorder in the community as a means of planning services (Rutter, Tizard, & Whitmore, 1970); and, second, it studies the causes of disorder (Costello, Foley, & Angold, 2006; Rutter, 2007; see also chapter 5). Epidemiology differs from clinical medicine primarily with respect to studying disorders in the context of a community, rather than the individual (Costello, Egger, & Angold, 2005). Analyses are based on counts of individuals but the inferences concern population risks and outcomes, rather than the development of a disorder at an individual level.

In this chapter, we focus on using epidemiology to provide data that are needed for the planning of services; chapter 5 considers its use in inferring possible causal influences. As we note, the delineation of such influences and of their patterns of variation across groups constitutes an essential element in planning services. Both uses require rigorous attention to many details of design, measurement and data analysis – which are well described in several key sources (Detels, McEwen, Beaglehole et al., 2002; Fombonne, 2002; Rothman & Greenland, 1998; Susser, Schwartz, Morabia et al., 2006; Verhulst & Koot, 1995).

Information Needed for Planning Services

The efficient and cost-effective planning of services involves consideration of a wide range of features. The starting point is often seen as the determination of the number of individuals in a particular population with disorders causing either current impairment or carrying risks for later hazards. That necessarily requires information on the extent to which disorders of any given type involve impairment or future risk (Costello, Egger, & Angold, 2005; Ezpeleta, Keefer, Erkanli et al., 2001). Questionnaire surveys on their own generally provide an inadequate means of obtaining this information, although they may constitute a most useful step in the overall planning. However, service planners need to know several other crucial bits of information. Thus, it is necessary to know whether there are effective treatments for these disorders and, if they exist, are they ordinarily available as part of existing services?

A somewhat related issue concerns the extent to which disorders tend to be recurrent or chronic. This information may strongly influence priority setting in resource allocation for services. The long-term cost of an untreated disorder is another key piece of information of relevance to service planning (Costello, Copeland, Cowell et al., 2007). For example, the significance of conduct disorder as a priority for services was given added weight when the considerable costs to a range of services (mental health, education and the justice system) were shown (Scott, Knapp, Henderson et al., 2001).

A further consideration is the extent to which the professionals in existing services recognize disorders when they present. Planning services on the basis of the true prevalence of disorders as ascertained by experts is not of much use if the professionals operating existing services are unable to recognize the disorders needing intervention. Similarly, it is important to know the extent to which families appreciate the needs. Do they share the professionals’ view that particular features mean that there is a disorder that could be responsive to intervention and are they willing to accept the services on offer?

Over recent decades, psychiatrists have become concerned with diagnostic distinctions. In parallel, service providers have often wanted to restrict services to individuals with a particular diagnosis. It might seem to follow, therefore, that the need is to know the frequency of the particular diagnoses that constitute passports or entry tickets to particular forms of service provision. However, that would be a cardinal error because of the extensive evidence that it is common, perhaps even usual, for individuals to show multiple features of psychopathology representing supposedly different disorders (see chapter 2). Moreover, although there are important associations between types of disorders and the types of treatment that are most effective for them, the associations are relatively modest and there are few truly specific effective treatments, either pharmacological or psychological.

Knowledge of the number of individuals for whom services ought ideally to be made available is not sufficient in itself because services need to take account of where such individuals are to be found. Are they evenly distributed throughout the community or are there particular high-risk groups or particular high-risk geographical areas? Epidemiology
CHAPTER 6

has also been very useful in tracking changes over time in communities – for example, the rising rates of psychoactive medication, the altering patterns of substance use, variations over time in rates of suicide and attempted suicide, and changing rates of children being taken into care or of homelessness. It may also document changing patterns in in-patient provision or of the other residential facilities. The basic point is that epidemiology can provide an essential backdrop of factors (other than the number of children with disorders) relevant to the planning of services.

Epidemiology Comprises the Scientific Study of the Distribution of Particular Features in Populations

There is sometimes a tendency to think only in terms of the distribution of disorders and also to assume that populations must represent the entire general population. Neither assumption is warranted. To begin with, as discussed in chapter 5, the focus may be on risk factors rather than disorders. A classic paper in the field of internal medicine was titled “The epidemiology of uniforms” (Morris, Heady, & Raffle, 1956). This particular study was not concerned with the general population; rather, it was a study of the records of uniform size in bus conductors and bus drivers in order to determine the risks for heart disease associated with being overweight and with lack of exercise. Service planning ought to be influenced by knowledge of the distribution of risk factors and their association with the development of disorders requiring intervention.

In the same way, service planning needs information on the extent to which there is a disproportionately high or low rate of disorders in particular segments of the population – such as those with physical ill-health, with scholastic difficulties, or in so-called “looked after” children in residential care or family foster care. A relevant historical example is provided by the Isle of Wight study (Rutter, Graham, & Yule, 1970; Rutter, Tizard, & Whitmore, 1970). The initial prompt for the study concerned a query from the British Department of Education to Tizard (and then Tizard & Rutter) whether the strong association found in the early part of the 20th century of scholastic problems being much more frequent in children with chronic physical disabilities still applied in the latter part of the 20th century. As the epidemiological research went ahead, further queries were posed as to whether the rate of disorders was the same in inner city areas such as London as on the Isle of Wight (Rutter, 1981) and whether the rates of disorder found in the pre-adolescent years were the same as those during the teenage years (Rutter, 1979).

Sometimes there has been an assumption that service planning needs to be concerned only with chronic disorders on the grounds that if the disorder is acute, one can assume that recovery will take place without the need for intervention. However, this is a mistaken assumption for several different reasons. To begin with, disorders may be acute because they are fatal. Thus, there has been a legitimate concern over the high level of suicide in young people (see chapter 40). Concern is not because one can do anything after the person has killed themselves, but rather because the fatal act raises questions as to whether it might have been preventable if appropriate services had been provided. Even when not fatal, acute disorders may have much longer-term clinical, and therefore service, implications. Thus, episodes of mania are often relatively short lived (see chapter 38) but bipolar disorders are associated with a high rate of recurrence and a high rate of impairment. Accordingly, even a short-lived episode of mania has implications for treatment provision.

For many purposes, prevalence constitutes the most appropriate index of rates of disorder. However, in some instances it is necessary to know about incidence – the rate of new cases arising over a particular period of time. This would apply to the effects of some acute major hazard in causing disorder (such as floods, earthquakes, being taken hostage or receiving a serious head injury). Similarly, in planning services it will be important to know the age period when a first psychotic episode occurs.

Because so many questions with respect to service planning involve the need to know about longitudinal course, there has been an increasing tendency for epidemiological studies to be longitudinal (see chapter 13). Longitudinal studies have been crucial in showing that cross-sectional epidemiological studies greatly underestimate the true rate of disorders in the community because so many disorders are recurrent. The cumulative prevalence is much higher than the cross-sectional prevalence at any single point in time (Kim-Cohen, Caspi, Moffitt et al., 2003).

Prevalence of Mental Disorder

Aware of the very different living conditions in developing countries, compared with the circumstances in western industrialized nations in which most epidemiological studies have been undertaken, researchers have sought to determine whether the differences have led to variations in the rates of mental disorders (Verhulst, 1995; Weisz & Eastman, 1995). As Fleitlich-Bilyk & Goodman have emphasized, the question requires an adequate sample size, a representative sampling frame, the use of standardized interview measures, and assessment of distress and impairment as well as symptoms (Fleitlich-Bilyk & Goodman, 2004). Their study in a predominantly urban municipality in Brazil found a prevalence rate for mental disorders of 13% in 7–14-year-old school children using the same instrument (Development and Wellbeing Assessment; DAWBA) as that employed in the British national survey (Ford, Goodman, & Meltzer, 2003; Meltzer, Gatward, Goodman et al., 2000), which showed a rate of 10%. The pattern of diagnoses was broadly similar in Brazil and Britain. A comparable study of the same age group in a Russian city (Goodman, Slobodskaya, & Knazyev, 2005) produced a rate of 15.3%. Again, the general pattern of dia-
In the small group of children receiving services, some parents were critical of the help being provided. Of course, in the 40 years or so since the surveys were undertaken, much more effective treatments have become available and people have become more aware of children’s difficulties and needs. Nevertheless, the point remains that the planning of services has to take into account what people want, and will accept, as well as expert assessments of need.

Epidemiology has an important role in examining population variations in people’s recognition of mental health service need. Thus, the comparisons between Thailand and the USA, and between Jamaica and the USA, undertaken by Weisz & Eastman (1995), showed that Thai adults tended to rate children’s problems as less serious, less unusual and more likely to improve without intervention than were US adults. Problems involving disruptive behavior were much more likely to result in clinic referral in the USA than in Thailand, whereas emotional problems were more likely to lead to referral in Thailand. In relation to attention deficit/hyperactivity disorder (ADHD), Ho, Leung, Luk et al. (1996) compared the epidemiological characteristics of ADHD in the UK and Hong Kong populations. They found that in Hong Kong parents and teachers reported higher levels of hyperactivity than in the UK, although on objective measures the rates in the two populations were comparable. It is suggested that cultural expectations about children being controlled and well regulated in their behavior accounted for this effect (Luk, Leung, & Ho, 2002). However, in general at the present, the database is too limited, and the number of systematic cross-cultural comparisons too few, for any general explanation of the meaning of these variations. What is clear, however, is that they should inform the planning of services. It is a major limitation of epidemiological studies of psychopathology that very few have assessed either family views on children’s problems or people’s willingness to access services offered. There is as yet no standard method of assessing these attitudinal factors and such information may in any case be best obtained with methods tailor-made for specific populations (for a useful exploration of these issues see Sayal, Goodman, & Ford, 2006).

**Age Variations**

A key issue with respect to the planning of services concerns possible age variations, because the type of services available tends to be different for each age group. For many years, the accepted view was that the problems of preschoolers were of little clinical significance. The Waltham Forest epidemiological study in London set out to test this notion by undertaking systematic assessments of 3-year-olds who were then followed up to age 8 years (Richman, Stevenson, & Graham, 1982). The findings at age 3 showed that some 7% had a moderate or severe mental disorder and a further 15% had mild problems. From a service perspective, it was important that the rates of disorder were much higher in children who showed language delay. It might still be argued that the disorders at
CHAPTER 6

age 3 were likely to be evanescent and would readily remit without treatment. The findings at age 8, however, negated this view. Of those with disorder at 3, 62% showed disorder at 8, compared with 22% of those without disorder at 3. Adverse family factors were associated with the development of disorder at 3, but were only marginally associated with its persistence. Rather, the form of the disorder at 3 years was strongly predictive; outcome was more likely to be poor in the case of disorders involving restlessness and overactivity.

Since this pioneering study, better measures of psychopathology have become available (Egger, Erkanli, Keeler et al., 2006). Studies using these methods have similarly shown that the rate of psychopathology in the preschool age period is broadly comparable with that in middle childhood (Egger & Angold, 2006). The limited available follow-up data on preschoolers have confirmed the early finding of substantial persistence of disorder (Campbell, 1994). It is clear that mental disorders in the preschool years are of clinical importance and services for this age group need to include the diagnosis and treatment of psychopathology.

A parallel question arose with respect to adolescence. It was directly tackled by means of a follow-up of the 10–11-year-olds in the Isle of Wight study (Rutter, 1979). The findings showed an increase in psychopathology, but this was largely a function of the adolescent’s own reporting, rather than that of their parents. Other evidence has shown that the rising rate of mental disorder in adolescence reflects the incidence of schizophrenia, depressive disorders, substance abuse and eating disorders (Rutter, in press). It is noteworthy, too, however, that the early-onset neurodevelopmental disorders also tend to persist through adolescence into adult life (see chapter 13).

Epidemiology of Services

In considering the planning of services, evidence is needed on the current provision of services and the extent to which such current provision actually deals with psychopathology in young people. This is where, for example, surveys of mental disorders in young people as they arise in either primary care services (see chapter 72), pediatric services (see chapter 70) or special education (see chapter 74) are relevant. To attempt to best use limited resources to meet the treatment needs of the population, a system of tiered service has been developed in the UK, although systematic evaluation of its effectiveness is as yet underdeveloped (Worrall-Davies, Cottrell, & Benson et al., 2004; see also chapter 71).

It remains to be seen whether this particular tier structure is the most appropriate one. In both developing and industrialized countries, the overall levels of disorder mean that a key service question concerns which types of problems can be appropriately dealt with in primary care (by family doctors, community nurses or volunteers) and which require highly trained specialists. It may also be relevant to consider when traditional healers may have an appropriate role. What are needed in these connections are systematic comparative studies (see, for example, Olds, Robinson Pettit et al., 2004b), rather than assumptions that lack an adequate empirical basis.

As discussed in chapter 10, mental health problems in young people are at least as likely (if not more so) to be dealt with outside mental health services as within them. Accordingly, service planning needs to consider the extent to which this is appropriate and, in so far as it is, what use can be made of interventions in these other services – whether they be social services, schools, community nursing or pediatrics. Epidemiological evidence will not itself indicate the value of interventions in these settings (unless the researchers deliberately plan to do that), but it does emphasize that service planners need to think broadly rather than narrowly.

In that connection, epidemiological studies can be informative in demonstrating the ways in which needs, rather than bureaucratic rules, must guide planning. Throughout the world, the holders of purse strings are inclined to control costs through decisions on groups that should not be eligible for services. Thus, for example, in some parts of the UK, it has been ruled that children with an intellectual disability are ineligible to receive NHS mental health services. Epidemiological data from the Isle of Wight survey (Rutter, Tizard, & Whitmore, 1970) onwards, have been consistent in showing that such children have an increased rate of psychopathology and that, often, the disorders are complex and require skilled specialist services (see chapter 49).

In considering existing patterns of service provision, and possibilities of their strengthening or expansion, attention needs to be paid to the role of charities, consumer groups and others outside regular state provision. Particularly during recent years, there has been major growth in the influence and the role of such non-governmental organizations. This is partly in terms of their providing important “ginger” group functions in terms of pointing to needs, partly in terms of their role of providing information and partly also their direct provision of services. For example, parent-led associations have certainly been important in the development of services for young people with autism spectrum disorders, specific language impairment and with cognitive impairment.

Patterns of Disorder

One of the most important findings to emerge from the Isle of Wight epidemiological studies was the extent of overlap among disorders. This was evident at several different levels. Thus, at a psychiatric diagnostic level it was clear that, although there were important distinctions between emotional disorders and conduct disorders, many children showed features of both (Rutter, Tizard, & Whitmore, 1970). In addition, there was substantial overlap between scholastic problems of various kinds, physical ill-health and psychopathology. Moreover, it was also apparent that service needs were greatest in the case of young people with problems in several different arenas, rather than just one. This led to a recommendation that service planning needed to be based on individual needs (taking into
account the overlap among problems), rather than individual diagnoses, important though they were for some purposes.

The much more recent Great Smoky Mountains study (Costello, Angold, Burns et al., 1996) also showed that service planning needs to be based on individual needs. It underlined the point that there were children who showed substantial impairment in their functioning as a result of mental disorders (approximately 10%), but yet where the disorders did not meet any currently accepted criteria for any one particular diagnosis (Angold, Costello, Farmer et al., 1999). The implication, again, was that planning needed to be based on impairment rather more than on whether particular diagnostic criteria were met.

Epidemiological and/or longitudinal studies have brought out the importance of considering continuities and discontinuities over time (see chapter 13). Thus, it has been found that in the majority of mental disorders in early adult life that are of a sufficient severity to involve active treatment, over half were first manifest before the age of 15. It might have been expected that there was substantial continuity in the form of the disorder, as shown at the different age periods, but there were important differences. It was particularly striking that conduct disorder in childhood constituted the form of psychopathology that was most likely to be associated with mental disorders in adult life, this tendency being evident across a broad range of diagnoses (Kim-Cohen et al., 2003). Similarly, other epidemiological studies have shown the frequency and importance of psychopathological progressions – as for example between substance abuse and depression (Brook, Cohen, & Brook, 1998; Rao, Daley, & Hammen, 2000).

Epidemiological and/or longitudinal studies have also been crucial in noting that schizophrenic psychoses in adult life are frequently preceded by neurodevelopmental impairment in early childhood and by psychotic-like manifestations in late childhood/early adolescence (see chapter 13). This has raised the issue as to whether it might be possible to prevent overt schizophrenic psychoses by appropriate interventions in earlier life. The difficulty, however, is not just the limited evidence on whether interventions could be successful at this early age, but also the problems of false positive indications for treatment. Most individuals with these precursors of schizophrenia do not go on to develop schizophrenia. Hence, early preventive interventions would involve treating a large number of individuals unnecessarily. That might not matter if the interventions were without risk but this is very unlikely to be the case.

Responsivity to Treatment

As discussed in numerous chapters throughout this volume, good evidence is available on the short-term effectiveness of both pharmacological and psychological treatment for psychopathology in young people. Moreover, there is growing evidence on which treatments are most effective for which problems (see chapters 60–73). That is very encouraging but, unfortunately, it does not lead very directly to recommendations on service planning because the evidence on efficacy largely stems from interventions by experts and the results of ordinary services are much less impressive. This was particularly striking, for example, in the multicenter American study for treatment of ADHD. Most treatments in the community involved the use of stimulant medication, which proved effective in expert hands. Results, by contrast, were much worse for ordinary treatment as delivered in the community and this was especially so with disorders that involved several patterns of psychopathology (Jensen, Garcia, Glied et al., 2005). Also, the particular forms of psychological treatment that had been shown to be most effective involved skills that are not widely available in ordinary services as provided in the UK or indeed in any other industrialized western country. It needs to be added that the evidence of efficacy of interventions is much better with respect to short-term benefits than it is for long-term ones.

Much the same applies in the field of universal preventive interventions. Thus, there are good studies showing the benefits of community-wide interventions focused on improving family functioning (Olds, 2002; Olds, Henderson, Cole et al., 1998; Olds, Kitzman, Cole et al., 2004a; Olds et al., 2004b).

The very large-scale British prevention program based on similar principles – “Sure Start” – does not seem to have had anything like the same success (Rutter, 2006). These are early days and it may be that the benefits are greater than suggested by early findings. Nevertheless, what is quite clear from the epidemiological evidence is that generally well-intentioned programs based on established principles may not work if adequate attention is not paid to the details of implementation (see chapter 60).

Patterns of Referral and Use of Services

An early British epidemiological study, the Buckinghamshire study, drew attention to the finding that young people’s referral to mental health services was driven at least as much by problems in the family as by the children’s own pattern of disorder (Shepherd, Oppenheim, & Mitchell, 1971). They concluded that the findings meant that rates of clinic referral provided a most unsatisfactory guide to the level of psychopathology in young people. Another lesson might be that the services needed to be geared to the family problems often (but not always) associated with child psychopathology as much as with the children’s disorders themselves. It should be noted that this association does not necessarily mean that the family problems caused the child’s disorder, but rather that it is when the two occurred together that help was most likely to be sought. With respect to uptake of services, in countries without free medical care, it has been striking that unmet needs for mental health services tend to be greatest in young people from economically disadvantaged families and from families with parental psychopathology (Flisher et al., 1997).

A further point evident in almost all epidemiological studies has been the relatively weak agreement between the reports of parents and the young people themselves (Achenbach,
McConaughy, & Howell, 1987; Borge, Samuelson, & Rutter, 2001; Eaves, Silberg, Meyer et al., 1997; Hewitt, Eaves, Silberg et al., 1997; Rutter, 1979; Rutter et al., 1970). To some extent this probably reflects differences in the perspectives of children and parents, but to a considerable extent it stems from the parents being unaware of the children’s impairment. Service implication stemming from the epidemiological evidence is that, particularly in the case of adolescents, services need to have the possibility of direct access by the young people themselves without necessarily having to rely on their being brought by their parents.

Historically, child and adolescent services have tended to be rather separate, with little connection between the two. The epidemiological evidence has raised serious queries on the problems of the degree of separation according to services for different age groups. Two rather different sets of findings are relevant. First, there are the numerous, high-risk epidemiological studies showing the extent to which parental mental disorder constitutes a risk factor for psychopathology in the children (Rutter, 1989). Much of the high-risk research was predicated on the basis of the genetic risks involved but it is clear that the mediation of risks is partially environmental as well as genetic. Early epidemiological and clinical studies (see e.g., Rutter, 1966) indicated how few psychiatrists dealing with adults even asked about the children, let alone paid attention to their needs. Fortunately, that has changed to a considerable extent (although it cannot be said to be really satisfactory now) and it is clear that when one member of the family has a mental disorder, attention needs to be paid to the possibility that other family members also have mental health problems. The finding that many disorders span age periods in crucial ways is also relevant. This is obvious, for example, with respect to prodromal schizophrenia, substance abuse problems and eating disorders. Most adult psychiatrists are ill-equipped to deal with the sequelae in adult life of serious problems that develop during childhood and many child psychiatrists do not have the experience of dealing with the disorders as they are manifest in adult life. Some of the issues this raises are outlined in relation to ADHD by Asherson, Chen, Craddock et al. (2007). Not only is it a more “joined-up” approach to services needed, but thought needs to be given to whether or not some services need to be problem focused, rather than age defined (see chapter 13).

Variations Across Groups in Rates or Patterns of Disorder

Funding agencies and policy-makers press for statistics that represent the true national rates of disorder. This is based on the totally mistaken assumption that this is what is needed for planning, but it is not. It is more important to understand the nature and origins of variation in rates within a population than to obtain ever more accurate estimates of general prevalence across an entire nation. It would make no sense, for example, to plan services on the expectation that the level and pattern of need would be the same in, say, inner London and rural Wales, or in US cities and in rural farm areas in the USA. Rather, what is needed is evidence on the extent to which rates and patterns vary across areas together with the reasons for such variation, if those can be identified (see e.g., Bird, Canino, Davi et al., 2001). Numerous epidemiological studies have shown that geographical variations are indeed quite large. What has been less forthcoming has been the evidence on the causes of such variation. A complication with any proposal simply to plan services to be located in geographical locations with the highest rate of those in need is the “ecological fallacy” (Pinatadosi, Byar, & Green, 1988). This arises because there will be in sum more individuals in need outside areas of greatest concentration of needs. For this reason there will continue to be a place for screening for needs at an individual or family level and not just to plan service delivery by geographic concentration.

Of course, valuable clues have emerged from the epidemiological research but too few studies have been designed in a way that could test competing explanations about the mediating causal influences. Nevertheless, what the research has shown are some of the most important high-risk groups (see chapters 5 & 25). For example, children in residential and family foster care have consistently been found to have unusually high rates of both scholastic difficulties and psychopathology (Meltzer, Gatward, Goodman et al., 2003; see chapter 32). Mental disorders are also high in homeless children (see chapter 25), asylum seekers (see chapter 31) and in those in prison or other forms of custodial care (see chapter 68).

Generalizability of Epidemiological Findings

As noted in chapter 15, epidemiological studies around the world have, on the whole, showed that the main risk and protective factors of mental disorders are broadly similar. Moreover, similarities outweigh dissimilarities even in the overall patterning and rate of disorders. Nevertheless, this does not mean that studies in industrialized western nations can be extended without question to developing countries. All too often, new surveys seem to have been planned as if the main question was whether the rates of disorder are higher or lower in some country as compared with, say, the USA or UK. Only very rarely is that the most important question. Rather, studies are needed to determine whether the patterning of risk factors has important service implications. Thus, for example, in parts of the world where serious malnutrition, HIV or malaria is common, how does that interface with risks for mental disorder? If the associations are very strong, that might mean that there should be a greater focus on pediatric care in the first instance, rather than mental health services provision. It is also relevant to know whether the community attitudes towards and perception of psychopathology vary in ways that have implications for either patterns of referral or for service provision (see chapter 15).
Highly Focused Epidemiological Studies

For many aspects of service planning, broad-based epidemiological studies using instruments that tap all the main types of psychopathology are highly appropriate. The British Office of National Statistics studies provide a good example of how this may be done and how it may be useful (Meltzer et al., 2003). However, there are certain needs that are not most satisfactorily met in this way. For example, many children with intellectual disability are dealt with in child and adolescent mental health services and it is clear that the rate of associated psychopathology is quite high (see chapter 49). However, broad-based mental disorder surveys are not likely to be very suitable for determining either the rate of mild intellectual disability or the patterns of association with psychopathology, and their meaning. This requires studies that are more specifically focused on the epidemiology of cognitive impairment and its correlates (Simonoff, Pickles, Chadwick et al., 2006). Much the same applies to the epidemiology of specific language impairment and of reading disability, both of which have quite strong associations with psychopathology (see chapters 47 & 48). Similar considerations apply in the case of autism spectrum disorders (see chapter 46). One of the problems here is that the epidemiological evidence is clear-cut that the manifestations extend much more broadly than the traditional diagnostic concepts. Detailed studies specifically focused on autism spectrum disorders are required – not only to determine the prevalence of this group of conditions, but also the variations in its manifestations and their correlates (see e.g., Baird, Simonoff, Pickles et al., 2006). It is clear that, as diagnosed, autism spectrum disorders have become much more common over time (Rutter, 2005). This rise is, without doubt, caused in part by better ascertainment and a broadening of the diagnostic concept but it remains uncertain whether or not, in addition to these methodological considerations, there has also been a true rise brought about by some environmental hazard.

General Population Screening

The evidence that the majority of young people with a mental disorder do not receive services might seem to point to the desirability of the widespread routine application of screening methods to determine which children have disorders and hence which ones should be targeted for intervention. The possibility raises several different issues. To begin with, as discussed in chapter 20, screening questionnaires have a place as the first stage in clinical assessment. In much the same way, they may be valuable in planning systematic interventions, such as in schools. By alerting families to the presence of possible problems, they may become interested in taking up the services on offer. What would not be helpful, however, is to imply that all high scorers will receive interventions if the services are not available to provide that. Raising false expectations is not desirable.

There is, then, the rather different issue of using screening instruments at a population level to pick out children who should receive a preventive intervention because they have an increased risk of developing some serious disorder later. Thus, politicians have seized on the evidence that antisocial behavior that begins at an early age is that which is most likely to persist into adult life. Their influence is that this means that parents should be compelled to receive interventions to improve their parenting and hence to reduce the risks for the children. A key problem, however, is that epidemiological evidence indicates that although the risks associated with an early onset are real, most children showing early conduct problems do not go on to show a life-course-persistent pattern (Odgers, Caspi, Broadbent et al., 2007). The intervention risks for false positives may not be trivial. In addition, there is uncertainty as to whether the interventions shown to be effective in treating early antisocial behavior are effective in the subgroup who are likely to continue into adult life. Somewhat similar issues arise with the prodromata of schizophrenia (see chapter 13). It will be appreciated that the concerns here arise from the problem of false positives rather than from the limitations in screening as such.

There is also the issue of using screening instruments in a total population sample as a guide to the possible overall level of disorder. There are many examples of this usage. The fact that the screening measure has only a moderate correlation with a fuller clinical assessment is not a concern with respect to population estimates, although the screen instrument cannot provide a valid diagnosis at an individual level. Nevertheless, there are three considerable problems with this use of screening. First, the presence of disorder is only one of many features on which information is needed for service planning. Moreover, most screens are not very satisfactory for the identification of unusual, highly specific disorders. Second, most emotional and/or behavioral items (whether in a questionnaire or a structured interview) involve judgments on the degree to which a child shows misery, anxiety, overactivity or some other feature. The Thailand and Hong Kong examples indicate that it cannot be assumed that raters in all cultures will make identical assumptions in making such judgments. Third, within all cultures, there is only a weak agreement among informants (such as parent, child and teacher) in their ratings. In part, this derives from differences in their opportunity to observe the relevant features but similar interrater disagreements arise even when they all observe the same features in the same situation. In this case, the disagreements may derive from the different raters using different comparisons (Borge, Samuelson, & Rutter et al., 2001). Thus, the rating of misery or anxiety may be made by parents on the basis of a comparison with other children in the same family, by teachers on the basis of a comparison with other children in the same school class and by the child/adolescent in relation to how they felt a year ago. Surprisingly, and regrettably, epidemiologists have failed to examine these possibilities systematically. The usual solution has been to use the “or” rule – that is, a behavior is treated as present if anyone reports it. Clearly, this “works” at a rough and ready level
CHAPTER 6

but it causes the risk of overestimating prevalence. Alternatively, some kind of latent construct may be used in order to focus on shared variance (see e.g., Simonoff, Pickles, Meyer et al., 1998). The problem with this solution is the opposite (i.e., the estimate will account for a small proportion of the total variance and hence greatly underestimate the prevalence).

We have discussed this issue at some length because the issues are poorly understood, with a resulting wrong expectation that there is some “gold standard” available if only someone would say what it is. There have been huge advances in the measurement of psychopathology, but major challenges remain.

Policy Decision-Making on Services

One further critical issue concerns patterns of policy decision-making in relation to services. The prevailing tendency in many countries today involves a view that efficacy requires competition amongst service providers. Epidemiology may well not be the best tool to identify such competition, but it can be informative in identifying the effects of market-driven inequalities in service provision.

Conclusions

In this chapter we have chosen not to focus on the many crucial technical considerations in undertaking epidemiological studies designed to be informative in the planning of services. That is certainly not because we regard methodological details as unimportant; on the contrary, they are crucial. However, our objective has been to provide an understanding for general readers of how epidemiology may be informative in service planning. Readers wishing to undertake such epidemiological studies need to turn to the various sources that provide a good account of the technicalities. We have assumed that there is a general wish for evidence-based policy-making. It has to be said that in most countries, although that may be the rhetoric, that is not actually the way decisions are made. Of course, politicians and other policy-makers need to decide on the values that they wish to use in the planning of services, but they will be foolish if they ignore the role of epidemiology in providing evidence that will enable them to consider whether the particular policies they favor are ones that will actually meet the objectives they have set. Epidemiological findings as such do not, and cannot, answer policy questions on service provision but what they can do, and can do rather well, is provide information that is essential in the overall process of planning effective services. As we have emphasized, the conceptual understanding of what is required has greatly improved in recent years. The challenges for the future are many, but the way to put all the information together for service planning is one of the most important.

References

Research on children’s testimony has been one of the fastest growing areas in developmental psychology. It encompasses such issues as the reliability of children’s statements, children’s understanding of legal concepts, courtroom preparation of child witnesses, competency tests, suggestibility, jurors’ perceptions of children’s credibility and detection of children’s deception. In this chapter, we restrict our coverage to the subtopic of children’s suggestibility, the most active topic within the research in this area, and one that cuts across many of the issues above.

Defining Suggestibility
One’s recall of past experiences is rarely error free. Errors can occur for a variety of reasons such as forgetting, lapses of attention in experiencing the event or in recalling its details, blocking of the memory by other experiences, or blending of two or more different memories (Schacter, 2001). Recall of one’s past can also be distorted by one’s beliefs of what should have happened. Finally, recall can be distorted by suggestions – interactions with others that result in incorporation of their beliefs into one’s own report.

Suggestions become incorporated into reports for a variety of social and cognitive reasons. Cognitive theories suggest that the original memory trace can be damaged, replaced or overshadowed by suggestions (Brainerd & Reyna, 2005), whereas social theories posit that although reports are consistent with the suggestions, the original accurate memory may nevertheless be maintained (McCloskey & Zaragoza, 1985). Both social and cognitive mechanisms may account for suggestibility effects: a child may initially acquiesce due to social factors (to please their interviewer) and with time this acceptance may affect memory, so that the child comes to believe falsely that the suggested incident actually occurred.

Experimental Measures of Suggestibility
In order to examine the direct influence of various types of suggestions on the accuracy of reports, a number of different paradigms have been used. These can be divided into two basic categories. In the first category, children are exposed to an event or activity about which the researcher has full knowledge of all the details. Children are asked to recall these experiences through the use of techniques that falsely suggest details that were not present during the event, or through neutral interviewing techniques that do not involve suggestion. A comparison of the errors made in the suggestive and neutral conditions allows a determination of the degree to which suggestions taint the child’s reports. Because the researchers have full knowledge of the original event, they can easily determine the accuracy of the child’s reports. In the second major paradigm, children are given suggestions about whole events that (according to parent reports) they have never experienced. The degree to which children provide details about non-experienced events is a measure of their suggestibility.

In this chapter, we first place the topic of children’s suggestibility in a broader societal context, citing annual estimates of the number of children brought to the attention of law enforcement, attorneys and mental health specialists. We then describe a recent UK case that serves as a basis for applying the research. Finally, we show how recent research in the field of suggestibility can provide a basis for scientific examination of the nature of the children’s reports and adults’ acceptance of these reports.

Social Context of Child Suggestibility Research
Scope of the Problem
According to the latest statistics, in 2003 there were 2.9 million reports of child maltreatment in the USA alone, of which 906,000 were classified as founded. Of these founded cases, 537,026 resulted in court action (US Department of Health and Human Services, 2005). In addition to children who enter the legal arena for issues related to abuse and maltreatment, there are many others who come into contact each year with the juvenile and family court systems for other reasons (witnesses to domestic violence, Persons in Need of Supervision [PINS] hearings, neglect/permanency hearings and custodial disputes). In the USA alone, there is an estimated 1 million children involved in divorce proceedings annually (Emery, Otto, & O’Donohue, 2005), many of whom are interviewed as part of the custody determination (see chapter 8 for comparable UK perspectives).

Thus, the numbers of young children involved in the various branches of the justice system becomes frighteningly large. In all of these situations, children may be asked to provide
Focus on Preschool-aged Children

In considering factors related to children's ability to provide accurate testimony about experienced events, much of the research in the past two decades has focused on preschool-aged children, and has been framed to address issues concerned with sexual abuse. There appear to be several reasons for this focus on young children. First, in the USA, where national archives are kept for each type of maltreatment, nearly 38% of reported cases of sexual abuse involve children aged 7 and younger (US Department of Health and Human Services, 2005).

Second, beginning in the 1980s, there were a number of highly visible cases in Europe, the USA, Australia, New Zealand and Canada in which young children claimed that their caretakers had abused them. The claims often included a con-mingling of plausible allegations with fantastic reports of ritualistic abuse, pornography, human and animal sacrifice, multiple perpetrators and multiple victims (e.g., California v. Raymond Buckey et al., 1990; Commonwealth of Massachusetts v. Cheryl Amirault LeFave, 1999; Lillie and Reed v. Newcastle City Council & Ors, 2002; New Jersey v. Michaels, 1994; North Carolina v. Robert Fulton Kelly Jr., 1995; State v. Fijnje, 1995). When these types of cases first came to trial in the 1980s, the major issue before the jury was whether to believe the children. Prosecutors argued that children do not lie about sexual abuse, that the child witnesses' reports were authentic and that their bizarre and chilling accounts of events, which were well beyond the realm of most preschoolers' knowledge and experience, substantiated the fact that the children had actually participated in them. Furthermore, they argued that patterns of delayed disclosures, denials and recantations were typical if not diagnostic of sexual abuse in children (Summit, 1983; Summit, Miller, & Velkamp, 1998). The defense in these cases argued that the children's reports were the product of repeated suggestive interviews by parents, law enforcement officials, social workers and therapists. Although the defense attempted to point out the potentially “suggestive” interview techniques that were used in eliciting the children's allegations, at the time there was not any direct scientific evidence to support the view that such techniques could actually lead children to make incorrect disclosures of a sexual nature. As will be shown, there is now sufficient evidence to support these views.

A Case Example: Lillie and Reed v. Newcastle City Council & Ors

To illustrate the issues that will be raised in this chapter, we provide the following case example. We chose this case because one of us (M.B.) served as an expert witness for the complainants, thus allowing us access to much of the official documentation. It was also chosen because the facts and the interviewing styles resembled those of a myriad of cases throughout the English-speaking world; these cases have given rise to much of the science on children's testimony, which in turn has been used to address issues arising in such cases.

Chris Lillie and Dawn Reed were two British daycare workers who were accused of sexually abusing 27 children at a daycare facility in Newcastle, England. The initial allegation was reported to the police by Mrs. Roberts in April 1993. She claimed that her 2-year-old son, Tim (the index child),¹ had indicated that Chris Lillie had touched him in the genital area. However, when interviewed by the police and social services a few days later, Tim denied that Chris Lillie had hurt him; physical examination also failed to show any positive evidence of abuse. Nonetheless, the investigation continued and Lillie was suspended from his duties at the daycare facility. Mrs. Roberts continued to supply the police with additional details: Tim was abused in a house with black doors and Lillie's coworker Dawn Reed was involved.

Several weeks after Mrs. Roberts' report, social services met with the parents of the daycare children and announced that one of the workers had been suspended because of an allegation of sexual abuse. Dawn Reed was officially suspended from the school soon after that meeting. Social services contacted families to determine whether the children had made any allegations or whether parents were concerned, as well as to provide parents with advice on how to question their otherwise silent children.

Approximately 29 children were interviewed at least once by the police and social services. A number of the children were interviewed two and even three times in order to elicit allegations of abuse. In June 1993 Lillie and Reed were arrested, after 4-year-old Mandy Brown claimed that she had been vaginally penetrated with a crayon at least 9 months previously. They were successfully granted bail, but just as they were leaving their cells, they were rearrested on the basis of a 3-year-old girl's allegation that she also had been abused. This child, who had not attended the daycare facility for over 1 year, made this statement after three investigative interviews. All interviews in this case were videotaped.

On the basis of a disciplinary hearing held by social services in February 1994, Lillie and Reed were dismissed from their positions at the daycare facility and, in July 1994, their criminal trial commenced. There were 11 counts involving 11 children (the index child Tim was not a witness). It was a very short trial because the judge dismissed the entire case on the grounds that the evidence was too weak to present to a jury. Lillie and Reed were legally free. However, because of the outrage of the parents and based on the city council's belief that the pair were guilty, an independent review team was

¹ The names of the children and their families have been changed to protect their identities.
set up to determine what, if anything, had gone wrong in the investigation. The review team’s mandate was to examine how the allegations of abuse arose, and to investigate specific complaints made by parents. They were not asked to judge the guilt or innocence of Lillie and Reed.

In 1998, after 4 years’ investigation, the review team issued its report, Abuse in the Early Years, and concluded: “From the evidence we have seen it is clear that Chris Lillie and Dawn Reed had conspired as a pair to abuse children and it is also clear that other people outside the nursery were involved.” Lillie and Reed became the objects of public hatred, in part incited by the headlines in the local newspaper. They went into hiding. Eventually, because of the efforts of two journalists, they brought a suit against the city council, the local evening newspaper (the newspaper made an out-of-court settlement) and the review team itself. After a 6-month trial, the judge ruled in favor of the complainants, awarding them the maximum penalty of £200,000 each. The review team was found guilty of libel; the city council was not found guilty on the grounds of “qualified privilege.”

We selected this case because it contains a variety of examples that have been examined in research on children and the law. In addition, it shares the following set of characteristics with other cases involving allegations of sexual abuse by young children that spurred the initial research interest in this area. First, the first child to make an allegation (the index child) did not originally make spontaneous statements but was questioned by an adult who was suspicious that something had happened to the child. When first questioned, the index child denied harm or wrongdoing; however, with repeated questioning, allegations began to emerge. Second, on the basis of the index child’s uncorroborated allegations, parents of children in the daycare facility were informed that a child had been abused or that abuse was suspected. Parents were instructed to look for symptoms of abuse (bedwetting, crying, nightmares) and to question their children about specific events. Third, as was the case with the index child, children at first told their interviewers that nothing had happened; however, after repeated questioning by parents, police, social workers and/or therapists, some of these children also reported abuse. Sometimes, it took months of questioning for them to provide an acceptable report. Fourth, there were a number of contaminating factors that could account for the common allegations of the children: the same small group of professionals interviewed all of the children, provided therapy for them and evaluated them for sexual abuse. In addition, parents and children interacted with each other and spoke about the newest claims or rumors. Fifth, although there was no reliable medical evidence of sexual abuse for the most part, most parents reported changes in their children’s behavior around the time of the alleged abuse, such as nightmares, bedwetting, baby-talk, resistance to going to the bathroom alone, refusal to attend daycare and much more. Finally, the children’s reports became more elaborated with time; for example, after naming a specific perpetrator, children included other workers at the daycare center or other people in the town in their accusations. Over a period of time, the children’s allegations became quite disturbing and bizarre; they alleged that they were penetrated with a sword, that needles were stuck into their bottoms, that there were monsters in elevators or that they were locked up in cupboards with no windows or handles. The following discussion and examples of this case are based on an analysis of the index child and six children that the prosecution had expected to testify at trial.

Scientific Analysis of the Case

There are two major competing hypotheses to account for the evolution of these children’s allegations (no disclosure, denial of abuse, disclosure and sometimes recantation) and their acceptance by the parents and professional interviewers. The first hypothesis (put forward by the review team) is that the children accurately reported acts of abuse. According to this hypothesis, sexually abused children deny and recant either because they are afraid (because of threats), ashamed, believe themselves to be culpable or are confused by the events themselves. The fact that the parents were able to recall that, prior to their disclosures, the children experienced a number of behavioral symptoms that were deemed characteristic of abuse was viewed as corroborative evidence of the children’s reports. The second hypothesis (put forward by the complainants) is that the children’s reports were a product of a vast array of suggestive interviewing techniques that were used to elicit reports of abuse. The parents’ recall of behavioral problems was not accurately dated but reflected memory errors resulting from their beliefs that their children had been abused. Each of these two major hypotheses will be evaluated in light of the scientific evidence.

Hypothesis 1: The Children were Abused

It is of primary importance to examine the evolution of the children’s reports of sexual abuse. The pattern that occurred in the present case has raised the most concerns among researchers: the children were initially silent; with one ambiguous exception, none of the children made any unsolicited or spontaneous statements about abusive acts. Rather, the allegations emerged only after an adult suspected that something has occurred and started to question the children. In Lillie & Reed, all the children initially denied that the event happened, but with repeated questioning (in this case mainly by the parents and the investigators) the children eventually made a disclosure. Some of the children recanted these disclosures only to later restate the original allegation after further questioning. The most popular embodiment of this sequence of behaviors is Summit’s (1983) description of the child sexual abuse accommodation syndrome (CSAAS). Summit intended to explain to clinicians why sexually abused children show this pattern of disclosure. The explanation rested on the assumption that these children are often frightened, confused and feel guilty. This explanation was fully accepted by the interviewers in the present case.

Because the CSAAS model was based on clinical intuitions rather than scientific findings, we recently reviewed the
CHAPTER 7

literature to determine its empirical support (London, Bruck, Ceci et al., 2005). We identified 10 studies in which adults with histories of childhood abuse were asked to recall their disclosures in childhood. Across studies, an average of only 33% of the adults remembered disclosing the abuse in a timely fashion. In some studies, approximately 30% of adults reported that they had never told anyone before the current interview about their childhood abuse (Finkelhor, Hotaling, Lewis et al., 1990; Smith, Letourneau, Saunders et al., 2000). These data support the claim of the CSAAS model that sexually abused children are silent about their victimization and delay disclosure for long periods of time.

Although informative on the issue of delay of reporting, these data are silent with regard to the phenomena of denial and recantation, because the participants were never asked, “As a child, did anyone ever ask you or question you about abuse?” We have no way of knowing whether these individuals denied having been abused and then perhaps subsequently recanted their reluctant disclosures. Another set of studies provides some data relevant to this point. We identified 17 studies that examined rates of denial and recantation by sexually abused children who were asked directly about abuse when they were assessed or treated at clinics. The rates of denial at assessment interviews were highly variable (4–76%), as were the rates of recantation (4–27%). We found that the methodological adequacy of each study (e.g., the representativeness of the sampling procedures and the degree to which sexual abuse was validated) was directly related to the rates of denial and recantation: the weakest studies produced the highest rates of denial and recantation. For the six methodologically superior studies, the average rate of denial was only 14% and the average rate of recantation was 7%.

Thus, although the retrospective studies of adults show that children often do not disclose their abuse, the studies of sexually abused children’s responses in a formal interview indicate that if they are directly asked, they do not deny, but rather disclose that they were abused.

Over the course of the investigation, parents recalled that their children experienced a number of behavioral problems, including not wanting to go to school, sleep problems, nightmares, tantrums, inappropriate touching and being afraid of men. These symptoms were interpreted by both professionals and parents as signs that the children had been abused. However, the central assumption that there is a common constellation of symptoms that are diagnostic of sexual abuse is not supported by the scientific evidence. There are no behavioral symptoms that are diagnostic of sexual abuse. Many of the problems cited by the parents (anxiety, enuresis, fears, night terrors and even sexual behaviors) either are common in children of this age or can be associated with other types of childhood behavioral disorders (Hagen, 2003; Kendall-Tackett, Williams, & Finkelhor, 1993). For example, Maddocks, Griffiths, and Anto (1999) compared the medical histories of 107 boys with histories of sexual abuse with 107 non-abused age-matched boys. There were no between-group differences in the number or type of somatic and physical complaints (17% of sexually abused boys presented with such symptoms compared to 23% of the control boys); however, symptoms were more likely to persist for 1 year or longer among the target group (7%) than among the non-abused group (<1%). Thus, using behavioral symptoms as indicators of abuse is not scientifically supported.

Hypothesis 2: The Children’s Reports Reflected Suggestive Interviewing Techniques and the Biases of their Interviewers

There is now a vast literature on the various situations and interviewing techniques that are known to produce false reports by children in experimental situations. In the present case, the children were subjected to just about every scientifically studied suggestive technique. The central driving force for the use of these techniques was the concept of interviewer bias, which we address next.

Interviewer Bias: The Central Characteristic of Suggestive Interviews

Interviewer bias refers to interviewers who hold a priori beliefs about the occurrence of certain events and, as a result of these beliefs, mold the interview to elicit statements from the interviewee that are consistent with these ideas. One of the hallmarks of “interviewer bias” is the single-minded attempt to gather only confirmatory evidence and to avoid all questions that may yield negative or inconsistent evidence. The biased interviewer does not ask questions about the allegations that might provide alternate explanations that are inconsistent with their beliefs or hypotheses. When confronted with a statement that runs counter to their beliefs, biased interviewers either ignore it or else interpret it within the framework of their initial hypothesis.

Biased interviewers’ beliefs are transmitted to the child through a range of suggestive interviewing techniques that are associated with the elicitation of false reports. Consequently, the child may come to inaccurately report the belief of the interviewer rather than the child’s own experience. A biased interviewer may be a police officer, a therapist or even a parent.

Below we provide two examples of scientific studies of the influence of interviewer bias on children’s report accuracy.

Chester the Janitor

Thompson, Clarke-Stewart, and Lepore (1997) conducted a study in which children viewed a staged event that could be construed as either a misdeed or an innocent act. Some children interacted with a confederate named “Chester” as he cleaned some dolls and other toys in a playroom. Other children interacted with Chester as he handled the dolls roughly and in a mildly abusive manner. The children were then questioned about this event. The interviewer was:

1 “Accusatory” – suggesting that the janitor had been inappropriately playing with the toys instead of working;
2 “Exculpatory” – suggesting that the janitor was just cleaning the toys and not playing; or
3 “Neutral” and non-suggestive.
In the first two types of interviews, the questions changed from mildly to strongly suggestive as the interview progressed. Following the first interview, all children were asked to tell in their own words what they had witnessed and then they were asked questions about the event. Immediately after the interview and 2 weeks later, parents asked their children to recount what the janitor had done.

When questioned by a neutral interviewer, or by an interviewer whose interpretation was consistent with the activity viewed by the child, children’s accounts were both factually correct and consistent with the janitor’s script. However, when the interviewer was biased in a direction that contradicted the activity viewed by the child, those children’s stories quickly conformed to the suggestions or beliefs of the interviewer. In addition, children’s answers to interpretive questions (e.g., “Was he doing his job or just being bad?”) were in agreement with the interviewer’s point of view, as opposed to what actually happened. When asked neutral questions by their parents, the children’s answers remained consistent with the interviewer’s biases.

**Surprise Party**

Bruck, Ceci, Melnyk *et al.* (1999) showed how interviewer bias can quickly develop in natural interviewing situations, and how it not only taints the responses of child interviewees but also the reports of the adult interviewers. In this study, a special event was staged for 90 preschool children in their school. In groups of three children, and with the guidance of research assistant A, the children surprised research assistant B with a birthday party, played games, ate food and watched magic tricks. Another 30 children did not attend the birthday party but in groups of two, they simply colored a picture with research assistants A and B. These children were told that it was assistant A’s birthday.

Interviewers (who were recruited from graduate degree programs in social work or counseling and who had training and experience in interviewing children) were asked to question four children about what had happened when special visitors came to the school. The interviewers were not told about the events but were simply told to find out from each child what had happened. The first three children that each interviewer questioned attended the birthday party and the fourth child attended the coloring event.

Bruck *et al.* found that the fourth child (who attended the coloring event and was interviewed last) produced twice as many errors as the children who attended the birthday party. For example, 60% of the children who only colored made false claims that involved a birthday party. This result suggests that the interviewers had built up a bias that all the children had attended a birthday party as a result of interviewing three consecutive children who actually had done so. By the time they interviewed the fourth child, they structured their interviews to elicit claims consistent with this hypothesis. Thus, if interviewers have the belief that all the children they are interviewing have experienced a certain event, then it is probable that many of the children will come to make such claims even though they were non-participants (or non-victims). Another important finding from this study was that even when the fourth child denied attending a birthday party, 84% of their interviewers later reported that all four of the children they interviewed had reported to them that they attended a birthday party. These data suggest that, regardless of what children actually say, biased interviewers inaccurately report the child’s claims, making them consistent with their own hypotheses. It is also important to note that this bias likely can influence the interview in the absence of conscious manipulation on the part of the interviewer.

The Chester and Birthday Party studies and others like them (Bruck, Ceci, & Principe, 2006) provide evidence that interviewers’ beliefs about an event can influence their judgments as well as their style of questioning. This, in turn, can affect the accuracy of children’s testimony. Finally, interviewers’ beliefs can affect their own ability to recollect accurately what the child actually told them during the interview. The findings from such studies highlight the dangers of having only one hypothesis about the event in question – especially when this hypothesis is incorrect. In applying the research on interviewer bias to a particular case, it is important to note that interviewer bias has a variety of manifestations and can occur at various levels of investigation of the case. For example, interviewer bias can be observed in a specific interview, in how an interviewer assesses the content or the impact of specific interviews or, at a higher level, interviewer (or investigator) bias is revealed by the types of evidence that are pursued or ignored at the investigational level.

**Examples of Interviewer Bias in the Present Case**

*The investigators did not consider other explanations for reports of touching.* When the investigators tried to get the children to tell or to show on their bodies how they had been touched by Chris and Dawn, many of the children talked about touching in the toilet (often with their clothes on) and having a hurt bottom. It is possible that these comments reflected actual toileting practices which the children reported when they were asked about things that happened to their bottoms or genitals. Given the age of these children, the workers did perform these duties. The interviewers did not appear to consider this hypothesis in the interviews.

*Investigators ignored that children did not demonstrate sexual touching accurately.* When children were asked to explain or to show where on their bodies they had been molested, a number of children pointed to many parts of their bodies that did not include their genitals. For example, one child stated that Chris had inserted a crayon into her vagina but it turns out, as seen below, that she may not have understood the nature of her claim:

Interviewer: Which bits of your body was Dawn tickling?
Child: That.
Interviewer: What bit’s that?
Child: It was my back.
CHAPTER 7

Interviewer: Your back. And was it any of the bits that Chris had tickled?
Child: Yes.

Another child showed similar confusions:

Interviewer: Which bits was he smacking?
Child: He smacked us there and he smacked us there, and he smacked us there, and he smacked us there, and he smacked us there, and he smacked us there, and he smacked us there, and he smacked us there. *(Child does not point to buttocks.)*
Interviewer: And was there any bits down the back way?
Child: No.

The same child showed a similar confusion in her second formal interview. When asked, “Did he use some part of his body to hurt you?” the child pointed to her stomach. When she was asked to point to her genitals, she pointed to her back. Thus, these children’s allegations about sexual touching were initially about being touched on various parts of their bodies, none of which included their buttocks and genitals. The investigators did not seem to notice the children’s ignorance of such matters and their repeated questioning may have resulted in these children becoming very knowledgeable about sexual touching. Their bias that the children had been molested by Chris and Dawn may have blinded them to this possibility.

*Investigators ignored children’s exculpatory statements about Dawn* There were a number of instances in which the children made exculpatory statements about Dawn. For example:

Interviewer: Is anybody else? Is Dawn in here or not?
Child: No.

Interviewer: And who was on the bus with you?
Interviewer: Anybody else?
Child: Not Dawn.

Interviewer: You know you mentioned somebody called Dawn. Who’s that?
Child: [coughs] The girl inside Chris’s [inaudible]
Interviewer: Did she do anything to you?
Child: No.

In her second of three interviews, this child made the following exculpatory statements about Dawn:

But don’t say nothing to Dawn cos she wasn’t silly. She just went into jail for nothing. Say Dawn can come out today. Say that. Cos Dawn done nothing.

Despite these and other denials that Dawn had not done anything, the investigators concluded that Dawn had abused these children.

When the children denied abuse, the investigators would not take “no” as an answer because of their primary hypothesis that abuse had occurred and that the children were too frightened to talk about it. Consequently, children were interviewed until they simply gave in to the interviewers’ requests to admit abuse. For example, one child ended the interview by moaning in her mother’s lap, another child whimpered at the end of one interview; in the third and final interview the star witness for the prosecution begged her mother to stop and when she did not, the child simply left the room. The interviewers nevertheless interpreted these behaviors as further signs of resistance as reflected in their continuing to question the children. For example, one social worker interpreted Child 2’s behavior during a suggestive interview as follows:

Investigator: Towards the end of the interview Child 2 appeared to become restless. I had visited Child 2 at home and not seen her display this sort of behaviour before. Although the interview had been fairly long I do not think she was tired, but rather pretending to be tired in order to avoid answering our questions. I recall that when we went out of the room Child 2 was running around and playful.

This interviewer did not consider the hypothesis that the interview was aversive to the child because she was being pressured to provide false information or information that she could not remember.

*Parents’ and investigators’ biases in reporting and interpreting behavioral problems* The primary source of evidence concerning the children’s behaviors and allegations was provided to the police, social services and the review team by the children’s parents. Thus, much of the primary evidence is only as reliable as the memories of these adults. Because parents recalled behaviors and conversations that had occurred months and sometimes years in the past, one might predict that there would be errors due to natural forgetting and due to other factors that allow one to reconstruct previous memories. In fact, there are many examples throughout the record that show changes in parents’ memories and discrepancies between parents’ and other observers’ reports of the children.

One type of pattern that is observed entails parents’ changing their reports over time such that the children’s behaviors in the past were recalled as worse as the case proceeded. For example, Chris and Dawn cared for Ricky when he was 3 years old. Ricky’s mother was interviewed by social services 15 months after he had left their care and 4 months after the investigation of abuse had begun. At that time she noted that Ricky had been disruptive and aggressive before he met Chris and Dawn and after he left their class. At present, however, she thought his behavior was much improved. She stated that she was pleased with the daycare facility, that she had a good relationship with Chris and was glad that her son had a male teacher. Two years later, she reported (to the review team) that she began to get very concerned because Ricky had become afraid of a male friend who, upon retrospect, was physically similar to Chris (Note, this had actually happened before Ricky met Chris). She reported that he began soiling
at night and having more tantrums. She reported that Ricky had spent about 1 year in the red room (Note, he spent 3 months). She rarely spoke to Chris and had had a poor experience with him. She used to dread picking Ricky up from the red room and was made to always feel ashamed about her son’s bad behavior. After Ricky had reported abuse, he spent a year in treatment because he was so traumatized.

The concept of hindsight bias could account for many of the changes in memories and reports throughout this case. Hindsight bias refers to the extent to which one changes one’s memory of prior events based upon what is known in the present. This is sometimes referred to as “I knew it all along effect” or “The Monday Morning Quarterback Effect” (Hastie & Hastie, 1990; Schacter, 2001). In a classic hindsight study, participants were asked to predict the outcome of a major political event (Fischhoff & Beyth, 1975). Two weeks after the event participants were asked to recall what they had predicted prior to the event. Although they were told to explicitly recall what they thought would happen before the event occurred, participants exhibited a significant bias, rating events that actually occurred as being more probable than they initially had.

In another study, doctors were asked to make an independent diagnosis (a second opinion) for a case that had previously been worked up and diagnosed. Some of the doctors were given no information about the prior diagnosis. Other doctors were given the prior diagnostic label but were told to ignore it when arriving at their independent opinion. This latter group of doctors was more likely to make a diagnosis consistent with the first label, compared with doctors who were not given this information (Arkes, Watmann, Saville et al., 1981).

In addition to interpreting past behaviors as signs of abuse, there was also the matter of the children’s behaviors after they disclosed abuse. It seemed as though the children’s behaviors actually became worse in some instances as the investigation proceeded. The problem was that these behaviors were interpreted as corroborative signs that abuse had occurred; they were seen as consequences of the abuse. However, there were a number of other highly plausible explanations that were never considered. For example, the children’s behaviors became worse because they were treated as victims and came to believe they were victims. The following interaction suggests how children may have become frightened or disoriented because of the interviewing practices that were used to help them reveal their abuse. It is possible that these suggestions caused the children to believe that something awful had happened to them.

**Interviewer:** You know, there’s nothing for you to be frightened of, you know. You’re not frightened are you?
**Child:** No.

**Interviewer:** You don’t have to be frightened to tell us anything cos you’re safe here and there’s nothing to be worried about.
**Child:** No, there’s no monsters here.

**Interviewer:** Of course there isn’t. Has somebody been talking that there’d be monsters here?

**Child:** No.

**Interviewer:** Why do you say that?
**Child:** I do.

**Interviewer:** Are you frightened of monsters?
**Child:** No.

**Interviewer:** Who’s told you about the monsters? Has somebody told you that there’s monsters?
**Child:** No.

**Interviewer:** Cos mummy and daddy look after you, you know . . . You know mummy and daddy look after you and I’m just here to help you. There’s nothing to be worried about. These monsters that you talk about, where do they go?
**Child:** [inaudible]

**Interviewer:** Where do they come from?
**Child:** Nowhere.

**Interviewer:** Has somebody told you a story about monsters?
**Child:** No.

**Interviewer:** You don’t have to be frightened, you know. You can tell me anything. You can. Mummy says it’s all right. We just want to help you. If somebody’s told you about monsters, I’d like you to tell me. Cos you know, nobody can hurt you. Nobody’s going to hurt you. There’s nobody going to come and take you away or anything. Mummy and daddy love you and they look after you. And I’m just talking to you to try and help you, cos I care about you. And there’s no monster going to come. You’re safe. I just thought maybe somebody told you about them.

In another example, all of Janie’s troubling behaviors were seen as consequences of abuse, although there were other factors that could have had an important role. Specifically, when Janie was with Chris and Dawn she loved school. Problems began after she left the care of Chris and Dawn, in March 1992; sleep problems increased in September 1992, and in January 1993 she did not want to go to school. Her mother initially thought these problems were related to her meeting her current partner because Janie kept asking about her dad. However, her behavioral problems began to increase after she was interviewed by the police and social services. She had terrible nightmares, she became antagonistic towards her mother’s partner, and she initiated inappropriate touching with children. Although these symptoms could be trauma-related, the question that could be raised is “what trauma?” The investigators believed it was the trauma of the abuse, but it could just as well have been the trauma of pressurized interviews, a new man in the house and the false belief that she was abused. These alternative hypotheses were never considered.

In summary, as parents learned more about the case and became more concerned or convinced that their children were victims, their perceptions of the severity of the child’s behaviors, prior to April 7, 1993 (the time of the initial disclosure) increased. As seen from the example above, the timing of the behavioral problems also changed so that these occurred when the children were cared for by Chris and Dawn. Thus,
hindsight bias provided the parents with stronger beliefs that their children had been abused. In addition, the fact that all of the children’s poor behaviors were also viewed as signs of abuse fueled the investigators’ and parents’ confirmatory bias that the children had been abused. It was this confirmatory bias that was central to the entire case. The ways that this was made apparent to the children are reviewed in the following section.

Suggestive Interviewing Techniques
Interviewer bias influences the entire architecture of interviews and is revealed by the methods or strategies used by interviewers to elicit the children’s allegations of abuse. The following techniques were used in the interviews with the children in the current case:

- The children were given little opportunity to say in their own words what, if anything, had happened.
- Interviewers quickly resorted to the use of specific yes/no or forced-choice questions that required monosyllabic responses (e.g., “Was it this or that?”).
- Interviewers’ statements and questions contained sexual content and details about the case that may not have been part of children’s initial knowledge.
- Questions were repeated within and across interviews.
- Interviews continued or were repeated until the child provided information consistent with sexual abuse.
- Interviewers used bribes or threats of punishment (“I will give you a treat if you tell me” or “We can’t go home until you tell what happened”).
- Interviewers used selective reinforcement in response to children’s statements. They rewarded children for abuse consistent statements but ignored or made negative comments in response to denials of abuse or related activities.
- Interviewers made “atmospheric” statements that conveyed the theme that something bad happened (e.g., telling the child not to be afraid, that he or she should not be afraid, that he or she is being brave, that he or she is going to be protected).
- Interviewers invoked statements of other people (“Your mom told me that . . .” or, “All your friends have talked about this, now it’s your turn”).
- Children spoke among themselves about the allegations.
- Interviewers induced negative stereotypes of the suspected perpetrator (e.g., telling the child that the suspect does bad things, that he or she is in jail).
- Props, such as dolls, toys and drawings, were used to elicit statements about touching.

The results of the scientific literature indicate that the use of these suggestive techniques, especially by biased interviewers, can bring children to make claims about events that they have never experienced. This is especially so when these techniques are used repeatedly and in combination (as was the case in Lillie & Reed) because the concentration of suggestive interviewing provides the child with a clear view of the biases of the interviewer and thus promotes the risk of their complying with the perceived beliefs of their interrogators.

In the next section we provide a brief overview of the scientific literature on some of the suggestive interviewing techniques that were used in Lillie & Reed (for a more detailed description see Bruck, Ceci, & Principe, 2006).

Repeating Interviews and Repeating Questions
In formal investigations, children are often interviewed on many different occasions. There are numerous concerns about the influence of these repeated interviews on children’s reports, especially when these are conducted by biased interviewers. In these situations, children are repeatedly exposed to (mis)leading questions and to other suggestive techniques. The results of several studies indicate that when this occurs, children’s reports become highly tainted, sometimes after just one or two interviews.

For example, preschool children were interviewed on five different occasions about two true events and two false events (Bruck, Ceci, & Hembrooke, 2002). The two true events involved the child helping a visitor in the school who had tripped and hurt her ankle and a recent incident where the child was punished by the teacher or the parent. The two false events involved helping a lady find her monkey and witnessing a man steal food from the daycare facility. In the first interview, children were simply asked if each event had ever happened to them. If they said yes, they were asked to describe the event. During the next three interviews, the children were suggestively interviewed (e.g., they were asked repeated leading questions, they were praised for responses, they were asked to try to think about what might have happened, they were told that their friends had already told and now it was their turn). In the fifth interview, a new interviewer questioned each child about each event in a non-suggestive manner. Across the five interviews, all children consistently and accurately asserted to the true event about helping a lady who fell in the daycare facility. However, children were at first reluctant to talk about the punishment event; many of the children denied that the punishment had occurred. With repeated suggestive interviews, the children agreed that the punishment had occurred. Similar patterns of disclosure occurred for the false events; that is, children initially denied the false events but with repeated suggestive interviews, they began to assert to these events. By the third interview, most children had asserted to all true and false events. This pattern continued to the end of the study. Thus, although suggestive interviewing techniques promote the disclosure of true embarrassing events, they are equally effective in promoting false allegations.

One of the rationales for reinterviewing children is that it provides them additional opportunities to report important information that was forgotten or simply not reported in earlier interviews. Thus, it is assumed that, when children provide new details in subsequent interviews, these new reports are accurate memories that were not remembered in previous interviews. Another rationale is to allow children to rehearse, so that their memories will not fade over a period of time. However, the results of recent studies dispute this claim. One
set of studies consistently shows that reports that emerge in a child’s first interview with a neutral interviewer are the most accurate. When children are later interviewed about the same event and report new details not mentioned in a previous interview, these have a high probability of being inaccurate whether children are interviewed by a neutral interviewer (Peterson, Moores, & White, 2001; Pipe, Gee, Wilson et al., 1999; Salmon & Pipe, 2000) or by a very suggestive interviewer (Bruck, Ceci, & Hembrooke, 2002). Thus, insertion of new but inaccurate details can be a natural memory phenomenon; it can be due to prior suggestions that become incorporated into later reports; but it can also be due to the demand characteristics of the interview. When interviewers urge children to tell them anything (that is consistent with the bias of the interviewer), these requests for additional information will sometimes result in false reports that are supplied by the children to comply with their perception of the interviewer’s wishes.

Although these studies show the detrimental effects of repeated interviews, there is an important qualification to this conclusion. There are a number of studies in which children who are provided with misinformation across multiple interviews are no more likely to incorporate this information into a later report than children who receive only one suggestive interview. The major factor appears to be the timing of the suggestive interviews. If the first suggestive interview occurs soon after an event and the second interview occurs close to the final interview, then misinformation effects are maximized (Melnyk & Bruck, 2004). There are several interrelated qualifications to bear in mind. As shown in some of the studies in this chapter, one suggestive interview can destroy the reliability of a child’s report, but it may also take several suggestive interviews to move the child from making simple assents to providing some elaboration to the false allegations (see Bruck, Ceci, & Hembrooke, 2002, in which repeated suggestive interviews were associated with more elaborated narratives of false events).

Just as there are risks associated with repeated interviews, there are also risks associated with repeating questions within the same interview. Biased interviewers sometimes repeatedly ask the same question until the child provides a response that is consistent with their hypothesis. Poole and White (1991) found that asking the same question within an interview, especially a yes/no question, often results in young children changing their original answer (see Cassel, Roebers, & Bjorkland, 1996, for similar effects when children are asked repeated leading questions). Furthermore, when children are asked the same question on numerous occasions, they sound increasingly confident about their statements even if these are false.

When questions are repeated within or between interviews, they need not be verbatim to produce deleterious effects. It is the repetition of questions about a specific theme (the suspected perpetrator does bad things) that compromises the reliability of children’s reports. Garven, Wood, Malpass et al. (1998) found that preschoolers provided increasingly inaccurate responses to misleading statements and questions as a suggestive interview proceeded. In this study, children were suggestively interviewed for 5–10 minutes about a stranger who came to read their class a story. As a result of the suggestive devices used by the interviewers, children falsely claimed that the visitor said a bad word, threw a crayon, broke a toy, stole a pen, tore a book and bumped the teacher. Of particular importance, the children came to make more false claims as the interview progressed; that is, within a short, 5–10 minute interview, children made more false claims in the second half than in the first half of the interview.

In summary, if children’s allegations are elicited by specific leading questions that have been repeated within the same interview or across interviews, there is a high risk that the children’s statements will be unreliable. Conversely, children’s answers to open-ended questions asked prior to any suggestive interviewing have a high probability of being accurate.

The following example shows how a child’s denials of abuse become allegations of abuse after repeated specific questions:

Q: What about Dawn, because you had some things to tell me about Dawn as well, didn’t you, eh?
Child: No.
Q: You said there were some silly things about Dawn, eh?
Child: No, that was ages ago when I come here.
Q: But you said that you got touched by Dawn and can you – I just need to know where she touched you. It’s all right.
Child: On my fairy (Note, this is the term children used to refer to their vagina).

In Lillie & Reed, all children had repeated interviews before they made allegations of abuse. Although this analysis focuses mainly on the children’s statements in the videotaped interviews, it is important to note that the children were questioned before these official interviews were recorded. The record shows that children had several to many sessions with parents, friends of parents, relatives and professionals. For example, one mother first suspected that her child had been abused in May 1993. Her child was interviewed at the police station in June 1993 but made no allegations consistent with sexual abuse. Then she was questioned many times over the next 6 months. On December 1, 1993, when she was interviewed for the second time at the police station, she made a few allegations consistent with abuse. Given the denial of wrongdoing in June, followed by an enormous amount of repeated interviewing during the next few months, the few allegations that emerged in December were not “fresh” utterances but may have been contaminated by multiple retellings and questionings.

Atmospherics or Emotional Tone of the Interview

Interviewers can use verbal and non-verbal cues to communicate their bias. These cues can set the emotional tone of the interview. Children are quick to notice the emotional tones in an interview and to act accordingly. For example, in some studies when an accusatory tone is set by the examiner (e.g., “It isn’t good to let people kiss you in the bathtub,” or “Don’t
be afraid to tell”), children are likely to fabricate reports of past events even in cases when they have no memory of any event occurring. In some cases, these fabrications are sexual in nature.

In one such study, children played with an unfamiliar research assistant for 5 minutes while seated across a table from him. Four years later, researchers asked these same children to recall the original experience (Goodman, Batterman-Faunce, Schaal et al., 2002). The researchers created “an atmosphere of accusation,” telling the children that they were to be questioned about an important event and saying things like, “Are you afraid to tell? You’ll feel better once you’ve told.” Although few children had any memory of the original event from 4 years earlier, five out of the fifteen children incorrectly agreed with the interviewer’s suggestive question that they had been hugged or kissed by the confederate, two of the fifteen agreed that they had had their picture taken in the bathroom, and one child agreed that she or he had been given a bath. In other words, children may give inaccurate responses to misleading questions about events for which they have no memory when the interviewer creates an emotional tone of accusation.

In Lillie & Reed, the children were repeatedly told not to be frightened, not to be afraid and that they were brave. In the June 22 interview with Julie, the word “frighten” was used nine times. The following excerpt shows the potentially damaging effect of this strategy, which was repeated by the police investigator (POL), the mother (MOM) and the mother’s friend (FR).

**POL:** I was wondering if maybe Julie was frightened.
**POL:** Do you think she’s frightened to tell me?
**FR:** So that nobody can harm her, can they not, Julie?
**POL:** What of?
**JULIE:** Chris.
**FR:** What for? You’re safe.
**POL:** We’re all there to look after you and there’s nothing for you to be frightened of.
**FR:** So that nobody can harm her, can they not, Julie?

**FR:** What did he do when he was naughty, Julie?
**POL:** I think Julie’s still a little bit frightened but she doesn’t have to be.
**MOM:** What did Chris tell you to be frightened of, Julie?
**JULIE:** Monsters.

**Rewards and Punishment**
Rewards and punishment shape the emotional tone of an interview and provide another means for the interviewer to express bias. The use of rewards and punishments in interviews with children can have beneficial as well as negative consequences. The use of these may motivate children to come to tell the truth. On the other hand, children may learn that if they produce stories that are consistent with the interviewers’ beliefs, they will be rewarded by their interviewers.

The following study conducted by Garven, Wood, and Malpass (2000) illustrates how the use of rewards and punishments in an interview can quickly shape the child’s behavior and have long-lasting consequences. Children between the ages of 5 and 7 years attended a special story time led by a visitor called Paco. During this 20-minute visit, Paco read the children a story, handed out treats and placed a sticker on the child’s back. One week after the visit, the children were asked mundane questions (“Did Paco break a toy?”) and fantastic questions (“Did Paco take you somewhere in an airplane?”). Children in the neutral-no reinforcement condition were simply asked a list of 16 questions and provided with no feedback after each question. Other children, in the reinforcement condition, were asked the same 16 questions, but in addition, they were provided with feedback after each question, as illustrated by the following example:

Interviewer: Did Paco take you somewhere on a helicopter?
Child: No (Note, this is an accurate denial).
Interviewer: You’re not doing good. Did Paco take you to a farm?
Child: Yes (Note, this is an incorrect assent).
Interviewer: Great. You’re doing excellent now. **(The next question is asked.)**

The reinforcement had large negative effects on the accuracy of children’s responses. Children in the reinforcement condition inaccurately assented to 35% of misleading mundane questions and to 52% of the misleading fantastic questions. The comparable rates for the non-reinforcement group were 13% and 15%. In a second interview, a week later, all children were asked the same questions, without any reinforcement. The same high error rates continued for the reinforcement group. When children were challenged and asked in the second interview, “Did you see that or just hear about that?” children in the reinforcement group stated that they had personally observed 25% of the misleading mundane events and 30% of the misleading fantastic events. Children in the non-reinforcement group only made these claims 4% of the time.

These findings show how quickly reinforcing statements can shape children to provide inaccurate responses no matter how bizarre the question. Furthermore, the inaccurate responses persist upon a second questioning, with a number of children claiming that they actually observed the suggested but false event.

Rewards and punishments can take a more explicit form such as promising children a treat if they tell the right answer or threatening the children if they provide an undesirable answer. There is a long history of psychological research that shows the effects of such techniques (Ettinger, Crooks, & Stein, 1994; Zigler & Kanzer, 1962).

There were a number of examples of rewards and punishments being used in the present case. For example:
Interviewer: Well, you tell me now, what did he do? Was he naughty?
Child: I don’t know.
Interviewer: Yes, you do.

Interviewer: What did you have on?
Child: This dress.
Interviewer: No, you didn’t.
Child: I did.
Interviewer: You didn’t have it then. Did you have your clothes on all the time?

MOM: Listen. Come here. Listen, will you talk to me before the interviewer comes back? Sh, sh, sh, sh (trying to quiet child who is moaning). Listen. You’re being very silly aren’t you? You’re being very silly. Can come on. Listen. You know what? Eeh, aren’t you just acting like a baby? You’re a big girl. You’ll not get any juice, mind. Vanessa (the interviewer) will not give you if you start acting like a baby. Listen, I want to talk to you.

Peer Contamination

The effect of telling children that their friends have “already told” is a much less investigated area in the field of forensic developmental psychology. Certainly, the common wisdom is that a child will go along with a peer group. But will a child provide an inaccurate response just so he or she can be one of the crowd? Can simply discussing information between children affect their answers? The most recent and most relevant studies in the literature suggest that the answer is “yes” (Principe & Ceci, 2002; Principe, Kanaya, Ceci et al., 2006).

Preschools in groups ranging in size from 6 to 8 took part in a contrived “dig” with a fictitious archeologist named Dr. Diggs (Principe & Ceci, 2002). Dr. Diggs led the children through an event in which they used plastic hammers to dig pretend artifacts (e.g., dinosaur bones, gold coins). Dr. Diggs also showed the children two special artifacts: a map to a buried treasure and a rock with a secret message. The children were warned not to touch these because they could be ruined. All children in the study participated in or viewed these core events. However, one-third of the children also saw Dr. Diggs ruin the two special artifacts (hereafter referred to as the target activities) and show upset about their loss. A second third of the children were the classmates of those in the first group but did not witness the target activities. The remaining children were not the classmates of those who witnessed the target activities, nor did they witness the target activities themselves; they thus served to provide a baseline against which to assess the effects of peer contact. Following the dig, the children were interviewed in either a neutral or a suggestive manner on three occasions. The suggestive interviews for children who did not view Dr. Diggs ruining the special artifacts provided children with this information. Children in the neutral interview were not given information about the two target events. In a later interview, children were asked questions about the dig. Children who had not reported the two absent special activities were prompted to disclose more by the interviewer’s telling them that their friends had already told.

Children who were classmates of those who saw Dr. Diggs ruining the two artifacts were more likely to claim that they had viewed the target activities (i.e., they incorporated the misinformation from the previous interview) than children who did not view the special activities and were in another classroom. These data suggest that there was contamination from classroom interactions; children who had not experienced the target events learned of them from their classmates and thus were more likely to assent to false events. Finally, telling children that their friends had told increased their false assent rate.

Principe et al. (2006) conducted another study in which they found that children who overheard a child talking were as likely to falsely claim to have seen the event in question (a rabbit that escaped from a magician) as were peers who actually saw it escape. Moreover, in this study, the effect of suggestive questioning did not notably increase their false reports; children were as likely to report falsely if they overheard peers talking about the rabbit, regardless of whether interviewers employed suggestive questions.

In Lillie & Reed, children often had the opportunity to talk with each other throughout the investigation. Further, they were told that their friends had come and talked about “silly things”:

Interviewer: You know your friends that you played with at nursery school? I’ve been talking to them. They were telling me about some silly things that happened at the nursery. Do you know about them things? . . .

Child: Don’t know that.
Interviewer: Shall I help you a bit? They were telling me about their teachers, when they were in your class?

After the accusations of abuse, teachers in the daycare facility kept “disclosure logs” to record children’s statements about abuse. Some of the examples show how children talked among themselves about abusive subjects in what seemed to be a very playful atmosphere.

Child 1: They had real snakes, they went SSS, they were toys in the cage outside.
Child 2: I saw the snakes and cage, but I ran up the steps, the snakes are called _____ the same as me. (Note, this is the first time Child 2 mentions snakes).
Child 2: And do you know what? Chris and Dawn kicked me.
Child 3: Why did they kick you?
Child 2: Cos they thought I was a pirate lady.
Child 1: And they slapped me cos they thought I was a doggy.

(Both Child 1 and Child 2 laugh and begin to jump on a piece of equipment.)

It appears that the first allegations of Child 2 and Child 3 may have emerged from these sessions.

Summary

We have provided examples of only some of the suggestive techniques used in Lillie & Reed (for more details see http://
CHAPTER 7

www.richardwebster.net/cleared.html; http://www.hmcourts-service.gov.uk/judgmentsfiles/j1302/lillie_reed_part_1.htm. Although one can never know whether or not the children were actually abused, the materials clearly show that all children were subjected to an array of suggestive interviewing techniques. As documented in the scientific literature, these techniques can destroy the accuracy of children’s reports, and they can bring children to believe the suggestions themselves.

Going Beyond Suggestive Interviewing in Lillie & Reed
We presented the Lillie & Reed case to demonstrate how the scientific literature on the reliability of children’s statements addresses a variety of important issues that this and other cases raise. In this section, we address some misconceptions that have arisen and that need correcting.

Misconception 1: Suggestibility studies show that children can only be led to make false reports about unemotional, unimportant events This is incorrect. Suggestive techniques result in a wide range of false allegations. Although for ethical reasons there has never been a study in which researchers explicitly attempted to suggest to children that they were abused, nevertheless, there have been a number of studies in which children have been led to make false allegations about bodily events which, were they to occur in the real world, would cause a great deal of concern and further investigation. In research studies, children have made false claims about “silly events” that involved body contact (e.g., “Did the nurse lick your knee?” “Did she blow in your ear?”), and these false claims persisted in repeated interviewing over a 3-month period (Ornstein, Gordon, & Larus, 1992). Children falsely reported that a man put something “yuckie” in their mouth (Poole & Lindsay, 2001). Preschoolers falsely alleged that their pediatrician had inserted a finger or a stick into their genitals (Bruck, Ceci, Francoeur et al., 1995), or that some man touched their friends, kissed their friends on the lips and removed some of the children’s clothes (Lepore & Sesco, 1994). A significant number of children falsely reported that someone touched their private parts, kissed them and hugged them (Goodman, Rudy, Bottoms et al., 1990; Goodman, Bottoms, Schwartz-Kenney et al., 1991; Bruck, Melnyk, & Ceci, 2000). Children assented to suggestions that a doctor had cut out a bone in the center of a child’s nose to stop the child from bleeding (Quas, Goodman, Bidrose et al., 1999). Children have also elaborated their false narratives with emotional terms (e.g., “It hurt”; “I cried”; “I was happy”; Bruck et al., 1995; Bruck, Ceci, Hembrooke, 2002). Thus, the suggestibility literature is a valid basis for evaluating the possibility that suggestive interviewing can result in false allegations about emotionally evocative events which may include bodily harm.

Misconception 2: The problem with suggestive interviews concerns young children; older children are immune to these techniques This is not the case. Suggestive techniques used in the studies with young children also produce tainted reports or false memories in older children, adolescents and adults (Lofus, 2003). The same principles hold across a wide variety of ages. For example, Porter, Yuille, & Lehman (1999) asked parents of college students about six categories of negative emotional events (serious medical procedures, serious animal attacks, getting seriously hurt with another child, serious indoor or outdoor accidents, and getting lost) that may have happened to their children between the ages of 4 and 10 years. Next, the college students were interviewed about one of the events that the parents said had occurred when they were children and one event that had not occurred. Over three interviews, the interviewers tried to implant a memory of the false event, instructing the subjects to engage in daily recall to try to imagine themselves in the event. Overall, 26% of participants created complete memories for the false emotional events. Another 30% provided some details of the false events, but did not produce a full narrative. Thus, a total of 56% of the college students felt that they had experienced an event that, according to their parents, had never happened.

By inference, one might assume that children in middle childhood must also be quite suggestive, given that both younger and older groups are. Recent evidence supports this view; susceptibility to suggestion is highly common in middle childhood, and under some conditions there are small to no developmental differences in suggestibility. For example, Finnila, Mahilberga, Santtilaa et al. (2003) staged an event (a version of the Paco visit we described earlier) for 4- to 5-year-olds and 7- to 8-year-olds. One week later, half the children were given a low-pressure interview that contained some misleading questions with abuse themes (e.g., “He took your clothes off, didn’t he?”). The other children received a high-pressure interview; they were told that their friends had answered the leading questions affirmatively, they were praised for assenting to the misleading questions, and when they did not assent, the question was repeated. In both conditions, there were no significant age differences in the percentage of misleading questions answered affirmatively, although a significant number (68%) were assented to in the high-pressure condition (see also Bruck, London, Landa et al., 2007). Older children are quick to notice the emotional tones in an interview (which convey bias), and to act accordingly. For example, the Goodman et al. (2002) study described above found that children 7–10 years of age falsely assented to misleading questions that involved inappropriate touching activities.

Conclusions

When the first high-profile child sexual abuse cases emerged more than two decades ago, the scientific community had little to say about children’s susceptibility to suggestive interviewing techniques. Since then, we have discovered compelling empirical evidence that children can come to falsely report events that did not happen, and may even come to report events that are sexually themed. To compound the problem, once a child has been subjected to suggestive techniques, his or
her erroneous reports are often indistinguishable from accurate reports. False reports that emerge in response to suggestive interviewing are often stylistically indistinguishable from true narratives. For example, they cannot be distinguished on the basis of linguistic markers, temporal terms or narrative coherence. Even trained experts in the field cannot, on the basis of their reports, identify which children have been suggestively interviewed (Bruck, Ceci, & Principe, 2006). In summary, there are no scientifically acceptable markers for judging the accuracy of a child’s statement after exposure to suggestive interviews.

There has been a substantial research effort to develop standardized interview protocols that, if used appropriately, help interviewers avoid suggestive techniques. One such protocol was developed by Lamb, Sternberg, and Esplin (1998; see also Memorandum of Good Practice, 1992). The protocol requires trained interviewers to encourage suspected child abuse victims to provide detailed life event narratives through the guidance of open-ended questions (e.g., “Tell me what happened”; “You said there was a man; tell me about the man”).

The use of specific questions is allowed only after exhaustive free recall. Suggestive questions are highly discouraged. These types of practices prevent interviewers not only from using suggestive techniques but, most importantly, from adopting a specific bias of wrongdoing.

Throughout this chapter we have focused on issues that primarily arise during investigations involving child witnesses. However, the issues we have covered apply to all adults who interact with children and who rely on children’s reports as a primary source of information in making decisions or recommendations. This includes child and adolescent psychiatrists, who are not immune to the potential problems of interview bias (e.g., having a high suspicion that the child has an anxiety disorder and failing to rule out other explanations for the child’s behavior) or of using suggestive interviewing techniques (e.g., repeating questions, asking leading questions, rewarding specific statements). In summary, individuals who are charged with the task of interviewing or evaluating children should be especially fastidious in their use of leading questioning and other suggestive techniques. Interviewers should do their utmost to be aware of and minimize their own biases and should be willing to consider alternative theories when questioning children.

CHAPTER 7

Any child with mental health problems is likely to encounter a variety of professionals and agencies. Each of these has their own role, responsibilities and perspective. At their best, this can lead to fruitful cooperation in the best interests of the child. At their worst, this can lead to failures in communication, failure to take responsibility, failure to “own” the problem; in short to failure of the child. Every professional involved with the child has first to ask themselves what sort of a problem it is and which service or services will be best equipped to help solve it. If legal measures may also be required, a further question is whether these should be directed primarily towards the child or the child’s family. We first sketch the legal position of the various agencies and professionals, and consider the role of expert witnesses, then look at the legal position of the child’s family, and finally at the legal position of the children themselves. We use examples from the UK but attempt to draw out principles that hold across other judicial systems.

Different Services – Different Perspectives

Education

Education is the one universal service, free to every child of compulsory school age, irrespective of learning disability, mental illness or emotional and behavioral disorders. Indeed, education is the one right specific to childhood that is spelled out in the European Convention on Human Rights: “No-one shall be denied the right to education.” Europe assumes that each member state offers an education service but does not lay down any particular standard. Children are entitled to be provided with the education offered by the educational system in their own country. If for whatever reason that educational system is inadequate to meet their special needs, they may have little recourse under the European Convention. The United Nations Convention on the Rights of the Child (UNCRC) is more specific but creates no rights enforceable in UK law because it has never been made part of domestic law.

The aspiration now is that as many children as possible will be educated in mainstream schools with special help if necessary. If a school encounters problems with a child with mental health difficulties, a great deal will depend upon whether teachers define the problem as a pedagogical or a disciplinary issue (see chapter 74). If it is defined as a pedagogical problem, the solution may eventually lie in the complex process of assessing and providing the child with a statement of his or her special educational needs, which the authorities will then be under a duty to meet. The legal duties attaching to educational provision are unlike those relating to health and social care because the parents of children with special educational needs have defined rights to be involved in the decision-making process and to challenge the authorities’ decisions in the special educational needs and disability tribunal (SENDIST). Unlike other tribunals in the field of health and social care, SENDIST has the power to order the authorities to provide the education that it decides the child needs.

However, if the school instead classifies the child as having a disciplinary problem, the solution may be very different. It will lie in an escalating scale of formal disciplinary measures including temporary or permanent exclusion. These may solve the school’s immediate problems, but will do nothing to meet the long-term educational and mental health needs of the child. The children’s services authority has the duty to provide an education for excluded children, but this will

1 Education Act 1996, s 14.
2 Protocol 1, article 2.
3 The European jurisprudence is discussed in Ali v. Lord Grey School [2006] UKHL 14; [2006] 2 WLR 690; a boy who had been kept out of school when he should have been allowed back, thus losing months of his education, had no remedy because his parents had failed to take up alternatives. Nevertheless, a pupil will have a remedy if he is denied access to a minimum level of education: per Lord Hoffmann, at para 59.
4 See article 28; the minimum is free compulsory primary education for all.
5 Education Act 1996, s 316. These provisions date back to Warnock (1978).
rarely meet the standards of mainstream schools, and will carry its own stigma and disadvantage. The child and his or her parents may challenge the exclusion, but here the focus is more like that in a criminal trial: was the child guilty of the conduct complained of and did the punishment fit the crime? Only indirectly will the disciplinary process be concerned with whether the school was meeting the child’s needs.

The other side of the coin is that parents have an obligation to ensure that their children receive an education suitable to their age, ability, aptitude and any special educational needs they may have. If a child is not going to school, the children’s services authority may either prosecute the parents or take action in respect of the child. Recent well-publicized prosecutions suggest that they are increasingly insisting that parents take their responsibilities seriously. However, if the child rather than the family is seen as the origin of the problem (as discussed in chapter 35), the children’s services authority have few effective remedies for truancy or school refusal. In England and Wales, what used to be called the “status offences” of childhood have been abolished: being beyond parental control or in moral danger, falling into bad associations, or persistently failing to go to school are no longer possible. The Criminal Justice System in England and Wales, on the other hand, sees children of 10 years or over as sufficiently mature to be held fully responsible for their criminal behavior. This age is controversially low (Commission on Families and the Wellbeing of Children, 2005; Royal College of Psychiatrists, 2006). In Scotland, the age of criminal responsibility is set even lower, at 8 years, but children who plead or are found guilty are dealt with in the more child-friendly children’s hearings rather than in court (McDiarmid, 2005; Scottish Law Commission, 2001). The criminal justice system aims to deter, punish and reform. The rules of the criminal law are the same for adults and children. The differences lie in the court procedures and the sentences available. In the 1970s and into the 1980s, the emphasis of the juvenile justice system was on prevention and reform (Home Office, 1965, 1968). Much of the responsibility for tackling juvenile offenders was passed to the social services authorities (now children’s services authorities), who followed a welfare rather than a punishment model (Parsloe, 1978). The longer children could be kept out of the penal system the better. That way the system could do them no harm and they would eventually grow out of their offending behavior. By the 1990s, children were being cautioned time and time again and hardly ever brought to court. This gave the impression that they could break the law with complete impunity unless they did something really serious or became involved with an older gang. The legislative pendulum soon swung sharply back towards punishment and deterrence (Home Office, 1998). Greater efforts are also being made to get parents to take responsibility for their children’s misbehavior.

The Criminal Justice System
The one net that children are less and less likely to avoid is the criminal justice system. Civil law recognizes that children are not yet sufficiently mature to play a full part in civil society. The criminal justice system in England and Wales, on the other hand, sees children of 10 years or over as sufficiently mature to be held fully responsible for their criminal behavior.

8 Education Act 1996, s 19.
9 Education Act 1996, ss 7, backed up by the offences in ss 443–444B.
10 The penalties for a parent who knows that a child is not going to school and fails without reasonable cause to make him or her attend were increased in 2002 to include imprisonment: see Education Act 1976, s 444. Fixed penalty notices against any parent whose child fails to attend school regularly were introduced in 2004: see Education Act, 1996, s 444A.
11 Children Act 1989, s 31, replacing Children and Young Persons Act 1969, s 1. For a discussion of the history of these provisions, see Dingwall, Eekelaar & Murray (1983).
12 The common law presumption that a child of 10–13 years inclusive was doli incapax until the prosecution proved that he knew what he was doing was seriously wrong was abolished by the Crime and Disorder Act 1998, s 34.
14 Binding parents over to take proper care and exercise proper control over their children (now under the Powers of Criminal Courts [Sentencing] Act 2000, s 150) and ordering them to pay their children’s fines have a long history; but parenting orders, requiring them to attend counseling or guidance programs, were introduced by the Crime and Disorder Act 1998, ss 8–10, and parenting contracts by the Anti-Social Behaviour Act 2003, s 25.
16 A reprimand is given for a first offence, a final warning for the second. The third must be charged and prosecuted, irrespective of its triviality.
18 In 2005, 10,588 ASBOs were issued to persons aged 10–17 years, compared with 185 in 2001.
Once taken to court, the range of sentences available for juveniles is still different from those available for adults, but an offender is likely to climb the ladder from the less to the more serious disposals more quickly than he or she did before. This is one reason for the sharp rise in the numbers of children detained in secure institutions run by the penal rather than the children’s services authorities.\(^{19}\) Indeed, the UK locks up more young people under 18 than most other European countries (NACRO, 2003), not a record of which the UK can be proud. The UN Committee on the Rights of the Child has expressed its deep concern over “the increasing number of children who are being detained in custody at earlier ages for lesser offences and for longer sentences” (UN Committee on the Rights of the Child, 2002). These large numbers of young and juvenile detainees were also criticized more recently by the Council of Europe’s Commissioner for Human Rights (Gil-Robles, 2005). Child offenders are even more likely than adults to have mental health problems, but there are far fewer resources available to meet those needs in penal establishments (young offender institutions) than there are in the local authority secure children’s homes, to which a minority are sent. Although specialist mental health services in the local authority institutions are far from ideal (Kroll, Rothwell, Bradley et al., 2002), those in young offender institutions are often very poor (Harrington & Bailey, 2005).

Whichever way the pendulum swings, it is universally recognized that child offenders merit a different approach from adults. The UNCRC requires member states to promote measures for dealing with children outside court and to provide a variety of dispositions “to ensure that children are dealt with in a manner appropriate to their well being and proportionate both to their circumstances and the offence.”\(^{20}\) While the system no longer thinks that the whole problem, and therefore the whole solution, lies with the family rather than the child, there may be other steps that could be taken to bring home some of the responsibility to the parents. Some would like to see the link with the child care system restored at least so as to enable the criminal court to require the children’s services authority to investigate and decide whether social rather than penal action would be more appropriate (Butler-Sloss, 2003).

**Children’s Services**

In England and Wales, the children’s social care section of the local children’s services authority has both the duty and the power to take steps to protect a child from significant harm. Unlike some other countries, other services and professionals have no mandatory duty to report cases of suspected child abuse and neglect to them. In practice, however, failure to report may be less of a problem than failure to recognize abuse when it occurs.\(^{21}\) An even greater challenge may be to persuade children’s social care services to take action when others think they should.

Child protection is only one of a range of social care services provided for “children in need.”\(^{22}\) In keeping with the family-centered philosophies of both the European Convention on Human Rights and UNCRC (see p. 99), it is the duty of the children’s services authorities to “promote the upbringing of such children by their families.”\(^{23}\) These are target duties owed to the particular client group, rather than enforceable duties owed towards particular children or their families.\(^{24}\) There is no statutory procedure, like the process of “statementing” a child with special educational needs, for identifying a child’s social needs and ensuring that these are met. Those who are lucky enough to be advised by a knowledgeable lawyer may apply for a judicial review of a refusal to provide support services. This is concerned with the legality of a particular administrative decision but not its merits. It is not for the courts to take the tough decisions about the allocation of scarce resources which Parliament has entrusted to the providers of both health and social services. The courts can only ensure that service providers act within the law. This includes acting rationally and fairly. Authorities are allowed to take resources into account, but they may have to explain why they are offering a service to one person but not to another.

Nevertheless, children’s services authorities do owe some duties to the individual child. Reports of suspected abuse or neglect must be investigated and action taken where necessary to protect the child (see chapters 28 & 29). Before the Human Rights Act 1998, it was held that children’s social services could not be held liable either for negligently failing to protect a child or for negligently taking action to remove or keep a child away from home.\(^{25}\) The European Convention, however, brings positive as well as negative obligations. There is the negative obligation to refrain from unjustified interference with the right to respect for family life, but also the positive obligation to protect a child from death or serious ill-treatment. In the light of these, courts have now held that the authorities do owe duties of care towards the child.\(^{26}\)

Social care workers should therefore conduct a comprehensive assessment of the child and his or her family. Their focus will inevitably be upon the interaction between children and their families, because any compulsory intervention that they promote will operate to interfere in the legal relationship between child and family (see p. 101). They are bound, therefore, to assess the extent to which the child’s problems are the product of his or her home environment. Of course, they

CHAPTER 8

will have to rely upon the specialist mental health services if specialist assessment is necessary at the outset and for any future treatment of the child.

Mental Health Services

The only role of the child, adolescent and family mental health services is to provide a specialist service for the child and his or her family. Unlike both the education and social care sections of children’s services authorities, they have virtually no coercive powers to back up the service they wish to offer, and can rarely be obliged to offer a service that they do not wish to offer. There are a few cases where compulsory intervention under the Mental Health Act 1983, may be necessary and appropriate (see p. 107). There are also a few cases where a hospital wishes to take a particular course of action which is opposed by either the child or the family. In England and Wales, an NHS Trust could invoke the inherent jurisdiction of the High Court37 or apply for a “specific issue” about the child’s upbringing to be decided.28 The most obvious examples involve the treatment of anorexic teenagers or giving blood transfusions to the children of Jehovah’s witnesses.29 In most cases where the relationship between the professionals and the family of a child with mental health problems breaks down, such one-off determinations are unlikely to provide a long-term solution. If the professionals think that legal proceedings should be taken against either the child or the family, they will have to refer the case for the children’s services authority to take action. Children’s services will then be “in the driving seat,” although assessment and treatment should be a multidisciplinary endeavor.

Nor can health professionals be obliged to offer a service that they do not wish to offer. Like all professionals, they owe a duty of care to their own patients. If they negligently fail to diagnose or to treat, and the patient suffers harm as a result, they may be held liable in damages. The most obvious examples are a child psychologist who fails to diagnose dyslexia or a child psychiatrist who negligently diagnoses child abuse.30 The courts have interpreted the scope of their legal duty, so that it is owed only to their child patient and not to the child’s parents. The courts in the UK and elsewhere have been well aware that if professionals also owed a duty to the parents, they might hesitate to diagnose abuse and the child would go unprotected.31 That aside, parents have sometimes tried to use wardship or judicial review to oblige health authorities, hospitals or individual doctors to provide treatment that they do not wish to provide. Thus far, while the courts have been prepared to reassure the authorities in advance that a course of action that they do wish to pursue will be lawful,32 they have not been prepared to order the medical authorities to provide treatment for an individual patient that they consider will be futile or counterproductive.33 The Human Rights Act has not altered these fundamental principles.34

The main role of a mental health professional in legal proceedings is therefore not as claimant or defendant, applicant or respondent, but as an expert witness in cases brought by others. Before examining the principles of law applying to those cases, it may be helpful to examine the role of the expert witness.

Role of the Expert Witness

Expert medical witnesses fall into two broad categories. Psychiatrists and other professionals who are already working with the child and his or her family may be asked to report on the history, diagnosis and treatment to date, together with their assessment and recommendations for the future. As expert witnesses, they are entitled to offer their professional opinions as well as their factual accounts. No doubt they will bring the independence expected of any professional to that task. This should include a willingness to acknowledge that medical records are not always perfectly accurate or complete and may from time to time repeat or rely upon unverified hearsay.35 But they are essentially witnesses of fact and the child is their patient.

They have a different role in the proceedings from that of an independent expert who has been commissioned to make a report and recommendations to the court.36 An independent expert may be commissioned by any of the parties to the case, but the court is firmly in charge of whether and how many experts may be instructed and in which disciplines.37 In

---

27 Better known as the wardship or parens patriae jurisdiction derived from the Crown’s guardianship over all minor children, but can be invoked for a single issue without making the child a ward of court.

28 Children Act 1989, s 8(1).

29 A standard form of order has now been developed. This requires that every effort is made to avoid giving a blood transfusion, but that if there is no alternative, it may be done. Parents are generally advised not to consent, but not actively to oppose such orders.

32 Extending the effect of the wardship jurisdiction over children to mentally disabled adults, principally to authorize the non-therapeutic sterilization of mentally disabled women and girls or the withdrawal of artificial nutrition and hydration from patients in a persistent vegetative state: see B (A Minor) (Wardship: Sterilization) [1988] AC 199; Re F (Mental Patient: Sterilization) [1990] 2 AC 1; Airedale NHS Trust v. Bland [1993] AC 789; R (on the application of Burke) v. General Medical Council [2003] EWCA Civ 1003.

34 Summed up in R (on the application of Burke) v. General Medical Council [2006] QB 273, para 50.

35 This concern has led some to argue that the standard of proof of the continuing conditions for detention in mental health review tribunals should be higher than the usual balance of probabilities.

37 This is provided for both in the Family Proceedings Rules 1991, rule 4.18 and the ordinary Civil Procedure Rules 1998, rule 35.4.
child protection proceedings, following the Cleveland Inquiry Report (Butler-Sloss, 1988), the object is now to prevent the child being subjected to multiple examinations and assessments. The court’s expectations of an expert in child protection proceedings are laid down in the Code of Guidance for Expert Witnesses in Family Proceedings. The expert’s overriding duty is to the court and takes precedence over any duty to the party who has instructed them (see chapter 4). The court always hopes that the experts will be able to clarify, narrow and if possible agree upon the issues in the case. The common practice is for a single expert to be jointly instructed by all parties, usually led by the children’s guardian who is appointed by the court to act for the child in the proceedings. An assessment carried out by a jointly instructed expert is not without problems. The family may be very happy to agree with the proposed assessment before they know the result, but if they are unhappy with the result, they may want a second, third or fourth opinion. The courts try hard to resist this “expert shopping.” Parents or children who have serious concerns about the accuracy or rigor of a report will face formidable difficulties if they try to challenge it without expert evidence of their own. It is no simple task to reconcile the need of the child to be spared endless and intrusive investigations with the right of both child and family to a fair trial of the issues. The lack of contradiction or opposition places a heightened duty of independent professionalism upon the expert witness and of vigilance upon the court. Issues upon which there is proper room for professional disagreement should be identified at the outset, so that two experts can be appointed without adding to the delays. Expert witnesses enjoy the same immunity from suit in respect of their evidence as any other witness, but this does not include immunity from professional discipline.

Another problem is that child protection law in England and Wales draws a clear distinction between an assessment of the child, which is within the court’s power to direct, and what, in truth, amounts to treatment of the parents, which is not. This distinction does not always reflect the realities of psychiatric practice, particularly in some of the most complex and difficult cases. It is not possible to separate the assessment of the child from the assessment of the parents. What requires assessment is the relationship between them and the capacities of the parents to meet the needs of the child. Moreover, what begins as assessment may move into assessment with therapy and move again into therapy with continuing assessment. As Dr. Kennedy of the Cassel Hospital has forcefully argued (Kennedy, 2001), doctors are assessing their patients all the time. Nice legal distinctions mean nothing to them.

None of this would matter were it not for the problems in funding the very specialist resources that some of these deeply damaged families require. The court can only require the parties – whether the local children’s services authority or the legal services commission that is funding both the child’s and the parents’ representation – to pay for an assessment which is necessary to enable the court to perform its own function. The court’s function is only to decide what order, if any, to make about the child’s future. The court has no power to order either the local children’s services authority or the health services to provide any particular form of treatment for the child or their family (see p. 101).

Families and Their Children

The Family and the State

The legal status of children as minors, let alone their physical and financial dependency, means that they are different from adults in two respects. First, they have claims upon other people that adults do not have: claims to be nurtured, cared for and brought up to play their full part in adult society. Second, the people with the responsibility of meeting those claims have both the right and the responsibility to make decisions on behalf of their children. As we shall see in the next section, these do not stay static throughout childhood: the claims change and the child’s own autonomy grows. In some respects, a child remains a child until he or she reaches adulthood, in England and Wales at the age of 18. It is a cardinal feature of western democratic legal systems that parents and families, rather than the state, have the primary right and the primary responsibility to bring up their children: to meet their claims for nurture, care and upbringing and to decide for themselves how this will be done. “It is important in a free society to maintain the rich diversity of lifestyles which is secured by permitting families a large measure of autonomy in the way in which they bring up their children.” (DHSS, 1985, para 2.13) It is the hallmark of a dictatorship to gain control of the children and distance them from the varied and subversive influences of their families (Hale, 2005a). This is why the European Convention on Human Rights, drafted in 1950 in the twin shadows of the Nazi totalitarianism of the recent past and the Stalinist totalitarianism of the then present, guarantees to everyone – parents and children alike – the right to respect for their private and family life, their home and their correspondence. The UNCRC also requires states to recognize that, “Parents or, as the case may be, legal guardians, have the primary responsibility for the upbringing and development of the child. The best interests of the child will be their basic concern.”

Historically, English common law placed this legal responsibility upon the fathers of children born to married parents and (eventually) upon the mothers of children born to unmarried parents – whether the local children’s services authority or the legal services commission that is funding both the child’s and the parents’ representation – to pay for an assessment which is necessary to enable the court to perform its own function. The court’s function is only to decide what order, if any, to make about the child’s future. The court has no power to order either the local children’s services authority or the health services to provide any particular form of treatment for the child or their family (see p. 101).

39 This will usually be a Children and Family Court Advisory and Support Service (hereafter CAFCASS) officer.
40 Protected by article 6 of ECHR as well as common law.

Legal issues
parents. The position now is that if the parents are or have
been married to one another at any time since the child’s con-
ception they are both legally responsible for his or her upbring-
ing – they alone are deemed to have “parental responsibility”
for the child.46 If they are not married, the default position
is that the mother alone has parental responsibility; but the
father may acquire it, either by agreement with the mother,
or by court order or, since December 1, 2003, simply by being
registered as the father on the child’s birth certificate.47
The state’s role is to supplement and enable the parents’ role.
UNCRC requires state parties to render all parents “appro-
priate assistance . . . in the performance of their child-rearing
responsibilities and shall ensure the development of institutions,
facilities and services for the care of children.”48 State parties
also recognize “the right of the child to the enjoyment of the
highest attainable standard of health and to facilities for the
treatment of illness and rehabilitation of health”49 and “that
a mentally or physically disabled child should enjoy a full
and decent life, in conditions which ensure dignity, promote
self-reliance and facilitate the child’s active participation in the
community.”50 All but two of the members of the UN have
ratified this Convention.51 Some who have ratified the Con-
vention are relatively poor developing countries for whom these
rights can only be aspirational. In the UK, they are not, or
should not be, mere pious aspirations.

Intervening in Family Life
What are the professionals to do if they disagree with the child’s
parents about what the child needs? Everyone hopes that it
will never come to this. Every effort will be made to persuade
the parents to agree. If they do not, most legal systems pre-
sent two possible ways of overcoming their objections.

The earliest was the threat of prosecution for child neglect
or abuse. In English law, it is an offence for a person over
the age of 16 who is responsible42 for a person below that
age, wilfully to assault, ill-treat, neglect, abandon or expose
that child in a manner likely to cause unnecessary suffering
or injury to health.53 This entails positive obligations on the
part of a parent (or other person legally liable to maintain the
child): he or she is presumed to have neglected the child in
such a manner if he or she fails to provide the child with
adequate food, clothing, shelter or medical aid.44 In English
law, the fact that a parent has religious or conscientious
objections to medical treatment is not a defense,55 but failure
to appreciate the risks could be.56

Some legal systems may be reluctant to go beyond the threat
of prosecution to secure parental compliance, but this will not
help the child unless the threat is effective. It is least likely to
be effective against inadequate parents who simply do not
appreciate the risks. What are the professionals to do if the
parents refuse their advice? It should not be forgotten that we
are talking here of the child’s rights, on the one hand to appro-
priate health care and on the other hand the child’s right to
decide what should happen to his or her own body (see p.
103). In English law at least, we are not talking about the
parents’ right to sue for harm done to them by the unau-
thorized treatment of their child. They have no right to sue
for damages on their own account.57 They could only sue on
behalf of their child for the harm done to him or her by the
unauthorized invasion of the child’s own bodily integrity.

The person actually looking after the child (including a health
care facility) is sometimes entitled to act without taking the
matter to court. A somewhat neglected provision of the
Children Act 1989,58 states the obvious: “A person who (a)
does not have parental responsibility for a particular child;
but (b) has care of the child, may (subject to the provisions
of this Act) do what is reasonable in all the circumstances
of the case for the purpose of safeguarding and promoting the
child’s welfare.” This is clearly enough to authorize a non-
parent to provide the child with day-to-day care and also
treatment in an emergency or which it is unreasonable to
delay until the parents can be consulted. In some cases, dis-
cussed in detail below, the child may be competent to consent
to his or her own treatment even if the parents object. For
one-off treatments, the hospital or doctors might apply for
a specific issue order authorizing the treatment in the child’s
best interests.

Children with mental health problems or learning difficul-
ties are likely to present more long-term and complex problems.
The family environment and dynamics may be an impor-
tant part of the child’s problems. The legal system provides
machinery to enable the professionals to step in and provide
the care and treatment which they believe that the child needs
even if the parents resist this. Because of the principles of
parental responsibility and respect for family life, there are two
basic requirements, one procedural and one substantive.

46 Children Act 1989, s 2(1).
47 Children Act 1989, ss 2(2) and 4, as amended by the Adoption
and Children Act 2002, s 111. 83.2% of births outside marriage were
jointly registered by both parents in 2004. The father is liable to
support the child even if he does not have parental responsibility.
48 Article 18.2.
49 Article 24.1.
50 Article 23.1.
51 The exceptions are Somalia, which has said that it will do so when
it has a functioning government; and the USA, which objects to some
of the Convention’s principles.
52 This includes having formal parental responsibility or actual care:
Children and Young Persons Act 1993, s 17.
53 Children and Young Persons Act 1933, s 1(1).
54 Children and Young Persons Act 1993, s 1(2)(a).
55 R v Senior [1899] 1 QB 283.
57 The parent’s right to claim against third parties who injured his
child was abolished by the Law Reform (Miscellaneous Provisions)
Act 1970.
58 s 3(5). Indeed, in the light of ss 1(1) and 17 of the Children and
Young Persons Act 1993, it could be argued that this should have
imposed a positive duty to act where the child would otherwise be
caued unnecessary suffering or injury to health.
The procedural requirement is that action can only be taken with the authority of a court order obtained by due process of law. In England and Wales, responsibility for undertaking proceedings to intervene compulsorily in family life lies, not with the health authorities, but with the children’s social care departments of local children’s services authorities. These are the public bodies charged with the overall responsibility of protecting children from harm. This is because the eventual outcome of most care proceedings is that the authority will have to take parental responsibility for the child. Care by a local authority may not be ideal, but at least the child should thereby have, or have access to, the full range of facilities needed to discharge those responsibilities, including the health and education services. Neither the health nor the education services are equipped to cater for everything that parents should provide for their children, nor can they find alternative families for children who need them.

The substantive requirement is that, although the welfare of the child is the paramount consideration, it must first be shown that the child is suffering or likely to suffer significant harm. Harm is so widely defined that it is very likely that a child with mental health problems whose health or educational needs are not being met will be suffering or likely to suffer significant harm. That is not the end of the matter. It must also be shown that this is attributable to a lack of reasonable parental care, whether because the parent cannot or will not provide it, rather than to the failure of the services themselves to deliver what the child needs. Only once the harm threshold has been crossed can the court decide what will be best for the child. This includes deciding whether making an order will be better for the child than not doing so.

This puts the court in a quandary. Only by looking into the future can it decide what will be best for the child. It must therefore be shown a plausible care plan for the child and have some confidence that it will be carried out. Unless there is some other individual able to take responsibility for the child, the court can only choose between a care order, a supervision order or no order at all. While a care order places the child in the care of the designated local authority, with parental responsibility being vested in that authority, a supervision order merely places the child under the local authority’s supervision, with the parents’ own legal role being unaffected. Despite the apparent strength of a care order, the court has no power to impose conditions on it or to insist that the local authority discharge their parental responsibilities in a particular way. This can be another source of frustration for health-care professionals whose recommendations for treatment are not always adopted by the local authority looking after the child. Some look back nostalgically to the days of the old wardship system, when, theoretically at least, the court could direct how the child was to be cared for and review the case at regular intervals. However, the reality was often very different. Courts have neither the resources nor the expertise to act as substitute parents for children.

In most cases, the court has no choice, because the risk of leaving the child at home is now too great. The real choice is between planning to reunite children with their families and planning to place them with permanent alternative families. This raises an even greater dilemma. If the authorities intervene early, before a child suffers permanent harm, the more likely it is that he or she can be successfully placed for adoption with a new family. The later things are left, the more harm is done, and the more difficult it will be to repair the damage successfully. The dilemma is particularly acute with emotional neglect and abuse, which may take many years to result in significant harm to the child (see chapter 28). Can such early intervention be justified in human rights terms?

**Influence of Human Rights Law on Child Care Law**

The European Convention prohibits any interference by a public authority with the right to respect for family life unless three conditions are fulfilled. First, the intervention must be in accordance with the law; it must comply with a national law that is sufficiently clear and certain for people to be able to conduct themselves accordingly. Second, it must be for a legitimate aim; in this case, for the protection of the rights and freedoms of the child. Third, and most important, it must be "necessary in a democratic society"; the means used must be proportionate to the legitimate aim pursued and the reasons given must be relevant and sufficient. The jurisprudence of the European Court of Human Rights in Strasbourg is consistent. The aim of any public authority removing a child from home must generally be to reunite the family; permanent removal requires exceptional justification in the interests of the child. The reasons for cutting off children from their families of birth will be scrutinized with much more care than the reasons for initially removing them from home.

UK courts are conscious that their task is to ensure that compulsory intervention in family life is no more than is necessary to achieve its aim of protecting the child from harm.
significant harm in the particular circumstances of the case. What is the court to do if it decides that the local authority should take steps to make possible the reunification of mother and child but the local authority fails to do this? And what is the court to do if it decides that the child needs a permanent family elsewhere but the local authority fails to take timely steps to find one? The Children Act 1989, denies the court any continuing role in supervising the local authority’s discharge of its parental responsibilities. Yet this may lead to breaches of either the parents’ or the child’s human rights. In the former situation, a parent might complain that the authority was acting in breach of either his or her own or the child’s Convention rights; in the latter, the child might do so. It can certainly be argued that if the state destroys the family life of a child in his or her birth family, it has a positive obligation to use its best endeavors to supply the child with a new family. In many cases there may be no-one to take action on behalf of the child. The Court of Appeal tried to solve this problem by giving the court a way of ensuring that the case came back to court if major steps in the care plan were not implemented. However, in Re S (Children) (Care Order: Implementation of Care Plan) the House of Lords decided that the Human Rights Act did not allow the courts to alter a “cardinal feature” of the Children Act by putting things into the Act which were not there.

Compulsory adoption is clearly the most drastic possible interference in the family life of a child, the parents and their wider family (see chapter 33). The UK is unusual amongst European states in allowing children to be adopted into a new family without their parents’ consent. So far, the issues have not been thoroughly explored in Strasbourg. There has been no direct challenge to this aspect of UK law. The European Court has scrutinized with special care the proceedings for the removal of a baby shortly after birth from a mother thought to have a factitious illness, followed very swiftly by an order freeing the baby for adoption. The move towards more open adoption, already well under way in England and Wales before the Human Rights Act, 1998, was motivated by the child’s rather than the parents’ needs. The ability of birth parents to retain some contact with their child may also help to make compulsory adoption more Convention compliant. The dilemma still remains that adoption is the preferred solution precisely when the harm (or most of it) has yet to be done. This makes the professional task of accurately assessing the future risks all the more important.

The recent House of Lords decision in Re G (A Child) (Interim Care Order: Residential Assessment), although concerned with the mental health of the mother rather than the child, illustrates many of these issues. The mother’s second child had died in infancy having suffered multiple injuries. The court could not decide whether the mother or the father was responsible, but the risk was such that the mother’s first child by an earlier relationship was removed. She then formed a new and more promising relationship. Could they be allowed to parent the new baby? Initially the local authority’s care plan was adoption. The court directed an assessment of their suitability for the intensive program offered by the Cassel Hospital. This was successful, but who would pay for the next phase? The local NHS authorities could not fund the treatment of everyone from all over the country who might benefit from this very intensive and specialist work. The local children’s services authority responsible for this child’s care and safety were unwilling to devote a large proportion of their budget to funding in-patient treatment which was principally aimed at keeping the family together in a safe place while addressing the mother’s problems. The legal services commission could assist in funding the evidence-gathering necessary for the legal proceedings but not the treatment necessary to enable the mother to parent the child safely. The House of Lords decided that neither the local authority nor the legal services commission could be obliged to fund the mother’s treatment. Fortunately, by then the family had completed the program at the Cassel so successfully that they had been allowed home together without a court order. This was indeed “planned and purposeful delay” but not at all what the legislation intends. Without the earlier pressure from the court, the child would have been placed for adoption. In the light of the horrific injuries suffered by the older child, this might well have survived scrutiny in Strasbourg. But who can doubt that it was right to try to enable this mother to parent this child?

**The Individual Child – the Ethical Dilemmas of Adolescence**

Most common law legal systems contain case law emphasizing the principle that for adults, medical treatment without

---

68 The very issues which the Court of Appeal had been trying to resolve in Re S (Children) (Care Order: Implementation of Care Plan) [2002] UKHL 10; [2002] 2 AC 291.
69 This aspect of the Court of Appeal’s judgment in the Re S case was not challenged in the House of Lords. See Re W and B [2001] EWCA Civ 757; [2001] 1 FLR 582.
70 Hence there is now a procedure for the local authority to refer cases where the care plan has not been achieved to the Child and Family Court Advisory and Support Service (CAFCASS) so that they can consider whether to take action for the child.
72 Adoption and Children Act 2002, ss 47 and 52. Evidence given in the recent House of Lords case of Down Lisburn Health and Social Services Trust v. H [2006] UKHL 36 suggested that only the UK, Portugal and perhaps one other country allows this. However, adoption may take different forms in different countries, so that exact comparisons are not always possible.
74 Apparently still uncommon in Northern Ireland, where freeing for adoption is still the common practice in contested cases.
76 See her unsuccessful appeals, first against the finding of non-accidental injury, then against the removal of the child: [2001] 1 FCR 97; [2001] 1 FLR 872.
consent involves an intolerable invasion of bodily and personal privacy. But children in developed societies grow up fast. Why should they be treated differently, particularly when they reach adolescence? In most developed countries, there has been a growing realization that adolescents have a strong personal interest in taking responsibility for decisions affecting their future, perhaps including their own medical treatment. Although most countries have legislation setting a relatively high age for achieving legal maturity, many legal systems have a hotchpotch of laws which also allow teenagers legal capacity to undertake various activities before they reach legal adulthood. Below such fixed ages, the traditional legal approach has been to assume that parents are the appropriate people to determine what happens to their children’s bodies when receiving medical treatment. Now such an approach appears outmoded.

“Important physical, cognitive and psychological developments take place during adolescence. Adolescence begins with the onset of puberty; from puberty to adulthood, the ‘capacity to acquire and utilise knowledge reaches its peak efficiency’; and the capacity for formal operational thought is the forerunner to developing the capacity to make autonomous moral judgments. Obviously, these developments happen at different times and at different rates for different people. But it is not at all surprising to find adolescents making different moral judgments from those of their parents. It is part of growing up.”

In the UK, a ground-breaking decision of the House of Lords in the early 1980s reflected the clear view that to ignore the decision-making capacities of teenagers under the age of 16 might be counterproductive, especially given the increase in sexual activity amongst young teenagers.

Paradoxically, while most doctors sympathize with the need to adopt more liberal attitudes towards adolescents’ own powers of consent, they are also aware that some adolescents are particularly ill-equipped to reach decisions that affect their long-term well-being. Rather than producing greater maturity, adolescence sometimes marks the onset of psychological ill health which hampers the ability of young patients to consider treatment options with any detachment. Doctors may turn to the courts for assistance if they consider that their young patient’s refusal to undergo essential medical treatment is not only ill-considered but dangerous.

**Adolescents’ Right to Say Yes to Medical Treatment**

**Consent and Adolescents Under 16**

Some legal systems give specific legal authority to adolescents to take responsibility for their own medical treatment long before they attain the legal age of majority. The meaning of such provisions is clear enough; on attaining the required age, teenagers gain the legal right to consent on their own behalf to the treatment specified. However, what does the law say about the legal competence of teenagers below the specified age? The House of Lords in *Gillick v. West Norfolk and Wisbech Area Health Authority* emphasized that English legislation does not preclude minors below the age of 16 from consenting to any medical advice or treatment. Lord Scarman made it clear that parents lose the right to veto any decision their children may make at the point at which: “The child achieves a sufficient understanding and intelligence to enable him or her to understand fully what is proposed. It will be a question of fact whether a child seeking advice has sufficient understanding of what is involved to give a consent valid in law.”

This approach to assessing capacity to consent to treatment apparently gives adolescents considerable freedom regarding their own medical treatment. Indeed, Lord Scarman’s *Gillick* competence formula, to all intents and purposes, provides an excellent method whereby English doctors can identify those teenage patients who are sufficiently mature to reach responsible decisions for themselves. It allows a doctor to adopt a far more intelligent approach to the concept of capacity than one merely relying on age or even on the research evidence on children’s cognitive growth. The test is a functional one – whether the minor has capacity to comprehend and therefore consent to the procedure depends on the gravity of what is proposed. Even so, the difficulty implicit in the test for assessing *Gillick* competence is its deceptive simplicity (Fortin, 2003). It fails to provide doctors with any clear guidelines over the circumstances in which they should accept that an

77 See, inter alia: *Re F (mental patient: sterilization)* [1990] 2 AC 1, per Lord Goff at p. 72. There “is the fundamental principle, long established, that every person’s body is inviolate”; *Sidaway v. Board of Governors of the Bethlem Royal Hospital and the Maudsley Hospital* [1985] AC 871, per Lord Scarman, at p. 882; *Re B (adult: refusal of medical treatment)* [2002] EWHC 429 (Fam) [2002] 2 All ER 449, per Dame Elizabeth Butler-Sloss, paras 94, 104.

78 In common with most other European countries, the legal age of majority throughout the UK is 18.

79 For example, English law permits teenagers to consent to medical treatment, to marry (with parental consent), smoke and leave full-time education at the age of 16. At 17 they may drive a car.

81 *Gillick v. West Norfolk and Wisbech Area Health Authority* [1986] AC 112. See discussion below.

82 Statistics issued in 2005 indicated that the UK has the highest teenage birth rate in western Europe, twice as high as Germany, three times as high as France and six times as high as the Netherlands.

83 For example, the English Family Law Reform Act 1969, section 8(1) provides “The consent of a minor who has attained the age of 16 years to any surgical, medical or dental treatment which, in the absence of consent, would constitute a trespass to his person, shall be as effective as it would be if he were of full age; and where a minor has by virtue of this section given an effective consent to any treatment it shall not be necessary to obtain any consent for it from his parent or guardian.” See also the Age of Legal Capacity (Scotland) Act 1991, s 2(4).

84 [1986] AC 112.

adolescent may consent to a particular procedure without involving his or her parents (Brazier & Bridge, 1996). Indeed, their Lordships only offered greater clarity over the provision of contraceptive advice and treatment – detail that was rapidly adopted by health service providers.\(^8\) In other contexts, the Gillick competence formula indicates merely that if doctors are satisfied that the procedure is in an adolescent's best medical interests and that he or she can adequately understand all the issues involved, the doctor can proceed with treatment. Nevertheless, doctors also risk angering some parents if they go ahead with treatment without prior consultation.

Professional guidance provided by the British Medical Association (BMA) elaborates upon the Gillick formula and provides doctors with more practical advice on assessing children's competence in a medical context (BMA, 2001). It uses the test of competence first established by the courts for testing the legal competence of adult patients.\(^7\) When tackling the difficult problem of assessing the competence of a young person in the context of his or her family, it warns doctors that young people can be strongly influenced by their parents over treatment options, and suggests that older children should be given opportunities to discuss their treatment without their parents being present (BMA, 2001). Such advice is useful; without it the uncertainty of the Gillick test might deter doctors from proceeding with any treatment for adolescents that is not trivial, unless they can involve their parents.

**Influence of Human Rights Law on Adolescents’ Right to Say Yes to Medical Treatment**

International human rights law recognizes that an important aspect of an adult's right to self-determination includes the right to decide what should happen to his or her own body.\(^8\) This growing emphasis on the value to adults of autonomy is bound to impact on our ideas about children's developing maturity. Perhaps for this reason, far greater attention is currently being given to the requirements of international instruments such as the UNCRC. Its provisions encourage adults to treat children as people in their own right, rather than adjuncts of their parents and families. In particular, article 12(1) requires states to give all children who are capable of forming their own views, the right to express them freely in all matters affecting them and the right to have their view given “due weight in accordance with the age and maturity of the child.”

In the UK, because it has not been incorporated into domestic law, the UNCRC is of persuasive importance only. Nevertheless, a commitment to human rights has been made explicit by the entrenchment of a charter of human rights into domestic law.\(^9\) The Human Rights Act 1998, superimposes on the principles of common law a further layer of legal requirements. Consequently, the principles of law established before the implementation of that legislation can be challenged if they fail to match up to the demands of the European Convention on Human Rights. In recent case law, the English courts have emphasized that the notions of teenage autonomy developed by the House of Lords in *Gillick* have been reinforced by the values underlying many Convention rights. Thus, the *Gillick* competent child has this added form of legal protection, both in the context of medical treatment and in other areas of life.\(^10\)

Meanwhile, human rights legislation also carries a potential risk for the maturing adolescent. It offers an extra source of power to parents wishing to retain control over their offspring, by reference to their own rights under such instruments. An English mother recently claimed, albeit unsuccessfully, that the *Gillick* decision had now to be reinterpreted in the light of the Human Rights Act, 1998. She argued that article 8 of the European Convention on Human Rights gave her the right to be notified by any medical professional consulted by

\(^8\) The so-called “Fraser guidelines,” promulgated by Lord Fraser in *Gillick v. West Norfolk and Wisbech Area Health Authority* [1986] AC 112, at p. 174. He stated that a doctor could proceed to provide contraceptive advice and treatment provided he was satisfied on five matters: (1) that the girl (although under 16 years of age) will understand his advice; (2) that he cannot persuade her to inform her parents or allow him to inform the parents that she is seeking contraceptive advice; (3) that she is very likely to begin or to continue having sexual intercourse with or without contraceptive treatment; (4) that unless she receives contraceptive advice or treatment her physical or mental health or both are likely to suffer; (5) that her best interests require him to give her contraceptive advice, treatment or both without the parental consent. These guidelines have been adopted in a series of official guidance documents, the latest being Department of Health (2004).

\(^7\) The capacity test established for adult patients by Thorpe J (as he then was) in *Re C (refusal of treatment)* [1994] 1 FLR 31, at p. 33. Adopted by Wall J in *Re C (detention: medical treatment)* [1997] 2 FLR 180, at p. 195, when considering whether to overrule the refusal of an anorexic teenager to accept treatment. The test itself was later refined by Butler-Sloss LJ, in *Re MB (medical treatment)* [1997] 2 FLR 426, at p. 437. It requires the patient to show an ability to comprehend and retain treatment information relevant to the decision, especially as to the likely consequences of having or not having the treatment in question, to use it, and to weigh it in the balance when arriving at a decision. See now the similar, but more expanded test of *in capacity adopted by the Mental Capacity Act, 2005, s 3(1).* The 2005 Act authorizes decision-making on behalf of incapacitated adults (and minors over the age of 16 with disabilities causing incapacity lasting into adulthood) in a variety of general contexts.

\(^8\) Inter alia: *YF v. Turkey* (2004) 39 EHRR 34: the European Court of Human Rights stressed at para [33] that article 8 of the European Convention on Human Rights, which covers the physical and psychological integrity of a person, protects against compulsory medical intervention, even if that intervention is of minor importance. “A person’s body concerns the most intimate aspect of one’s private life”; *Storck v. Germany* (2006) 43 EHRR 6: the European Court of Human Rights held that an adult’s rights to liberty under article 5 of the European Convention on Human Rights was infringed by her being detained in a psychiatric clinic against her will on her father’s authorization alone, without a court order.

\(^9\) The Human Rights Act 1998 was implemented in the UK on October 2, 2000. A charter of human rights was entrenched into Canadian law by the Canadian Charter of Rights and Freedoms, 1982.

\(^10\) For example, *Re Roddy (a child) (identification: restriction on publication)* [2003] EWHC 2927 (Fam), [2004] 2 FLR 949.
her daughters under the age of 16. The court rejected her arguments, emphasizing that the principles established by the House of Lords in *Gillick* had survived unscathed the implementation of the Human Rights Act. The mother's right to bring up her daughters free from state interference, as guaranteed by article 8, was not so extensive that it overrode her daughters' own need for medical privacy. This was an important affirmation of adolescent autonomy. Nonetheless, the challenge demonstrates the fact that there remains an uneasy boundary between parents' rights and children's rights, making further parental challenges a distinct possibility.

**Right of the Adolescent to Say Yes to Medical Confidentiality**

As Brazier points out, “Doctors, like priests and lawyers, must be able to keep secrets . . . Most people do not broadcast their medical problems from the rooftop” (Brazier, 2003). Doctors' legal obligation to maintain their adult patients' medical secrets can never be absolute; nevertheless, its overriding importance has been reinforced by human rights law which maintains that patients' right to personal privacy embraces the right to medical confidentiality.

Are doctors legally obliged to respect the confidences of young patients in the same way? Doctors should not disclose the medical details of children too young to consent to their own treatment to anyone other than those with parental responsibility over them. As in the case of adult patients, such confidentiality cannot be absolute. The doctor must be prepared to pass on medical information to assist a child protection investigation into alleged abusive practices. Official guidance clearly sets out the circumstances justifying their sharing such information with other agencies, in the public interest. It suggests that in some circumstances, “Sharing confidential information without consent will normally be justified in the public interest. These are: when there is evidence that the child is suffering or is at risk of suffering significant harm; or where there is reasonable cause to believe that a child may be suffering or at risk of significant harm; or to prevent significant harm arising to children and young people or serious harm to adults, including through the prevention, detection and prosecution of serious crime” (HM Government, 2006, para 3.12, emphasis as written).

In many ways, medical confidentiality is far more important to the teenager than to the younger child. Teenagers are not only becoming sexually active at increasingly young ages (Parliamentary Office of Science and Technology, 2004), but a growing body of research indicates that they are deterred from seeking medical advice and treatment over sexual matters, such as contraception and abortion, by fears about lack of confidentiality and privacy (French, Joyce, Fenton et al., 2005; Save the Children, 2002; Social Exclusion Unit, 1999). A teenager legally competent to consent to medical treatment certainly has a right to medical confidentiality. As with younger children, child protection concerns may override a doctor's obligations to respect teenage patients' confidences and, depending on the circumstances, he or she should consider passing on such information to the relevant child protection agencies, even if they disagree with his or her doing so (HM Government, 2006, para 3.12). However, such a situation is rare.

Teenagers' overriding fear is that their doctors will inform their parents of their medical consultations (Social Exclusion Unit, 1999, para 7.7). Health agencies are well aware that unless doctors can allay such fears, the rate of teenage pregnancy will continue to rise, with girls continuing their sexual activity unprotected by contraceptive measures (Department of Health, 2004). Nevertheless, some, like Mrs. Axon (see footnote 96), urge that caring parents should be informed of their teenagers' medical consultations. As noted above, the High Court recently confirmed the commonly held view that a teenager who is sufficiently competent to consent to a medical procedure (the *Gillick* competent teenager) is also legally entitled to medical confidentiality, whether it is contraceptive advice and treatment that are being sought, or abortion advice and treatment.

There seems little legal basis for the official assumption that the *Gillick* incompetent teenager is also entitled to medical confidentiality. The strict legal position is a controversial one; it assumes that because such young patients cannot legally consent to any treatment, they cannot claim the legal right to confidentiality either, and that if their doctors cannot persuade them to discuss matters with their parents, the doctors can themselves disclose any medical information to the parents (see discussion in Fortin, 2003). Nevertheless, because the younger, more immature teenager is unlikely to be deterred from sexual activity by her parents learning of her request for medical advice and treatment, it is undoubtedly sensible for the official guidance to encourage doctors to respect the confidentiality of all patients under the age of 16.

---

92 There are rare circumstances where disclosure may be justified “in the public interest,” for example, where failure to disclose appropriate information would expose the patient or someone else to risk of death or serious harm. The principle of disclosure “in the public interest” has its roots in the decision of Scott J, in *W v. Egdell* [1990] Ch. 359.

93 Under article 8 of the European Convention on Human Rights.

97 Ibid, at para 91.

98 In England, successive documents issued by the Department of Health have stressed that doctors who are unable to persuade teenagers under 16 to involve their parents in any treatment decisions involving contraception, sexually transmitted infections or abortion, must always maintain strict medical confidentiality (Department of Health, 2004).
CHAPTER 8

Adolescents’ Right to Say No to Medical Treatment

The fact that adolescents commonly experience mood swings ranging from intense exhilaration to extreme depression is probably at least in part attributable to the fact that their brains are still undergoing profound physical changes, combined with hormonal development (Cynonowski, Frank, Young et al., 2000; Juvenile Justice Center, 2004; Maughan & Kim-Cohen, 2005). These developmental considerations are reviewed in chapter 13. During the teenage years, the frequency of many psychosocial disorders increases (Green, McGinnity, Meltzer et al., 2005). Indeed, there seems to be a consensus that the overall prevalence rate for child and adolescent mental health problems has been rising in nearly all developed countries (Collishaw, Maughan, Goodman et al., 2004). Although children of all ages clearly have a right to the “highest attainable standard of health,” severe eating disorders, suicide attempts and deliberate self-harm, aggression and violence obviously need urgent treatment and may even endanger others if left untreated.

What then should a medical team do if, for example, a teenager rejects life-saving treatment? The principles established by the House of Lords in Gillick v. West Norfolk and Wisbech Area Health Authority101 suggest that an intelligent teenager has the legal right to determine his or her own destiny. Nevertheless, in England and Wales, doctors have obtained judicial authority to side-step such refusal. The judiciary have found it difficult to stand aside and allow teenage patients to risk death by refusing essential treatment. The Court of Appeal considered two applications, both involving adolescents with serious psychological problems.102 It held that under its inherent jurisdiction (see p. 98), a court can override a young patient’s wishes and authorize life-saving treatment103 in his or her best interests.104 Such a judicial response is not surprising, given that a court may find it impossible to reach the conclusion that it is in the child’s best interests to be allowed to die.105 Although this approach is not unique (Ferguson, 2004), it makes a substantial inroad into the principle of adolescent responsibility (Douglas, 1992), albeit after a legal proceeding in which the child’s voice will be heard.106 Even more controversially, the view was also expressed that anyone with parental responsibility for a teenage patient, even if Gillick competent, could provide doctors with the legal authority to carry out much needed treatment, despite the teenager’s own clear opposition.107

Such an approach is problematic. In the first place, it is doubtful that the House of Lords in Gillick intended to produce such an outcome. Lord Scarman’s words certainly suggest that when a child attains Gillick competence, the parents’ right to determine questions about their child’s medical treatment terminates and that thereafter they cannot veto or override his or her wishes on such matters. Nevertheless, this approach may make good sense to a doctor attempting to treat a severely ill, but uncooperative teenager. After all, because doctors only recommend treatment that is in a patient’s best interests, the teenager is far more likely to risk death (or serious harm) by refusing treatment than by accepting it. To the child, however, it has produced a situation that appears illogical and which is certainly confusing. It allows a Gillick competent teenager to consent to medical treatment, while withholding from the teenager’s parents the right to veto their son’s or daughter’s decision; but it also allows the parents to override that same teenager’s refusal to accept such treatment. In some cases, of course, doctors will obtain no assistance from parents whose strong religious views dictate their own opposition to the treatment their child is refusing. Then doctors have no option but to seek judicial authority to go ahead with treatment against the young patient’s wishes. In the past, the English courts have responded to such applications by introducing stringent requirements into assessments of young patients’ legal competence. Thus, young Jehovah’s Witness patients have been defined as lacking sufficient competence to reach decisions over their treatment because they do not understand the manner of their impending death, together with the pain and distress accompanying it.108 Using this approach, a court can provide the doctors with legal authority for the treatment planned, despite there being far less stringent requirements adopted when assessing an adult patient’s best interests. The “best interests” formula is used when the courts exercise their inherent jurisdiction in relation to children.

99 UNCRC, article 24 (1).
100 The research summarized in Mind (2005) and BMA (2006) suggests that these conditions are increasing.
102 Re R (a minor) (wardship: consent to treatment) [1992] Fam 11: the Court of Appeal authorized the compulsory use of antipsychotic drugs to treat a 15-year-old suffering from increasingly paranoid and disturbed behaviour; Re W (a minor) (medical treatment: court’s jurisdiction) [1993] Fam 64: the Court of Appeal authorized the compulsory treatment of a 16-year-old in a dangerously anorexic state.
104 The “best interests” formula is used when the courts exercise their inherent jurisdiction in relation to children.
105 See Re E (a minor) (wardship: medical treatment) [1993] 1 FLR 386, at p. 394. Per Ward J: A court “should be very slow to allow an infant to martyr himself.”
106 In complex medical cases, the child is normally represented by CAF-CASS Legal.
107 Each parent, if married and, if unmarried, the mother, plus the unmarried father, provided he has parental responsibility (see p. 100).
109 “As a matter of law the parental right to determine whether or not their minor child below the age of 16 will have medical treatment terminates if and when the child achieves a sufficient understanding and intelligence to enable him or her to understand fully what is proposed.” Per Lord Scarman in Gillick v. West Norfolk and Wisbech Area Health Authority [1986] AC 112, at pp. 188–189.
1010 For example, Re E (a minor) [wardship: medical treatment] [1993] 1 FLR 386; Re L (Medical treatment: Gillick competency) [1998] 2 FLR 810; Re S (a minor) [consent to medical treatment] [1994] 2 FLR 1065 (McCafferty, 1999).
patient’s competence to refuse treatment. As critics point out, although few adults can comprehend the process of dying, the pain they would suffer, the fear they would undergo and relatives’ distress in watching them die, neither doctors nor the courts are entitled to overrule their refusal to undergo treatment for similar reasons (Huxtable, 2000).

The present law is also controversial in other respects. In particular, the courts have sometimes found themselves on a slope too slippery to resist when appealed to by doctors keen to provide much-needed treatment. Thus, while it may be morally justifiable to override the wishes of a teenager to prevent his or her “death or severe permanent injury,” cases where failure to treat will not produce such dire consequences are more problematic. Critics also object to the way in which the minor status of the uncooperative patient is allowed to dictate the outcome of a dispute over treatment, with the patient’s legal competence being treated as irrelevant. They see this as an arbitrary and status-driven form of decision-making (Ferguson, 2004; Huxtable, 2000). There is the additional objection that court orders cannot obviate the use of physical force – this may be unavoidable in cases involving the treatment of an uncooperative but fully grown teenager.

Doctors may themselves object to overpowering physically mature patients, whatever their age. Thus, there are some who, even before the Human Rights Act 1998 dictated a greater concern with individual autonomy, were suggesting that enforced survival to adulthood might not be in every child’s best interests (Bridge, 1999; Lewis, 2001).

Use of the Mental Health Legislation to Force Treatment on Adolescents Who Wish to Say No to Medical Treatment

It appears that in England attitudes to the use of the mental health legislation are beginning to change and that, particularly when treating eating disorders in older children, doctors are much more prepared to envisage its use. Nevertheless, in general, those caring for mentally ill or behaviorally disturbed young people have often been reluctant to use the mental health legislation to enforce their detention and treatment (BMA, 2001). The most common objection, often accepted by the English judiciary, is the perceived stigma attached to the use of compulsory powers. An individual may find it disadvantageous when older for it to become known that he or she has been treated under the mental health legislation during adolescence. Furthermore, those wishing to ensure that adolescents obtain the treatment they need have been able to turn to other methods. In the absence of parental consent, doctors have been able to turn to the courts to obtain judicial authorization for compulsory admission and treatment. This might appear preferable, because a court order may be of some comfort to doctors faced with a complex case and the child normally obtains some form of independent representation. Nevertheless, a seriously ill adolescent facing compulsory admission and treatment might prefer being admitted to hospital under the mental health legislation, rather than under the parental responsibility of his or her parents or the courts. This legislation applies to all patients requiring compulsory treatment for mental disorders, irrespective of their age. It recognizes that removing an individual’s liberty in order to treat them on a compulsory basis is a drastic step and it contains a set of strict legislative safeguards that apply to all mental health patients. Patients are legally protected from arbitrary restrictions on their liberty and unsupervised treatment regimes (Jones, 2005). These legal safeguards are designed to compensate for the fact that a patient’s competence to consent to or refuse treatment cannot prevent treatment taking place.

Planned reform of the mental health legislation in England has provoked a reassessment of the way in which teenagers with mental health problems should be dealt with under current law and practice. Perhaps prompted by a greater judicial.

114 For example, Re C (refusal of medical treatment) [1994] 1 FLR 31: the court respected the right of an adult paranoid schizophrenic to refuse an amputation of his leg to cure potentially fatal gangrene. There was no indication that he fully realized the implications which lay before him as to the process of dying.

115 This was the justification provided by Balcombe LJ, in Re W (a minor) (medical treatment; courts’ jurisdiction) [1993] Fam 64, at p. 88.

116 For example, Re K, W and H (minors) (medical treatment) [1993] 1 FLR 854: a psychiatric treatment unit obtained legal authority for the use of “emergency medication” when treating three mentally disturbed teenagers; South Glamorgan County Council v. W and B [1993] 1 FLR 574: a local authority obtained judicial authority for the forcible removal of a disturbed 15-year-old from home and her transfer to a specialized psychiatric unit for assessment and treatment.

117 For example, Re M (medical treatment: consent) [1999] 2 FLR 1097. See also Re C (detention: medical treatment) [1997] 2 FLR 180: Wall J indicated that he would override the anorexic girl’s refusal to accept treatment irrespective of her capacity to consent on her own behalf to medical treatment.

118 In Re S (a minor) (consent to medical treatment) [1994] 2 FLR 1065, at p. 1074 John J acknowledged that the possible use of force was “extremely distasteful.”

119 The patient safeguards contained in the current mental health legislation are to be strengthened by amendments to the 1983 Mental Health Act. See draft Mental Health Bill 2006 and Mental Health Bill Draft Illustrative Code of Practice (2006) Department of Health. Please note that the text represents the law at the point of printing which was prior to the passage of the Mental Health Act 2007.
CHAPTER 8

The government considers that medical practitioners should respect the right of competent teenagers to determine their own affairs. Detailed guidance will advise doctors to respect the wishes of Gillick competent teenagers, whatever their age. Doctors confronted by competent teenagers resisting treatment will be warned against relying on parental consent as a means of obtaining legal authority for such treatment. They will be advised that unless a Gillick competent teenager freely consents to the treatment, detaining a child in order to administer treatment may amount to a deprivation of his or her liberty and compulsion should only be attempted by using the mental health legislation, as in the case of adult patients.

Official thought is less coherent regarding the way ahead for the doctor contemplating the compulsory treatment of a teenager under the age of 16 who is not Gillick competent. The government argues that the doctor can still rely on the case law suggesting that a teenager’s resistance to treatment can be side-stepped by obtaining legal authority from his or her parents, and can therefore treat the teenager as an informal patient. Admittedly, doctors are to be warned about the possible limitations on parents’ powers to consent on behalf of their teenage offspring. Nevertheless, this regime will leave the parents of non-Gillick competent teenagers under the age of 16 with considerable power over decisions regarding unwanted treatment. It seems arbitrary to conclude that it is only when a non-Gillick competent teenager attains the age of 16 that his or her compulsory treatment acquires the need for outside scrutiny. Given the new demands of the Human Rights Act 1998, the case law on which such advice rests is by no means certain to survive scrutiny in a higher court. Furthermore, if introduced as planned, the new regime will be extremely complex and produce considerable uncertainty.

Whatever form the new mental health legislation eventually takes in England, doctors should reflect on the wisdom of turning to parents for legal authority to treat against the wishes of their teenage son or daughter, given how difficult parents will find it to be objective over the need for compulsory treatment. At present, a doctor’s reluctance to use the mental health regime automatically results in children losing all the important safeguards deemed so essential for adult patients. On the other hand, if the new laws lead doctors to use the mental health regime for the treatment of all those over 16 and for many under that age, they risk greater numbers of young people being compulsorily detained than ever before, perhaps for relatively trivial conduct disorders. This would depend upon the breadth of the new grounds for compulsory admission, which has proved one of the most controversial areas in the government’s proposals.

Influence of Human Rights Law on Adolescents’ Right to Say No to Medical Treatment

When teenagers refuse much-needed or live-saving medical treatment, it is difficult for their doctors to stand aside and allow them to take the consequences. Nevertheless, a court order overriding a teenager’s rejection of treatment has obvious implications for his or her physical dignity and self-respect. Court orders cannot obviate the need for physical force in some cases. However, as Gostin says, “Nothing degrades a human being more than to have intrusive treatment thrust upon him despite his full understanding of its nature and purpose and his clear will to say ‘no’” (Gostin, 1992). The human rights dimension of such a dilemma is obvious. Child patients, like adults, have a right to freedom from arbitrary deprivation of liberty and to protection from all forms of physical violence. Meanwhile, there are many who would deplore allowing teenagers to reach decisions that might undermine their long-term health and happiness, preferring to adopt a paternalistic stance, at least during their minority (Fortin, 2006).

To date there is no English case law indicating that teenagers resisting medical treatment will succeed if they appeal to the courts arguing that the European Convention on Human Rights protects them from such an invasion of their rights. There appears to be no Strasbourg case law that would directly support such arguments and challenges of this kind have been met with varying success in Canada (Ferguson, 2004). Today, an English teenager objecting to having his or her wishes
Conclusions

Most mental health practitioners will never need to refer to the principles reviewed above. They would certainly be wise to clarify their legal position over a proposed course of action; nevertheless, specialized treatment is often provided in circumstances that produce few concerns about the legality of the course taken. Even when disputes or challenges do arise, the legal principles governing them may provide little real assistance. The law is often too blunt an instrument to take full account of practitioners’ real concerns (Kennedy, 2001; King & King, 2006). Furthermore, recourse to the law may polarize positions, making it difficult for either “side” to work purposefully together in the future, even for the sake of a young patient who requires treatment. Despite these shortcomings, the legal principles governing this area of medical practice do at least encourage practitioners to keep a young patient’s interests center stage, without losing them under a welter of adult perspectives.

What Clinicians Need to Know about Statistical Issues and Methods

Andrew Pickles

Although as an academic discipline statistics is often associated with mathematics, from its beginnings it has also had strong links to science. Most appreciate the link as an area of application of statistics. Less well appreciated is that science has motivated methodological development in statistics. Indeed, one could argue that the whole rationale for the use of statistics is as an objective and efficient operationalization of the scientific method in a context of complex data, and in practice almost any study yields complex data. Statistical methods should achieve this in several ways. First, by requiring precise operational definitions of theories and critical differences or contrasts. Second, by providing methodology for estimating scientifically meaningful quantities as precisely as possible and freed from as many sources of bias as possible. Third, by providing a framework for determining whether data are consistent or inconsistent with a particular theory.

Some introductory statistics classes and books give the impression that statistics is much concerned with making assumptions; assumptions that appear abstract, derived from probability theory, with little meaning and anyway probably rarely met in practice. This is unfortunate, because in the great majority of cases the assumptions correspond to critical scientific simplifications of a kind that most scientists and clinicians could easily comprehend and would have considerable intuitive insight into whether they are likely to be met or not. Moreover, it is crucial for the quality of the science that it be understood that such assumptions are being made.

As an example, consider the very commonly made assumption of independence among observations. In scientific terms, this requires that no observation influence another, that sets of observations are not subject to the effects of some shared factor not explicitly accounted for in the analysis and that the sampling of one subject has not influenced the probability that another subject be sampled. Thus, this assumption would not be an appropriate one where sibships of children had been selected, instead of individual children, or where some children were picked and then their friends. In such circumstances, progress might be possible where such clusters of observations were independent. As a second example, consider the homoscedasticity or homogeneity of variance assumption required for the simple difference of means t-test. In scientific terms this requires that within each of the groups that are the focus of study, there is no greater variability in one group than another. Great care is often spent in collecting a carefully selected and fully characterized “case” group, whereas the “control” group is often just a group who are “not cases,” drawn from the general population or a “convenience sample” – sometimes just a collection of individuals from other studies or even individuals rejected from other studies. It is therefore unsurprising that control groups are often more variable than case groups. In other circumstances, cases may be defined as the most severe in a distribution of severity, with controls drawn from the mean. Here, particularly with a distribution long-tailed at the abnormal end, the cases may be more variable than the controls (Roach, Edwards, & Hogben, 2004). Any homogeneity of variance assumption would be inappropriate.

What are we Trying to Do: Hypothesis Testing or Estimating Effects?

Child psychiatry has been strongly influenced by the practice of psychology of placing great emphasis on hypothesis testing. This approach focuses on assessing the evidence in a data set against some null hypothesis; for example, the hypothesis that “This treatment or putative risk factor has no effect.” Commonly, the evidence is presented in the form of a P value for some measure of effect, the probability that we might have obtained an effect as large or larger than that obtained from our observed data as the result of the chance sampling of participants and events. Non-psychiatric epidemiology and the main body of medical statistics has moved away from this focus to emphasize instead the careful estimation of effects and their presentation together with a confidence interval. The confidence interval characterizes the uncertainty we have in the estimate obtained from our data, which may be high or low as the result of chance sampling of participants and events. This approach has a range of advantages, some of which we elaborate in the following sections. For now, note two advantages. First, it avoids the distinction between descriptive and theory testing studies being drawn on the basis of the statistics used. Some studies are more descriptive than others, but that relates more to the prominence and use of theory in the choice of data to present and its manipulation. Second, the hypothesis test rejects a hypothesis based on the evidence
of the study being reported in isolation. Such a perspective no longer fits the industrial scale of modern research where few individual studies are thought to be individually potentially decisive. Instead, studies are seen as contributing, and hopefully through some future systematic review/overview/meta-analysis, to a pool of effect estimates that will be used as the basis for some more robust and confidently held conclusion. As a consequence, while having a large study is desirable, more important is that the study is undertaken to a sufficiently high standard that it will pass the quality criteria for eligibility for inclusion in an overview.

**Common Misunderstandings, Study Design and the Natural History of “Findings”**

Nonetheless, it remains a weakness of readers and editors that they are drawn to reports of significant associations and effects rather than reports of non-significant effects. As a consequence, the P value remains the statistic upon which the success or failure of a study is often seen to rest. That this is the case is a major flaw. The size of the group difference or other parameter that is estimated that measures the contrast or effect of interest is the key statistic, together with some measure of the precision with which this has been estimated, preferably a confidence interval. The confidence interval gives the reader the opportunity to reflect upon the range of possible values that might be considered as potentially consistent with the data and assess whether effects of this magnitude would be, say, of clinical importance. This last emphasizes the importance of measuring the effect of interest in units that are as meaningful as possible – indeed, more than one form may be useful. For example, treatment effects are often reported in terms of both reductions in risk and the number needed to treat in order to cure or avoid one case/death (equal to 1 over the absolute risk reduction). In other circumstances, reporting in a form to allow comparison can be important. For outcomes on a continuous scale, a commonly used effect scale for group comparisons is Cohen’s d, defined as the difference between two means divided by the pooled standard deviation for those means. Cohen (1992) suggests a value of d of 0.2 is indicative of a small effect, 0.5 a medium and 0.8 a large effect.

Study size also needs to be considered in relation to assessing whether significant effects are likely to be important. Those who undertake small studies often think that if they find something significant then it must be a substantial effect because it was significant even in a small study. The more skeptical point of view starts from expecting most of the targets of interest, notably treatments, to have no effect. At the traditional P = 0.05 level of significance, both small and large studies have a 1 in 20 chance of finding something as appearing to have a significant effect that in fact has no effect. However, in the small study the magnitude of the estimated effect will necessarily have to be large for it to appear as significant. What happens when we consider the case of assessing a number of possible factors, only one of which in fact has a true effect? Then, although both large and small studies have the same chance of falsely identifying one of the no-effect factors as significant, the larger study has greater power to detect the effects of the one factor with a true effect – it has more chance of finding the true-effect factor as significant. Thus, of the effects found to be significant, a higher proportion of those from a small study will be false and of an exaggerated size compared to the proportion from a large study. Funnel plots (Light & Pillemer, 1984) can display this graphically. Figure 9.1 shows data from a set of acupuncture studies. It illustrates the diminution of effect size reported as the sample size increases, to the point where the largest study shows no effect. If the true effect was zero, then we would expect a collection of smaller studies to give estimates scattered symmetrically either side of zero. Fig. 9.1 has a near complete absence of study points on the left-hand side, a pattern that suggests the effects of considerable publication bias – the selective submission and acceptance of reports indicating a positive effect.

Indeed, there is a common natural history for many “findings” from small studies (Ioannidis, 2005). First, a small study finds a significant association and persuades an editor of its interest value. Much note is taken and it receives many citations. Then many small studies fail to replicate the finding, but because everyone knows that small studies have low power this comes as no surprise and, as we have seen, most do not see the light of day. By chance alone, some studies do find a positive effect and are published as apparently replicating the interesting finding. Eventually, perhaps a decade later although the timescale is shortening, the finding is tested out in a large and often more rigorous study, fails to replicate and, because the size of the study demands it be published

![Fig. 9.1 From Tang, Zhan, and Ernst (1999).](image-url)
whatever its conclusion or because this failure is now seen as overturning a received wisdom, the results are published in a prominent journal. Patients then need to be persuaded that something formerly considered effective is now considered ineffective.

In fact, sample size and publication bias are not the only reasons for this “natural history.” Although there are critical exceptions, because large projects cost more and are commonly staffed by more experienced researchers, they tend to be superior on a whole range of methodological measures of quality, such as being prospective rather than retrospective, randomized rather than observational, having blind assessments, and being better analyzed and reported. Each of these factors tends to exclude possible biases that can contribute to artifact, and indeed reported effect size does seem to decline as the methodological rigor of the study increases (Schulz, Chalmers, Hayes et al., 1995). More recently, some apparently robust findings from epidemiology have been tested out in randomized trials, considered most as the ultimate test of causal effect. Results from several high-profile treatments have been not just disappointing but, in the case of hormone replacement therapy (HRT), really most worrying. The major epidemiological studies (Stampfer & Colditz, 1991) suggested beneficial effects of HRT (for cancer and coronary heart disease) but the trial findings suggested it was dangerous (Hulley, Grady, Bush et al., 1998). One explanation relates to the longer treatment examined by the epidemiological studies, and would emphasize the complementary contributions of epidemiological and trials methodology. However, many worry that the discrepancy lies in the failure of the epidemiological studies to control for confounders (see below), biases arising from systematic differences in those who did and did not receive HRT treatment (e.g., inadequate control of socioeconomic position; Lawlor, Davey Smith, & Ebrahim, 2004). We are yet to see whether this general concern should apply to psychiatric epidemiology. There are some reasons to suggest it may not because many psychiatric disorders are relatively common and effect estimates for risk factors comparatively large. Moreover, some of the flaws in the rigor and objectivity of observational research may be soluble. Nonetheless, this experience does suggest the need for more critical evaluation and skepticism.

Confounding, Selection and Randomization

Rarely is an outcome of psychiatric interest related to just a single causal factor. In practice, many different processes are and have been at work to give rise to the current mental state of a child. Moreover, it is the nature of many of the factors of interest in child psychiatry that they co-occur. Poor families tend to live in poor neighborhoods, with poor educational opportunities and experience psychosocial risks and stresses that give rise to discord. Thus, a group of children identified by any one of these factors will also have an unusually high frequency of the other factors. There are at least two distinct aspects of this problem that are important. The first is that these other factors may have effects which we could attempt to account for. The second is that in our sample the variation among subjects in the factor of interest is correlated with variation in these other factors. This latter is commonly referred to as a selection effect that those who are selected to be exposed to one risk factor have commonly experienced and are experiencing other risks as well. The effect of our factor of interest will be confounded with the effects of these other risks.

Broadly speaking, we can attempt to solve our problem if we can deal with either of the two aspects of the problem. The obvious approach to dealing with the independent effects of possible confounders, that of adjustment, is addressed in the next section. The second aspect of the problem, that of selective exposure, can be dealt with if we can identify circumstances under which the exposure is assigned at random and thus in a way that is not correlated with any other factor. Random assignment is possible in experiments and trials and without dispute provides the most convincing route to estimating effects unconfounded with those of other possible exposures. In practice, it is becoming increasingly common that even trials cannot make this attribution of effect unambiguous. In psychiatry, the target disorder may itself interfere with the ability of the patient to comply with the assigned treatment and to complete the measurement protocol of the trial, and patients are less deferential and exercise their rights to switch treatment more often. As a consequence of such selective treatment exposure mechanisms, treatment received soon becomes correlated with all sorts of possible confounders. Nonetheless, as we shall see, we can continue to exploit the initial randomization to assess the causal impact of treatment.

Simple Adjustment for Measured Confounders

One way of dealing with confounding is through standardization. Intelligence scores are standardized to remove the effects of age, usually by means of a calibration sample. The standardized score measuring the extent of deviation from the norm is a particular raw score at a particular age. Standardization can also take the form of weighting age-specific sample data to correspond to a population with a standard age distribution. Point prevalence is a rate per person (or 100 or 10,000 persons) of some disorder and so for prevalence standardization means adjusting the data to correspond to that from a population with a specified number of individuals in each age category. With episodic disorders, such as depression, we commonly consider period prevalence, which includes as affected additional individuals those who, although without the disorder now, report disorder in the previous weeks or months (e.g., 3 months). Standardization of period prevalence data invariably proceeds as for point prevalence data, but will give higher rates than point prevalence. However, for incidence, which is the rate of occurrence per person per unit time, both the numbers of individuals in each age category and the time each has spent in that age category at risk of the disorder occurring are important. We therefore standardize not to a specific age distribution but to a specific distribution of
person time (the product of persons and their time at risk) within each age category. Table 9.1 gives some illustrative data on the incidence of a disorder within three age categories for a risk-exposed and a risk-unexposed sample. The person-years have been calculated by summing the number of years each individual has spent at risk within that age category. The overall incidence is the number of incident cases divided by the person-years and the overall incidence rate ratio for risk-exposed to risk-unexposed is 0.039/0.015 = 2.6. However, the exposed group has more older children, for whom the incidence rate is higher; and the unexposed group more younger children, for whom the rate is lower. We can calculate standardized rates for hypothetical samples that had equal person-years of data in each age group (e.g., \(0.20\) standard rate is higher; and the unexposed group more younger children, for whom the incidence rate is higher; and the unexposed group more younger children, for whom the rate is lower. We can calculate standardized rates for hypothetical samples that had equal person-years of data in each age group (e.g., \([0.20 + 0.033 + 0.05]/3 = 0.034\) and \([0.010 + 0.017 + 0.027]/3 = 0.018\). This gives an incidence ratio accounting for age of 1.9. Further simple manual calculation would give a 95% confidence interval (CI) of 1.0–3.8 (see Clayton & Hills, 1993, chapter 14). This kind of adjustment for confounders is intuitive, can be presented in transparent steps and thus is easy to communicate. However, a more flexible tool is often required and for that we usually turn to some statistical model.

**Regression and the Generalized Linear Model**

For continuous outcome measures the familiar regression model is used to combine the effects of several factors. In this model, the expected or model predicted value of the outcome is assumed to be some linear combination of the predictor variables

\[ \text{E}(Y) = \alpha + \beta_1 X_1 + \beta_2 X_2 \]

and the variance of the outcome around its expected value is assumed to be constant (homoscedasticity). The \(X\) variables can be continuous or discrete (binary dummy categorical variables). This model subsumes analysis of variance (ANOVA) and analysis of covariance (ANCOVA).

Of course, there are many outcomes for which this model is not appropriate, and we then often turn to some form of the generalized linear model (McCullagh & Nelder, 1989). This allows two extensions to the ordinary regression model. First, a choice of link function that transforms the expected value of the response. For example, for a count response, such as that in Table 9.1, a log-link would be chosen such that

\[ \log[\text{E}(Y)] = \alpha + \beta_1 X_1 + \beta_2 X_2 \]

This would ensure that all predicted counts were positive. Second, a different distribution for the variability of the observed response can be chosen. The key feature of this choice is how the variability in the observed responses might be expected to increase with its expected value. For example, in ordinary regression no increase is expected while with a Poisson distribution the variance increases with the expected value. For the data of Table 9.1, a Poisson distribution is often thought plausible for counts arising from independent events. The combination of log-link and Poisson error gives a Poisson regression model. Applied to the data of Table 9.1, a model in which both risk group and age group are included as main effects is appropriate. However, because we are wanting to examine an incidence rate, observed as a count divided by a person-years denominator, this latter must also be included in the model. As we are using a log-link function, dividing by the denominator is equivalent to subtracting the log of the denominator from the linear predictor, a procedure that in generalized linear model (GLM) terminology is known as specifying the log(person-years) as an offset. Applying this model gives an estimate for the effect of risk group of 0.67 (standard error \([SE\] 0.35), but this is the effect on the log scale. On the risk ratio scale, the effect is \(\exp(0.67) = 1.9\) with a 95% CI given by \(\exp(0.67 \pm 1.96 \times 0.35)\) or \((1.0–3.8)\), answers very close to those obtained by the standardization of the previous section.

The other commonly used GLM, particularly in child psychiatry where incidence is harder to determine than point or period prevalence, is the logistic regression model suitable for analyzing binary outcomes. This model estimates odds ratios (OR), a measure of effect that has both desirable and undesirable properties. A desirable quality is that it is the only measure of association between risk factor and binary outcome that is unaffected by oversampling risk exposed or by over-sampling outcome cases (but not both of them at the same time). Thus, the OR estimate from a cohort study and a case–control study should be the same. An undesirable quality is that most readers and many authors interpret the OR as a risk ratio, something it approximates only rarely in psychiatry. An OR of 2 does not imply a doubling of the rate unless that outcome is very rare. If the rate in the unexposed group is 2% then the rate in the risk group does indeed almost double to \(2 \times 0.02/(1 + 0.02) = 4\%\), but with an unexposed group rate of 20% an OR of 2 implies a rate in the risk group of 2 \(\times 0.2/(1\]

and with an unexposed group rate of 80\%, then an OR = 2 implies a modest rate increase to \(2 \times 0.8/(1 + 0.8)\) = 89\% in the risk group.

Regression and the more general GLM make covariate adjustment straightforward. It is therefore widely applied. However, it should not be considered as a cure-all and should always be accompanied by a process of carefully thinking through what is being assumed. A typical example is shown in Fig. 9.2 for 167 children from a prospective study of autism (Lord, Risi, DiLavore et al., 2006). Figure 9.2 shows how initial verbal IQ is associated with initial diagnostic status of autism, autistic spectrum but not autism (PDD-NOS) and non-autistic spectrum (NS) as determined using an observation assessment, the ADOS (Lord, Risi, Lambrecht et al., 2000). We might wish to examine how diagnosis made at age 2 is associated with outcome at age 9, measured on the ADOS social and communication score, taking into account initial verbal IQ. We could do this by covariate adjustment for verbal IQ in an ANOVA where age 2 diagnosis was a between-subjects factor, or equivalently by including both diagnosis and verbal IQ as main effects in a regression. We would obtain the answer that compared to those initially diagnosed with autism, those with PDD-NOS score –2.52 (95\% CI, –4.69, –0.35) lower and those initially NS score –4.59 (95\% CI, –7.37, –1.80) lower on the ADOS at age 9, and that each additional verbal IQ point is associated with a 0.102 (95\% CI, 0.144–0.062) lower score. But what have we assumed in this adjustment process? We focus here on the assumption of linearity, both within and between groups, which has allowed us to make an adjustment across the whole range of IQ in the sample. A cursory examination of Fig. 9.2 shows that most of the children (in fact 71\%) with an initial diagnosis of autism have a verbal IQ below that of the child with the lowest verbal IQ in the non-spectrum group. Were we to control for verbal IQ by matching, a non-parametric approach that does not assume linearity, these children with autism and low verbal IQ would find no match in the non-spectrum group and would be dropped from the analysis. We could restrict our covariance adjustment approach to the verbal IQ range shared by all three diagnostic groups. The resulting analysis of 78 (previously 167) children gives estimates of outcome differences of –0.92 (95\% CI, –4.09, 2.26) and –3.94 (95\% CI, –7.37, –0.50), smaller and much less precise than the previous estimates. The covariance adjustment using the whole sample may be more powerful, but that power was gained at the expense of a more speculative assumption that the verbal IQ adjustment is correct even though in some areas of the scale that relationship is determined solely by children from one diagnosis. A compromise approach might be to allow more flexible non-linear adjustment. The results obtained using a fractional polynomial adjustment (Royston & Altman, 1994) for verbal IQ gave estimates of –1.98 (95\% CI, –4.20, 0.024) and –4.28 (95\% CI, –6.91, –1.64), estimates that fall between those calculated by the previous two methods.

The analyses above have assumed that the way that verbal IQ has an effect on the outcome is the same within each diagnostic group. Figure 9.3 shows the estimated relationship for each group, obtained from fitting a model that allowed an interaction term between diagnostic group and verbal IQ. Although this term was non-significant (\(F[2,161] = 1.63; P = 0.2\)), Fig. 9.3 clearly shows non-parallel lines. These imply that the difference among diagnostic groups in ADOS outcome score would depend upon the child’s initial verbal IQ, that the estimates for the main effects of group difference will typically represent the difference when the covariate (verbal IQ) is zero, an uninteresting point on the scale unless verbal IQ is rescaled such that zero represents a more meaningful point, and that the answer obtained from “adjustment” for verbal IQ may represent some sort of average difference that could hide important variation. Unless designed in advance (e.g., by
selecting only subjects who can be matched on verbal IQ, most studies do not have the power to test effectively for such variation. Unfortunately, designing a study to be powerful in this regard would make it clumsier to analyze for all but the designed contrasts. Moreover, the design would have increased power only with respect to the matched variables, and would exclude important subgroups of children, in this case the majority of autistic children who have low verbal IQs.

There remains the more general question as to what are relevant and suitable control variables. This is not a simple question to answer. We commonly find autism strongly associated with low verbal IQ. This may be partly the result of contamination, that low verbal IQ may result in an increased chance of false positive identification as being autistic using our current instruments. It may be that autism increases the risk of low verbal IQ, an association that might be expected to increase with development. Alternatively, low verbal IQ may increase the risk of autism. What is being achieved by controlling for verbal IQ, whether it is useful and how results should be interpreted, will differ according to which of these scenarios applies. Some argue that covarying for variables should only be undertaken to improve efficiency and that covarying in order to control for group differences in the covariate is entirely mistaken (Miller & Chapman, 2001). For practical research this would seem to be a counsel of despair. While rightly emphasizing the need for caution covariate adjustment, or some newer equivalents such as marginal structural modeling (see p. 120), undertaken in the context of supporting theory and evidence, is an essential and valid tool.

**Mechanisms, Statistical Interactions and Effects Scales**

The term interaction has distinct substantive and statistical definitions. As we shall see, because these usually relate to quite different concepts and each may be poorly defined in any particular instance, there is scope for much debate, mostly fruitless. The notion of synergy is often associated with interaction, where risk factors or characteristics have worse effects when they occur together than when each occurs by itself. The concept may be of special importance within psychiatry, where many of the features that are studied as being risk factors may in fact be risky only in certain contexts. For example, whereas high blood pressure or cholesterol levels seem to be almost universally bad for coronary heart disease, we cannot say that child antisocial behavior is universally increased as a result of:

1. Divorce, because it may be beneficial if the absenting father is themselves antisocial (Jaffee, Moffitt, Caspi et al., 2003); or
2. High levels of testosterone, because while its association with leadership may confer risk in neighborhoods where deviant peers are common, elsewhere its role may be socialized (Rowe, Maughan, Worthman et al., 2004).

Indeed, it is not unreasonable to expect that many behavioral responses may be adaptive or maladaptive depending upon the context. Effect modification also corresponds to synergy. In a clinical context, the effect of therapy may vary with the level of a moderator variable, such as family type. This makes resolving this confusion over interaction all the more pressing.

Where the response variable is continuous relatively little confusion arises. Thus, as in Fig. 9.3, slopes that characterized the relationship of one risk measure to an outcome score may be different in one group compared with another, and this slope variation can be tested by a test of the interaction term. A group that has a particularly steep slope would be indicative of a form of synergy, although how it was described might also depend upon where the mean levels for the groups lay (Fig. 9.3). More problematic is the circumstance where the outcome is a binary diagnosis or an incident event where we are examining factors that might contribute to the rate of occurrence. (Rothman, 1976; Rothman & Greenland,
1986), in enlarging upon the notion of component causes, describes how for causal factors that are not too common and where no synergism occurs, the combined effect of exposure to two risk factors should be additive in the rates of outcome occurrence to either exposure alone. Where synergism occurs (e.g., where one factor increases the risk of an individual being in a state of vulnerability), from which exposure to the second risk factor increases the risk of occurrence of the final outcome of interest (a two-stage model; cf. Pickles, 1993), then the risk factors will appear to act multiplicatively. However, for analyzing binary outcomes, the common models are the log-rate models of survival analysis and the logit model for period prevalence data. Additive main effects on these log-rate and logit scales (for low rates) imply multiplicative effects on the simple rate scale. For these models the absence of an interaction can be consistent with synergy, and a significant (negative) interaction consistent with no synergy. Simply put, there is no correspondence between the need for a statistical interaction and synergy, because the former depends upon the scale in which the main effects have been combined (Blot & Day, 1979).

Our task should be to fit a parsimonious but adequately fitting model (with or without interaction terms) with easily understood and well-behaved parameters, which the logit model is, but then to support the interpretation, particularly the public health interpretation, by examining group-wise predicted outcome rates. Examining other effect measures may be helpful, such as group-wise attributable fractions (see p. 121).

### Measurement Error

Psychiatry is one of the few areas of medicine that takes measurement error seriously. Nonetheless intuitive understanding of its impact on analysis is severely limited. Many researchers are familiar with the idea that if a risk factor is measured with error, then in any regression-type model where such a measure is used to predict an outcome, the estimated regression coefficient will be “attenuated” – the magnitude of the association will be lower and less significant than that obtained had the risk factor been perfectly measured. This conclusion, which is true in the simple bivariate case, is then interpreted to mean that the worst that can happen is that measurement error may reduce power and that our analyses might “miss” a few associations.

In fact, in more practical settings, where there are several possibly correlated exposures, with one or more measured with error, then such errors can have far more pernicious effects. We illustrate these in the next example.

#### Measurement Errors in Children’s Ability Scores

Ability scores were collected in children aged 6, 7, 9 and 11 years to measure continuity in general ability (Osbourne & Suddick, 1972). Summary statistics for these data are shown in Table 9.2.

**Table 9.2** Summary statistics for the repeated measures of childhood ability measured by Osbourne and Suddick (1972).

Fig. 9.4 An autoregressive model for continuity.

A plausible starting model is the first-order autoregressive model shown in Fig. 9.4, where ability at one age, having taken into account ability at the previous measurements, is not associated with any earlier measure.

A feature of such a model is that an early measure may influence a later measure but only through an intermediate measure. This is an example of “effect mediation” – the intermediate measure mediates the effect of the earlier measure. The model consists of three regressions (Y2 on Y1, Y3 on Y2 and Y4 on Y3), each with error terms that are assumed uncorrelated (E2, E3 and E4). In addition to estimating the standardized regression coefficients (0.809, 0.850 and 0.867, respectively), as one would do in standard regression modeling, we can assess the model’s goodness-of-fit by comparing observed and expected covariance matrix, from which we would conclude that the autoregressive model had a very poor fit ($\chi^2$ statistic of 61.82 with 3 degrees of freedom). Something is wrong, but what? For many researchers the instinct is to conclude that additional relationships must exist (e.g., from Y1 to Y3 and Y2 to Y4). These additional relationships correspond to “sleeper effects” which have no effect on the immediately next measure but yet can influence a subsequent one. There are circumstances where such effects are plausible (e.g., where the tests vary in content and two non-adjacent tests have more similar content, say, being more mathematical), but skepticism should be retained.

We should first take the issue of measurement error seriously. In the classic measurement error model, the observed
Chapter 9

A latent variable continuity model.

Fig. 9.5

measurement is additively related to a “true variable” F and a measurement error E of constant variance,

\[ Y = F + E \]

The “true variable” F is an example of a latent variable or factor, and in this simple case one that involves no regression coefficient or factor loading (and is also therefore a simple random effect). Usually, replicate measurements are necessary in order to identify and estimate the measurement error separately from the true variable. However, a structural equation model (SEM) of the four measurements can be fitted with constraints, enabling the variance for F and E to be identified with only single measurements per occasion (Fig. 9.5). Imposing constraints such that the measurement error variance remains the same over the four occasions achieves identification of the model and involves only one more parameter than the previous model (three regression coefficients between the factors and variances for F1, D2, D3, D4 and the single common measurement error variance for the E’s). Allowing for measurement error results in a huge improvement in model fit with it now fitting well (\( \chi^2 = 1.43 \) with 2df). Clearly, this model has no need of any additional sleeper effect, because it already fits so well. How has this come about?

In the model corresponding to Fig. 9.4, measurement error in the Y’s attenuates the coefficients estimated in each regression of one Y on the previous one, and the estimated coefficients are thus smaller than they would have been in the absence of measurement error. This underestimation results in the predicted association among the most temporally distant variables, Y1 and Y4 and which is given by the product of the standardized regression coefficients b1, b2 and b3, being even more underestimated (a 10% underestimation in each coefficient resulting in a \( 1 - 0.9 \times 0.9 \times 0.9 = 27\% \) underestimation of the b1 \( \times b2 \times b3 \) product). Allowing for measurement error corrects each regression coefficient and in so doing removes the gross underestimation of the model predicted long-term association.

There are numerous implications from this very modest example. The first is that in general, although measurement error in a covariate X1 may result in systematic underestimation of its relationship with some response, it can also give rise to overestimation of the effects of some other covariate, X2, with which X1 is correlated. Consider the often-repeated finding that current health is not only associated with contemporaneous risk factors, but also independently with the same risk factors measured earlier in childhood. Is this because the risk has its effect through an accumulation of risk exposure, or is it an artifact of measurement error in the risk measurements? This latter possibility is rarely properly explored.

When examining mediation it is important that the mediator, in particular, should be either well measured or modeled as a latent variable in an SEM.

These data can be used to illustrate a further important point, namely that achieving a good model fit is not evidence for the correctness of the model, merely that it is one contender. A natural alternative model for data of this kind is a growth curve model (Rogosa & Willett, 1985) in which each child is considered as having a trajectory defined by an initial ability, represented by a latent intercept factor – or random effect – F1, and a latent rate of improvement, represented by a slope factor – or random coefficient – F2 (Fig. 9.6). The intercept factor “loads” (i.e., regresses) on all four measurements with a common regression coefficient. The growth or slope factor loads on all but the first measurement with either distinct factor loadings on each path or with constraints such that the loadings vary in proportion with the time since the initial measurement (equivalent to allowing for the linear effects of time to be random). In almost all growth situations, values at the initial starting point are correlated with subsequent growth, requiring the two latent factors or random effects to be correlated. Again, we can impose restrictions such that the measurement error variances (E1–E4) are constant. This model has one fewer parameter than the model of Fig. 9.5 and yet fits these data better, indeed extraordinarily well (\( \chi^2 \) goodness-of-fit of just 0.92 with 3df).

Which of the two well-fitting models of Figs 9.5 and 9.6 should we choose? In this case, the choice is likely to rest upon theoretical considerations because we lack the data to discriminate effectively. The last model has the fewer parameters and in addition has the advantage of cleanly partitioning initial cross-sectional variation into one intercept factor
from subsequent change in the second slope factor. This has appeal, especially were the model to be extended to allow for the effects of exposures to be associated with each of the intercept and slope factors. Where continuous growth or continuous decline are not expected, but instead change may be reversible, then random coefficients can be extended to a quadratic in time (or still higher order terms).

**SEM with continuous and discrete variables and interactions: trajectory models**

Much theory relates to groups or a categorical typology of individuals. A classic example is the three groups proposed by Moffitt (1993) in relation to antisocial behavior; these are defined in terms of their longitudinal trajectory into the life-course-persistent group, the adolescent limited group and the never-antisocial group. Practical definition of these groups may be somewhat arbitrary so a method that would identify these groups directly from the data with only general guidance from the researcher has been seen as desirable. These ideas may be operationalized within a trajectory model, a form of growth curve model in which the variations in the possible values of the intercept and growth factors are restricted to belong, in this case, to just three sets of values. Such a model can be considered as a form of latent class model or a model-based cluster analysis (Curran & Hussong, 2003). We can compare the relative fit of a model with two or four, rather than three classes to assess how gross an approximation the restriction to just three classes might be. It should not, however, be considered as a tool that can identify how many classes actually exist. Two things argue against this. First, the number of classes found as providing the best fit according to some standard information criterion (e.g., BIC or Aikake), has been found to vary with the extent of the data available to the analysis. Second, although one can continue to add more classes, both some theory (Laird, 1978) and practice have shown that there quite quickly comes a point where no further improvement in fit occurs, and that the additional new class either looks just like an already existing class or is assigned a probability of zero, implying that nobody belongs to it. This set of classes is referred to as the non-parametric maximum likelihood (NPML) estimator of the latent growth distribution. Although the NPML estimator is formed of classes, it can be shown that it fully characterizes the latent growth distribution even if that distribution is not one of classes but one of continuous variability, as in a traditional growth curve model. As a consequence, showing that a latent trajectory class model fits quite well is merely to say that we can approximate the latent growth distribution, whatever its true discrete or continuous form, by these classes and not that the classes exist. Nonetheless, this can remain a valuable achievement, allowing for an effective summary of the data and for helpful theory building and testing opportunities.

As with latent variable models, we can examine how various risk factors and confounders may be related to the latent quantity, estimating OR for the effect of these factors on latent trajectory class membership probabilities. In addition, we can calculate so-called posterior probabilities, which are estimates for each subject of the probability that they belong to each of the three classes. Such models can be estimated in programs such as the SAS procedure TRAJ, the SEM program Mplus (Muthen & Muthen, 2001) or the very general Stata procedure gllamm (Rabe-Hesketh, Pickles, & Taylor, 2000).

One of the major limitations of SEM path models is their inability to represent interactions. In fact, this is not a strict limitation, because multiple group methods, models that allow random coefficients for example, gllamm (Rabe-Hesketh, Pickles, & Skrondal, 2003) and a number of other approaches enable these to be considered. Nonetheless, few substantive applications have pursued them. Skrondal and Rabe-Hesketh (2004) describe an enormous range of models that fall within the multilevel and SEM framework.

**Causal Analysis**

Structural equation modeling is often referred to as causal modeling, but although it can provide a framework within which analysis specifically concerned with attempting to isolate evidence for causation can be undertaken, in practice this is rarely done. More often its use is more akin to the methods that we have already described in an earlier section for dealing with confounders, namely of covariance adjustment assuming linearity, although perhaps with the additional sophistication of allowing for measurement error.

There is, however, a quite distinct collection of methods that specifically address causal interpretation (Greenland & Brumback, 2002). We will consider two of these, propensity score weighting and its “double robust” property when used in combination with covariance adjustment, and instrumental variables, which have the capacity to control for unmeasured as well as measured confounders.

**Propensity Score Approach**

Consider the case where, in the population, the effect of X on the outcome Y may be confounded only by measured confounders denoted by Z (where Z is a set of variables). The setting described above is far more general than this approach can tackle. Rosenbaum and Rubin (1983) proposed the propensity score approach for estimating the causal effect of X in this circumstance. For a binary exposure of interest X, the propensity score for a subject is the conditional probability of exposure given the vector of observed confounders Z. Such a propensity score is usually estimated by logistic regression with X treated as the binary response variable and the confounders Z as the predictors. It can be shown that the point estimate of the effect of X from an analysis that also includes the propensity score, or better still matches and stratifies on the propensity score (Rosenbaum, 2002), gives unbiased
estimates of the exposure effect under a wider range of conditions than an analysis that covaries for all the variables in Z. For example, if these have greater variability, or different patterns of correlation in one exposure group than another, as in Fig. 9.3, then direct covariate adjustment would increase the bias or even overcorrect.

An alternative way of using the propensity score idea, proposed by Robins and Rotnitsky (1995), is to weight individuals by the inverse of the probability of experiencing the exposure that they did (i.e., 1/propensity score for those that were exposed and 1/(1 – propensity score) for those that were not). In this weighted sample the exposure of interest is no longer correlated with the possible confounders Z and near standard analysis of such a weighted sample, a so-called marginal structural model (MSM), gives estimates of the effect of X unconfounded with the effects of Z.

The analysis thus consists of fitting the usual models for the effects of X on Y (e.g., linear or logistic regression), but with subjects weighted by weights \( w_i \). This must be performed within a procedure that recognizes these weights as probability weights and requires that the procedure calculates the standard error, and thus \( P \) values and confidence intervals, using the sandwich or robust estimator (Binder, 1983; Huber, 1967) or some other technique (such as bootstrap) that recognizes that, although a subject may be assigned a weight of two, they nonetheless can be expected to possess the variability of a single subject.

Both the propensity score and MSM models require that the propensity score model be right. This means that we tend to err on the side of more rather than fewer variables in the set Z for estimation of the propensity scores. However, we may also include possible confounders as covariates in the model for the outcome. This then provides what Robins refers to as “double robustness,” meaning that our estimate for the causal effect of X should be unbiased by confounders if either our covariate adjustment or the propensity score equation is correct – we do not need both to be correct.

In a longitudinal study we will commonly be concerned with a time-dependent exposure, \( X_0, X_1 \ldots X_K \), where we might wish to estimate the effect of a cumulative exposure. With exposures confounded with \( Z_0, Z_1 \ldots Z_K \) then we can again use weights for the probability of exposure, but now the weight’s denominator is the conditional probability that a subject experienced their particular exposure history.

In the single period case, the practical advantage of the MSM approach over more routine covariate adjustment is not obvious. However, in the multiperiod time-dependent case, the advantage of the MSM approach is clearer. Both approaches attempt adjustment for \( Z_0 \) where \( Z_0 \) is a confounder for later exposure. However, adopting the simpler covariate adjustment approach erroneously controls for the effect that earlier values of the exposure have on \( Z_0 \) (i.e., the value of the confounder during period k). Thus, it would also wrongly partial out causal effects that should be attributed to the exposure. An example is the study of the effect of antiretroviral therapy (the exposure) and CD4 counts (the confounder) on the risk of acquired immunodeficiency syndrome (Cole, Hernan, Robins et al., 2003). We have yet to see such methods used in child psychiatry.

**Instrumental Variables**

The approaches described above require full information on all the confounders of the causal effect of the exposure of interest because these are needed to define the propensity score or the inverse probability weights. Almost always there are numerous possible confounders that we simply have not measured. How then do we proceed?

A way to deal with unmeasured confounding involves having data on a variable R that precedes and is related to exposure but is not directly related to the outcome or the unmeasured confounders (Fig. 9.7). A variable with these properties, if it exists, is said to be an “instrument” for the unbiased estimate of the causal effect of the exposure. If all relations are linear, then the instrumental variable estimate of the causal effect is the ratio of the coefficient in the regression of Y on R to the coefficient in the regression of X on R. With adjustment for measured confounders and multiple instruments the estimation is more complex, although programs are commonly available.

The main problem with this method is that it is rare to identify good instruments. Most examples exploit the occurrence of “natural experiments.” Examples include using the Vietnam draft lottery number to examine the effects of traumatic event exposure (Hearst, Newman, & Hulley, 1986) and geographical variation in treatment provision to assess treatment impact on autism (Lord et al., 2006).

More recent novel applications include an example of Mendelian randomization. In this approach (presumed) functional genes are used as instruments for phenotypes thought to cause certain diseases (Davey Smith & Elrhum, 2005). Genotypic variation in the enzyme alcohol dehydrogenase makes some people drink much less alcohol (it becomes an unpleasant experience) while having no apparent direct effect on other behaviors, such as sociability, aggression or smoking. It thus provides a source of variation in alcohol consumption that is uncorrelated with many potential confounding variables. It has therefore been suggested as an instrument for studying the causal effects of alcohol on depression, antisocial behavior and even blood pressure.

Of course, the most obvious source of an instrument is from deliberate randomization within an actual experiment. In this context, the approach is becoming increasingly popular. The standard intention-to-treat estimator estimates the average effect of the treatment for everyone who was assigned for...
treatment, ignoring whether anyone actually took any of the treatment to which they were assigned or not. This declines in interest as the proportion of non-compliers with treatment increases, and we may want to know what the treatment effect would be on those who would take it if offered. Provided that the effect of being randomized to treatment was to increase exposure to the treatment of interest (and that certain other assumptions are met; cf. Dunn, Maracy, & Tormenson, 2005), then a causal effect is estimable using instrumental variable methods. However, the more complex assumptions and interpretation required for such an effect estimator means that it should supplement rather than replace the standard intention-to-treat estimate.

**Reporting Results**

Although statistical modeling may be increasingly used as the principal analysis tool, authors should nonetheless be expected to present tables and figures that display the essential features of the data in as raw a form as possible. For the reporting of results from trials sensible guidelines exist (e.g., CONSORT), while for epidemiological studies such guidelines are only now being drafted (e.g., STROBE). Estimates of effects should be reported in both standard form and in other ways that help interpretation. Mention has already been made of number-needed-to-treat for describing treatment effects. In observation studies, where causal interpretation is felt justified, quantities such as population attributable fraction (the fraction of cases that could be avoided if the risk exposure could be eliminated) can be helpful. More generally, comparing and describing results based on continuous-variable analysis and discrete/group based analysis is to be encouraged, because these two approaches offer quite different insights and strengths and weaknesses (Pickles & Ángold, 2003).

As far as possible, results should present both the evidence for and against the principal conclusions. In this respect, we have mentioned how estimates and confidence intervals are preferred to significance levels alone.

**Conclusions**

This chapter has highlighted just some of the careful considerations required in undertaking, interpreting and reporting analysis. The chapter does not provide an exhaustive overview of statistical methods and there are many useful and important tools that we have omitted; for example, measures of diagnostic validity and reliability (see e.g., Dunn, 2000). The principal message is that statistical science is not a set of recipes, nor a set of hurdles that must be jumped to get to publication, but a set of concepts and principles whose application delivers better science.

**Further Reading**

**References**

For better or for worse, money is always just below the surface in policy and practice discussions. Although the professional delivering one-to-one therapy, prescribing a course of medication or arranging a group activity might not have to be concerned about the associated costs, further along the management chain someone will be watching expenditure levels and trying to balance the books. While the budget holder may be focused on avoiding a financial deficit at the end of the year, someone higher up in the health, education or social services system will need to consider wider strategic options and will be looking to achieve best value for money in the use of available resources. If a new treatment (such as a new drug or new mode of family therapy) is introduced – and known to be effective – budget holders will want to know whether it is affordable and worth what it costs to provide. If needs and their consequences are enduring, governments will want to know the associated long-term expenditure implications and how to contain them.

The underlying challenge common to all of these wants is scarcity: there are never enough resources to meet all of society’s needs. This is the most fundamental, pervasive, durable and indeed important justification for a better understanding of the economics of child and adolescent mental health. Scarcity is an endemic, indeed permanent feature of all health and related systems and is the reason why choices have to be made between alternative uses of a particular resource or service. As we shall see, those choices between alternative uses give meaning to costs. Economics – and, in particular, economic evaluation – aim to provide evidence to inform both professional practice and strategic decisions about how to allocate available resources so as to get more out of them (in terms of – for example – better outcomes for children and families, or a fairer distribution of access or use of services), and about the incentives needed to help achieve those allocations.

Although the primary aim of any mental health system is to alleviate symptoms so as to improve personal functioning and promote quality of life, it is increasingly recognized that pursuit of such a laudable fundamental objective cannot proceed without regard for the economic consequences of the therapies, support arrangements or broad policy strategies put into place. Awareness of this need to improve not only the effectiveness, but also the cost-effectiveness of health care (and other sector) interventions and actions has produced various demands for economic evidence. There are requests for measures of the overall resource or cost impact of a particular health problem (often called cost-of-illness studies). There are demands for cost-effectiveness and similar analyses of particular treatments or policies, carried out either alongside trials or independently: these are evaluations that compare not only the outcomes of different interventions, but also the costs of achieving them. There are searches for new service and system reconfigurations that can improve the efficiency of use of available resources. And there are searches for improved incentive structures that could positively alter the ways that resources are deployed.

By way of illustration, Fig. 10.1 offers a highly simplified framework within which to locate some of these demands. Figure 10.1(a) is a selection of some of the many available interventions, some of the outcomes that could result from them and some of the long-term cost implications. The links between the first and second columns are the concerns of any treating professional: they want to know what are the effects of different therapeutic arrangements on the well-being of children and families. The links between the second and third columns are of particular interest to budget holders and governments: will better health and functioning reduce needs for services, and with what cost savings? Figure 10.1(b) shows the associated economic questions and how these are connected to the basic “clinical” concerns in Fig. 10.1(a). Figure 10.1 is therefore a hypothesis map: it points to the questions that tend to dominate the economics agenda in the child and adolescent mental health area – cost, cost-offset (comparing amounts expended with amounts saved) and cost-effectiveness – and each has associated with it a number of questions about incentives and disincentives. These concepts are introduced, defined and illustrated in this chapter.

**Costs in Childhood**

Mental health problems – if they are recognized and respond to – have cost implications. The most obvious effect will be on health service utilization, but there may be contacts with special education, social work, public housing, criminal justice...
and other service-delivering agencies. Indeed, the multiplicity of contacts and services is a marked characteristic of well-developed child and adolescent mental health systems (Glied & Evans Cuellar, 2003). If needs or problems are not appropriately treated, then there could be adverse effects on functioning, with implications for educational engagement and attainment, employment and income (in later years), as well as effects on families. A number of studies have described these costs during childhood and adolescence. For example, a small pilot study in London estimated the broad cost implications for services, families and the wider economy of childhood conduct disorder (Knapp, Scott, & Davies et al., 1998). Over a 1-year period these costs averaged £15,282 per family (range £5,411–40,896, up-rated to 2004–2005 prices). The financial impacts fell quite broadly across different sectors. In fact, although the children in this pilot study were all diagnosed as having a health problem and all were, at the time, being treated by specialist child mental health services, only 16% of the total cost fell to the National Health Service (NHS).

Romeo, Knapp, & Scott et al. (2006) offer a more recent estimate of costs for a similar group of children, again from south London. Eighty children aged 3–8 years referred for severe antisocial behavior to child and adolescent mental health services were found to use several services as a result of their severe antisocial behavior, provided by the NHS, education and other public sector services. There were also considerable non-service costs within the family. Mean annual cost of care was £5960 (ranging from as low as £48 for one child, to a high of £19,940 for another). Almost half of this total was borne by the family (Fig. 10.2). What this and the earlier study both show very clearly is the breadth of economic impact across a variety of service sectors and on families, although they can only measure what is provided (in terms of service-related costs) or what impacts are recognized (in terms of indirect costs).
We shall see in the next section that if behavioral problems in childhood or adolescence are inadequately addressed, then there are also likely to be substantial long-term costs stretching into adulthood.

A third example points to the high and enduring costs of autistic spectrum disorder. Patching together data from a number of UK studies, combined with estimates of prevalence, Järbrink and Knapp (2001) suggested that the lifetime cost of someone with autism and intellectual disability would be more than £4 million at today’s cost levels. Three-quarters of this amount is for living support (particularly special accommodation) and another one-eighth of the total is for day activities. Family inputs were not properly measured in this study, but there are a range of formal services included, such as special education, hospital services and voluntary support.

The extent to which the resource (cost) consequences of childhood or adolescent mental health problems fall outside the health sector will obviously depend on how that and neighboring sectors are organized and configured: different boundaries between health, social services, education, housing and other service sectors will mean redrawing the cost map. However, it will not change the fact that many young people with mental health problems have needs in multiple life domains, each of them with economic ramifications. Foster, Jones et al. (2005), for example, describe the economic implications of conduct disorder among adolescents in four US communities over a 7-year period. The cost difference between youths with and without conduct disorder was nearly $70,000. The distribution of costs between budgets was different from in the UK, partly because of differences in system structures.

These multiple impacts are obviously hard to measure, and much harder still to factor into decision-making. Not only does the decision-maker in, for example, the health sector need to find out the implications of their actions for other sectors, whether positive or negative, but they also have to think through the mechanisms needed to do something about them. A major problem in many systems is “silo budgeting”: resources located

![Fig. 10.2 Costs of children with persistent antisocial behavior. Total cost excluding benefits averaged £5960 per child per year, at 2000–2001 prices (benefits = £4307). From Romeo, Knapp, & Scott (2006).](image)

**Costs Continuing into Adulthood**

It is well known that mental health problems experienced in childhood or adolescence can have many and often serious adverse effects on psychosocial outcomes such as crime, relationships, substance misuse and on quality of life. Many studies have traced these connections between behavioral and emotional problems in childhood and adverse experiences of various kinds in adulthood (see chapter 13).

Many of these adulthood problems and experiences will have measurable cost consequences, and while any computed monetary indicators cannot hope to represent or cover the full set of experiences of individual children and adults, they have the virtue of expressing some of these experiences in magnitudes that are readily understood by those key policy-makers who hold the purse strings.

A few studies have explicitly explored the connections between childhood disorders and adulthood economic consequences. These latter include unusually high rates of utilization of health and other services (obviously with personal and societal costs), and impacts related to employment (such as not being economically active, being active but unemployed, being employed but frequently absent or unproductive, or working in a lower status occupation than would otherwise be expected). The latter will inevitably have impacts on earnings and could lead to individual and household poverty. Three examples can be offered.

**Evidence from the Inner London Longitudinal Study**

The Inner London Longitudinal Study collected data on 2281 10-year-olds in 1970 and selected 228 of them for intensive study: a random 1 in 12 sample of the population and a 1 in 2 sample of children with emotional or behavioral problems (Maughan, 1989). This group was interviewed again at age 28. Neither interview set out to collect “economic” data as such, but it was possible to construct service-related costs from the information gathered (Scott, Knapp, Henderson et al., 2001). Nevertheless, the computed cost averages are
CHAPTER 10

undoubtedly underestimates of the full costs because the data collection did not cover all possible issues and did not follow people continuously over time. Among the costs not measured were those associated with social work, voluntary sector service use, primary health care contacts, lost employment, divorce, undetected crime, the effects of crime on victims, the emotional impacts on other people and other transmitted effects to other family members or children. Many of these omissions are known to be substantial (see the other studies below). Notwithstanding these missing elements, conduct disorder in childhood (which was found for the most antisocial 3% of the population studied) and conduct problems (which were found for the next 9%) led to greatly elevated costs in adulthood for a number of agencies, and especially for the criminal justice system.

The links between conduct problems and conduct disorder in childhood and service-related costs in early adulthood were further explored through multiple regression analysis, adjusting for gender, parental social class, reading age and number of primary schools attended. A number of other factors were examined, but found not to be significant. Adjusting for those covariates, the estimated coefficient on the conduct disorder variable—the additional cost between the ages of 10 and 28 (aggregating across all 18 years) of having conduct disorder at age 10 compared to not having any antisocial behavior problems—was £45,784 (at 2004–2005 prices). The additional cost of having conduct problems (those who were less severely affected by antisocial behavior—the next 9% of the group) compared to having no such problems was £17,017. Given the underdeveloped and under-resourced nature of child and adolescent mental health services in the early 1970s, these cost differences might be interpreted as indicative of the economic consequences of not addressing (or inadequately addressing) antisocial behavior among 10-year-olds.

Evidence from the Maudsley Depression Study

The Maudsley long-term follow-up study of child and adolescent depression illustrates the persistent costs of comorbidity. It gathered data from people who attended child psychiatric services in south London for depression. They were followed up as adults—on average 21 years after they had been treated as children. All 149 people in the sample had received treatment for childhood depression; 53 of them had also been diagnosed with conduct disorder (Fombonne, Wostear, Cooper et al., 2001). The childhood and adulthood collections of data were made at a variety of ages. For those 140 people for whom all relevant data were available, costs of health, social care and criminal justice service use in adulthood were calculated. Mean annual cost in adulthood was £1219 (2004–2005 prices; Knapp, McCrone, Fombonne et al., 2002). The range was wide—from zero to £10,318. General hospital and psychiatric hospital costs accounted for just over half of the total.

Adjusting for an individual’s circumstances and morbidity at the time of their treatment as a child or adolescent showed that a number of factors were significant predictors of higher adulthood costs (McCrone, Knapp, & Fombonne, 2005):

- **Age at first contact with psychiatric services** Younger age was associated with lower adulthood cost.
- **Anxiety in childhood** A higher level of anxiety was associated with higher adulthood costs.
- **Peer–sibling relationship** Children with more difficulty with such relationships had lower adulthood costs, although it is not absolutely clear how to interpret this finding (one possibility is that it might be masking greater isolation in adulthood, resulting in lower rates of service use).
- **Comorbid conduct disorder** Individuals with both depression and conduct disorder had much higher adulthood costs than those with depression alone (the difference being more than £900 per annum).

These findings demonstrate how antisocial behavior among a juvenile group with affective disorders carries an elevated risk of subsequently high service use, even after adjusting for other factors. Moreover, the comorbid group had much higher utilization rates for out-patient care, in-patient care and prison stays; in contrast, the group with depression (alone) did not make higher use of any services than would be expected for the general population.

### Evidence from the Cambridge Study of Delinquent Development

The final example, again from a London sample, points to a wider set of undesirable economic consequences, in this case stemming from poor labor market attainments in early adulthood. The Cambridge Study in Delinquent Development (CSDD) sampled 411 boys born 1952–1954 (predominantly born into a working class environment) and has reinterviewed most of them eight times since, most recently at age 48 (Farrington, 2001). Healey, Knapp, & Farrington (2004) looked at the links between “troublesome behavior” in childhood and poor employment experiences (unemployment, low status employment, low earnings) at ages 18–19 and 32.

In childhood, sample members were described as “troublesome” (or not) based on peer and teacher ratings of behavior at school at age 8–10. A “troublesome” boy was one in the lowest quartile of the behavioral ratings distribution. In adolescence, a boy was defined as “delinquent” if he had a criminal conviction between the ages of 10 and 16, with data taken from the Criminal Records Office. Thereby, four mutually exclusive groups could be defined: troublesome and delinquent; non-troublesome and delinquent; troublesome and non-delinquent; non-troublesome and non-delinquent.

Among the findings from this study, childhood antisocial conduct at age 8–10 (being a troublesome boy) was associated with an increased risk of teenage unemployment and employment instability, although less strongly linked to poor employment outcomes identified at age 32. Antisocial tendencies that persisted from childhood and through adolescence (troublesome and delinquent) were strongly associated with a lower probability of employment participation at age 32, with long-term periods of unemployment in their late 20s and early 30s, and a persistent absence of success in the labor
market (lack of employment participation and/or low pay job status at ages 18 and 32).

Antisocial tendencies (troublesome and delinquent) were not associated with lower weekly earnings at age 32, which may be partly a result of a wage ceiling effect for this particular cohort, given that they came from a fairly narrow socioeconomic background. Nevertheless, the link between antisocial development and expected earnings from employment was marked: weekly earnings (calculated at 1985 wage levels but inflated to 2004 levels) adjusted for the probability of unemployment were £205 for those described as troublesome delinquents, but £301 for the rest of the cohort.

These associations are adjusted for covariates. For example, both poor school-leaving outcomes and subsequent adult convictions appeared to be important mediating factors behind these less favorable employment outcomes. Around 89% of the “troublesome delinquent” group did not study for or pass any school examinations, compared to 47% of the remainder of the cohort. Over 85% of this same group went on to receive a criminal conviction between ages 17 and 32 compared to only 26% of the remaining boys, receiving on average around five criminal convictions during their adult years up to age 32.

Cost-Offset Considerations

A question that governments and other macro-level decision makers often want answering is whether investment in preventive measures or better treatments during, say, the early years will pay off in terms of reduced economic impacts in adolescence and in later years. This is what economists would call the cost-offset question: it asks about the balance between amounts expended and amounts saved.

An example comes from the well-known Fort Bragg Demonstration (Bickman, Guthrie, Foster et al., 1995). The initial evaluation of the Demonstration, which introduced a continuum of care for children and adolescents with mental health problems, looked only at direct program costs narrowly defined. Subsequently, Foster and Bickman (2000) calculated a broader measure of costs, including mental health services used outside the catchment sites, other medical services used by children and services used by family members. The higher program costs of the Demonstration were found to be partially offset by reduced expenditures in these other sectors.

An earlier Swedish study by Gustafsson and Svedin (1988) looked at family therapy for children with psychosomatic or somatic disorders and its cost-offsetting properties. The calculated total cost of introducing the treatment was balanced by savings in in-patient stays for the children concerned. This and the Fort Bragg example, together with a few other studies, focus on the immediate potential for investment in a child or adolescent mental health service to “pay for itself” by reducing the need for other services.

There have also been studies that have looked at the long-term cost-offsetting properties of such investments. Cohen (1998), for example, looked at “high-risk youth” in the USA and the potential economic advantages from “saving” each individual by estimating costs over the lifetime associated with crime, drug misuse and dropout from school. The estimated monetary value of “saving each high-risk youth” was estimated to be between $1.7 million and $2.3 million. Cohen’s study was based on hypothetical valuations, whereas a second example – the HighScope Perry Preschool Study – was based on direct observations. Although not focused on children with mental health problems, this well-known and uniquely effective intervention is interesting and has been quite influential because of its finding of substantial savings in relation to crime, education and welfare payments, as well as higher taxes paid by those people who went through the preschool program (see, e.g., the summary by Schweinhart, 2004). However, these findings relate to a very small sample of individuals, and generalization from this study is far from straightforward.

In the UK, a recent report by Dretzke, Frew, Davenport et al. (2005) summarizes much of the evidence on the effectiveness of parent training programs for conduct disorders, and provides estimates of the cost of such programs (2005 prices):

• Group community-based settings Cost £633–944 per child, depending on group size.
• Group clinic-based settings Cost £444–660 per child, depending on group size.
• Individual home-based settings Cost as much as £4030 per child.

These estimates are higher than those suggested by previous authors in the USA and UK, but still look quite modest when compared with some of the estimates offered earlier in the chapter for the adulthood economic consequences of conduct disorder, measured in terms of health and social care service use, criminal justice system contacts, unemployment and earnings. In other words, there is again the strong suggestion that expenditure in childhood or adolescence in response to identified mental health needs will be more than matched by later savings because of reduced rates of use of a range of services.

Exploring Cost-Effectiveness

Knowing the costs in childhood associated with mental health problems helps decision-makers to gauge the overall societal impact of these conditions. Knowing what economic consequences these problems lead to in adulthood helps those same decision-makers focus their minds on the need for better preventive or treatment interventions in early years or subsequently. But neither of these bodies of evidence can tell a decision-maker how to make better use of available resources. For this purpose it is necessary to examine both the costs and the outcomes of different uses of those resources. This is what economists would recognize as the examination of cost-effectiveness.

Consider what happens following the development or introduction of a new treatment (say, a new medication intended...
CHAPTER 10

for treating childhood depression. Decision-makers face two
central questions when considering whether to use or recom-
mend this new drug as part of the treatment range. The
first is the clinical question: is the medication effective in al-
leviating depressive symptoms and generally improving child
health? Or, when considering two or more different drugs,
which of them has the better outcomes? If the question to
the clinical question is that the new medication is worse than
existing treatment options, then there is usually no need to
consider its use any further. However, if the new medication
looks equally or more clinically effective, the decision-maker
will then want an answer to a second question: is it cost-
effective? That is, does the treatment achieve the improved or
equivalent child outcomes at a cost that is worth paying?

These two questions (Is the treatment effective? Is it worth
it?) sit at the heart of cost-effectiveness analysis. It is import-
ant to emphasize that cost-effectiveness analysis does what
it says: it looks at both costs and effectiveness (outcomes).
Comparing the costs of one intervention with the costs of
another, without any evidence on outcomes, might be inter-
esting but does not constitute an economic evaluation be-
cause it does not provide enough information to assist service
professionals, managers or others to make choices between
alternative uses of their scarce resources. Similarly, calculating
the costs and outcomes of a single intervention could be reveal-
ing, but again is not especially helpful (and not an economic
evaluation) unless comparison is made with equivalent data
for another service, for otherwise the decision-maker will have
no benchmark against which to judge whether the observed
costs and outcomes are attractive.

Note that the second question in a cost-effectiveness anal-
ysis asks whether improved outcomes are “worth” the extra
cost. Deciding what is or is not “worth” the cost is far from
straightforward and not without controversy, as discussed
below.

There are different variants of cost-effectiveness that can
be applied to decision-making in health and related contexts.
They share a common approach to the conceptualization,
definition and measurement of costs, but they adopt different
approaches when considering and measuring the outcome
side of the evaluation, primarily because they seek to answer
slightly different questions. There is, however, some potential
for terminological confusion. The term “cost-effectiveness” is
used to describe a specific variant of economic evaluation as
well as to refer generically to the group of all such evalu-
ations. In this chapter I am using the term in its generic sense,
unless specifically stated to the contrary.

Question and Perspective

The choice of evaluative approach therefore depends on the
question to be addressed. If the question is essentially clinical
– what is the most appropriate treatment for a child with par-
ticular needs in particular circumstances, and whether to opt
for one therapeutic package or another – then information is
needed on the comparative costs of the different therapies and
the comparative outcomes measured in terms of symptom
alleviation, improved functioning and so on. In these circum-
stances, a cost-effectiveness analysis (in the narrow sense of
the term) would be appropriate and sufficient (see p. 129).

If, to take a broader stance, the question is whether to invest
available health system resources to treat either childhood
depression or asthma, then decision-makers again need to know
the relative costs of the two alternatives, but they now need
a measure of effectiveness that uses a common metric across
the fields of depression and asthma. The most commonly
such employed measure is “utility,” generated from health-
related quality of life scales (see p. 130). In these circumstances
a cost–utility analysis is needed (see p. 130).

To widen the perspective even further, if the question is
whether to invest more money in the health system or more
money in improving transport, launching a new environment-
mental policy or bolstering a country’s defense forces, then
the research question becomes one of asking what are the com-
parative costs and merits of the different investment options,
where “merit” will now need to be measured in a common
unit across all of these broad areas of public policy. The usual
choice of broad measure is monetary, leading to cost–benefit
analysis (see p. 130).

The choice of question clearly influences the type of evalu-
ation needed, but the choices are not mutually exclusive: a
single study could support more than one type of analysis.
A body of evidence that is well located within the clinical
domain will be exactly what the treating professional needs
but may not be appropriate for a higher level decision-
making body, such as a health ministry. The broader the
research question, the more demanding are the data needs:
brutally summarized, cost–benefit analyses are harder to do
than cost–utility analyses, which in turn are more difficult than
cost-effectiveness analyses.

Linked to the specification of the question to be addressed
is the perspective to be adopted. Is the evaluative information
needed to help resource allocation within a particular agency
(such as a child and adolescent mental health service) or within
a particular system (such as the health care system or educa-
tion system) or within the whole society? The breadth of per-
spective will determine the breadth of both the measurement
of costs and the effectiveness or outcomes.

Cost Measurement

There are a number ways to categorize the costs associated
with mental health problems. There are direct costs associated
with the treatment services and associated supports, some of
them delivered by non-health agencies. There are also indi-
direct costs, which may fall to families, or may be measured
in terms of lost productivity because of future disruptions to
employment patterns. There may also be some unmeasured
costs, perhaps reflecting the burden carried by family members,
or societal concerns about antisocial behavior. In evaluations,
the usual approach is to try to measure these elements as long-
run marginal opportunity costs (Knapp, 1993). This helps to
ensure that a long-term perspective on resource implications
is employed, that only those effects on resources attributable
to the program or service user are counted, and that costs are reckoned as opportunities forgone, not just money expended. How broadly the costs are measured will depend upon the perspective taken for the evaluation, which in turn depends upon the purpose of the study.

In carrying out evaluations in practice, the economist would be looking for data on service use patterns from one or more source. The data might come from organizational “billing” systems, recording the amounts that are transferred between a payer and a provider for services used by individual children or families. This is a common approach in US research, for example. In care systems without such payment mechanisms, there might nevertheless be routine information systems that record service contacts and referrals, which might provide the necessary data for an evaluation. However, in many countries there are no billing data, and organizational information systems may be rudimentary or inaccurate to provide the basis for cost calculation. In these circumstances, the usual approach is to collect information on patterns of service use through interviews with family members or service professionals (for which there are a number of tools, including the Client Service Receipt Inventory; Beecham & Knapp, 2001).

To the service use levels generated by information systems or from interviews the researcher would then attach unit cost estimates for each service (Beecham, 2000). It is not always necessary to calculate these unit costs anew. In England, for example, there is an excellent annual compendium of such unit costs which is very widely used in applied research (Curtis & Netten, 2006). This method of service use data capture (using a version of the Client Service Receipt Inventory and then attaching unit costs mostly drawn from the published annual compendium) was the approach employed in the two London cost-of-illness studies for antisocial behavior described on p. 124, whereas Foster and Bickman (2000), in their Fort Bragg study, were able to use records of financial transactions from local agencies.

Non-service costs are harder to measure than service costs, partly because of the difficulty of identifying the impacts (e.g., on parental employment patterns, or on a child’s own future earning capacity) and partly because of the difficulty of then attaching a monetary value. (For further discussion of these issues see Brouwer, Rutten, & Koopmanschap, 2001; Johnston, Buxton, Jones et al., 1999.)

**Effectiveness Measurement**

Probably the most intuitive mode of economic evaluation is cost-effectiveness analysis (CEA), now using the term in its narrower sense. It measures costs as set out above, and measures outcomes using instruments and scales familiar from clinical studies, because its focus is symptoms, behavior functioning, peer-group integration and so on. A CEA is employed to help decision-makers choose between alternative interventions available to or aimed at specific patient groups. An analysis would look at a single outcome dimension – such as change in a behavioral measure, or symptom-free days or self-esteem – and would then compute and compare the ratio of the difference in costs between two treatments to the difference in (primary) outcome (the so-called incremental cost-effectiveness ratio). For example, an evaluation of a home-based social work intervention for children and adolescents who have deliberately poisoned themselves by Byford, Harrington, Torgerson et al. (1999) measured suicidal ideation, hopelessness and family functioning as the main outcomes, and health, education, social care and voluntary sector services as the basis for cost measurement. Their randomized controlled trial, involving 162 children aged 16 years or under, found no significant difference in the main outcomes for costs, although parental satisfaction with treatment was significantly greater in the group that received a new social work intervention compared to those who received routine care.

A second example of a cost-effectiveness analysis is provided by Cunningham, Bremner, & Boyle (1995) who compared a large community-based parenting program for families of preschool children at risk of disruptive behavior with a clinic-based individual program. Among their outcome measures they chose adherence, behavior problems at home and child behavior more generally; their cost measures included the direct costs of the program plus costs associated with using other education and health care services. The community groups were found to report better outcomes, but they cost marginally more than the individual program.

An obvious weakness with the strict cost-effectiveness methodology is the focus on a single outcome dimension (in order to compute ratios) when people with mental health problems often have multiple needs for support and when most clinicians would expect to achieve improvements in more than one area. For this reason, cost-effectiveness ratios are sometimes computed for each of a number of outcome measures. This is sometimes called cost-consequences analysis. It has the advantage of breadth but poses a challenge if two or more ratios point to different interventions as the more cost-effective: in these circumstances, the decision-maker must weigh up the strength of evidence.

**Making Trade-offs**

Many evaluations of new interventions find them to be both more effective (the outcome profiles are better than for old or current interventions) but simultaneously more expensive. For example, the Cunningham, Bremner, & Boyle (1995) study found that a group-training program had better outcomes but slightly higher costs than an individual program. How is the trade-off to be made between the better outcomes and the higher expenditure necessary to achieve them?

The net benefit approach seeks to explicate the nature of the trade-off. It is most commonly seen today in the construction of cost-effectiveness acceptability curves (CEACs). These constructs show the probability that a new intervention will be cost-effective for each of a number of prespecified or implicit valuations of an outcome improvement by the decision-maker. To date, there is no published application of the use of the CEAC approach in child and adolescent mental health.
studies, but the technique has been highly instructive in other areas. An example that illustrates the approach would be the study by McCrone, Weeramanthri, Knapp et al. (2005) of computer-delivered cognitive–behavioral therapy (CBT) for anxiety and depression (among adults). These authors found the computer-delivered CBT to be more expensive in health service terms than standard primary care services, but also more effective in reducing depressive symptoms and anxiety. The fitted CEACs showed that, even if the value placed by society on a unit reduction in the Beck Depression Inventory was as little as £40, there was an 81% probability that the computer-delivered CBT would be viewed as cost-effective. Similarly, assigning a societal value of just £5 to each additional depression-free day would result in an 80% probability that CBT would be cost-effective. The advantage of the CEAC approach is that it makes transparent the trade-offs faced by decision-makers.

Utility Measurement
An increasingly commonly used evaluative mode that seeks to reduce outcomes to a single dimension is cost-utility analysis (CUA), which measures and then values the impact of an intervention in terms of improvements in preference-weighted, health-related quality of life. The value of the quality of life improvement is gauged in units of “utility,” usually expressed by a combined index of the mortality and quality of life effects of an intervention. The best known and most robust such index is the Quality Adjusted Life Year (QALY).

CUAs have a number of distinct advantages, including using a unidimensional measure of impact, a generic measure which allows comparisons to be made across diagnostic or clinical groups (e.g., comparing psychiatry with oncology or cardiology), and a fully explicit methodology for weighting preferences and valuing health states. But these same features have sometimes been seen as disadvantages: the utility measure may be seen as too reductionist; the generic quality of life indicator may be insufficiently sensitive to the kinds of symptom and functioning change observed for people with mental health problems, and effects of methylphenidate and placebo for treating hyperactivity. Costs were calculated based on the assumption that all follow-ups would be hospital-based. Non-responders and those terminating treatment would be treated on average for 6 weeks. There would be an average of five out-patient attendances in the first year of treatment, followed by 3-monthly routine appointments. The authors acknowledged the methodological limitations of the framework used in the study, but concluded that the short-term treatment of hyperkinetic children with methylphenidate may be cost-effective. Gilmore and Milne used a cost-utility framework to structure their hypothetical model. They calculated a cost per QALY of between £7446 and £9177, depending on the severity of disorder. However, the unproven validity of currently generated QALY estimates in the child and adolescent mental health field leaves this finding as, at best, tentative.

The quandary that faces researchers and decision-makers in the UK today, and in some other countries that have chosen a strategic evidence-based approach to resource allocation in the health system, is that a generic outcome measure such as the QALY, when combined with cost estimates, can point to ways of achieving improved value for money, but if that QALY measure does not reflect the underlying effectiveness changes in the field, then it must surely be of very limited usefulness.

Benefit Measurement
Cost–benefit analysis asks whether the benefits of a treatment or policy exceed the costs. This would allow decision-makers to consider the merits not only of allocating resources within health care, but also of considering whether it would be more appropriate to invest in other sectors such as housing, education or defense. In this form of evaluation, all costs and outcomes (benefits) are valued in the same (monetary) units. If benefits exceed costs, the evaluation would provide support for the treatment, and vice versa. With two or more alternatives, the treatment with the greatest net benefit would be deemed the most efficient. Cost–benefit analyses are thus intrinsically attractive, but conducting them is especially problematic because of the difficulties associated with valuing outcomes in monetary terms.

Comparing costs incurred (e.g., on treatments) with costs saved (e.g., on future health services no longer needed) is not a cost–benefit analysis but a cost-offset comparison. This confusion is unfortunately still quite common. A cost–benefit analysis must measure outcomes (in terms of improved health or improved quality of life) and then convert them to monetary values. Consequently, studies such as that by Jacobson, Mulick, & Green (1999) of an early intensive behavioral program for children with pervasive development disorder or
autism, which compared the costs of the intervention with cost savings into adulthood, are certainly interesting but not as helpful as studies that compare the costs and the outcomes of interventions.

The problem is that attaching values to the outcomes of child and adolescent mental health interventions is inherently complicated. Recent methodological advances in health economics may offer a way of obtaining direct valuations of health outcomes by patients, relatives or the general public. These techniques ask individuals to state the amount they would be prepared to pay (hypothetically) to achieve a given health state or health gain, or they observe actual behavior and deduce the implicit values (Olsen & Smith, 2001). They are likely to be quite difficult to apply in mental health contexts.

Another approach, which is beginning to be used more and more often to value health interventions, is “conjoint analysis”: individuals are asked to rank different real world scenarios, which may consist of several dimensions (including, for instance, health outcomes, quality of life, time inputs, discomfort and stigma) and by including cost as one of these dimensions a monetary value can be elicited. While quite complex, the conjoint analysis approach has the advantage of not specifically asking individuals to put a monetary value on health states or health gain, which can make the technique easier to administer than traditional willingness-to-pay studies (Ryan, 1999).

Body of Evidence

There remain very few completed economic evaluations in the child and adolescent mental health field, and a number of those that have been undertaken have some methodological or other limitations. (Among the common problems are small sample sizes, methodological weaknesses and other design issues.) Romeo, Byford, and Knapp (2005) found only 14 published studies that could be described as economic evaluations. One or two others have been published subsequently, and there are certainly quite a number now under way, but this accumulated volume of evidence about such a fundamental issue as the efficient way to use scarce resources is clearly very disappointing. Without such evidence, decision-makers may well take decisions that are utterly inefficient, wasting resources as a result.

How are we to judge the quality of these evaluations? Two immediate checks can be made, one in relation to costs and one in relation to outcomes:

• Have all the relevant costs been taken into account? As we have seen, there are many and various inputs to a broadly defined mental health system – from health, social care, education, housing, social security and other agencies – plus economic consequences in terms of lost productivity, premature mortality and family impact. It might be necessary to measure all of these, depending on the policy or practice question that needs to be addressed and the perspective necessary for the evaluation.

• Are all the dimensions of effectiveness taken into account? Good mental health care is obviously not just about tackling clinical symptoms, but about improving an individual’s ability to function in ways that are valued by them (such as performing well at school and integrating with peers) and of course about promoting quality of life.

Guidelines and quality checklists for health economist researchers and readers of their outputs are available (Drummond, Jefferson et al., 1996), addressing a wider set of issues than the two suggested above.

As well as a limited number of completed evaluations, there must also be concern that most of the completed economic studies have been undertaken in North America, parts of western Europe and Australia. Unfortunately, the results of economic evaluations often do not transfer well from one health care system to another, and therefore not between countries. This is primarily because of differences in the structure of health systems, financing arrangements, incentive structures and relative price levels. There might also be differences in the appropriate choice of comparator: a new therapeutic approach might look attractive compared to current arrangements in one country but not in comparison to what is generally the norm elsewhere. It is unfeasible and certainly unnecessary to carry out an evaluation every time a policy decision needs to be taken, but evidence-based decisions are generally thought to be better than evidence-free decisions. This could mean using the results from a study carried out in another country, updating a previous study or carrying out a modest adaptation to adjust for context.

Looking across the mental health field more generally, the accumulation of new cost-effectiveness evidence has accelerated in recent years. There have tended to be more cost-effectiveness studies in diagnostic areas when new classes of medication are launched because the pharmaceutical industry looks to economic evaluative evidence to support its marketing, and health care funding and delivery bodies also want their own independent evidence. Consequently, in other parts of the mental health territory, many economic studies of depression followed the licensing of the early selective serotonin reuptake inhibitors (SSRIs) and later antidepressants with other mechanisms of action. Similarly, the arrival of the atypical antipsychotics and the cholinesterase inhibitors stimulated much economics research on, respectively, the treatment of schizophrenia and Alzheimer disease.

Conclusions

The starting point for an interest in the economics of child and adolescent mental health is clearly scarcity: it is the recognition that there are not, and indeed there never will be, enough resources available to meet all of the needs of children and families. There is still a notion abroad in some parts of some health systems that incremental growth in budgets will gradually remove all need, but this is surely wildly overoptimistic. We cannot and must not avoid facing up to the choices that have to be made in the face of scarcity. In making those choices we would want our decision-makers to be explicit and transparent about the criteria that they are employing. Are they looking to maximize effectiveness in
terms of symptom alleviation or aggregate quality of life, to redistribute resources to poorer communities within society or to ensure that access to skilled resources is equally available to every family?

Within this set of criteria, cost-effectiveness obviously has a role. The cost-effectiveness criterion should probably be seen as secondary. If, for example, a therapeutic intervention has been shown to be effective in improving the well-being of children and families, and appears to be more effective than currently available therapies, then it would be natural to ask about the relative costs of the two options and to compare those costs with the outcome gains. Balancing outcome improvements with higher costs is, however, quite a challenge. A great many economic evaluations across the health spectrum today find that new therapies (whether pharmacological, psychological or organizational) offer better outcome profiles than currently prevalent interventions, but they do so at higher cost. The decision-maker, whether this is the individual care professional working with children and families, or their line manager and budget holder, or someone near the top of the health ministry, then faces a difficult trade-off: are the better outcomes from the new intervention worth the higher cost of introducing that intervention?

There have been a number of types of request for economic insights in the child and adolescent mental health field. In this chapter I have illustrated some of those, including requests to measure the overall cost impact of a particular disorder or diagnosis (so-called cost-of-illness studies). Second, there are cost-offset studies that compare the amounts expended on interventions with the longer term savings from introducing those interventions. Third, and much the most powerful and useful, are cost-effectiveness studies (using the term generically also to include cost-benefit and cost-utility studies). These weigh up costs and outcomes, and therefore give a more complete and rounded view as to the consequences of introducing different interventions.

The available economics evidence base in the child and adolescent mental health field is disappointingly underdeveloped at present, but more is now being invested in the area, including a number of new studies that will – in time – offer valuable new insights into the resource consequences and cost-effectiveness properties of different interventions aimed at meeting the needs of children and families.

Issues in the Study of Brain Imaging in Children

The study of the structure and function of the human brain was dramatically enhanced by the development of positron emission tomography (PET) and magnetic resonance imaging (MRI) in the last quarter of the last century. These methods are exciting tools for studying the development of brain structure and function throughout the lifespan. They can throw new light on developmental disorders and psychiatric conditions with their origin in childhood. As a result, an increasing number of neuroimaging studies are being published in this field. However, how have the techniques been applied and how do they influence what is being studied? We consider examples of neuroimaging studies in typical and atypical development to illustrate both the promise and the problems of these remarkable new tools.

At the outset we should point out some important limitations of brain imaging techniques often ignored in the over-enthusiastic interpretation of the compelling colored images of brains in action. Any study of abnormality in which brain structure or function in patients is compared with healthy controls is essentially correlational. If we find a significant brain difference we cannot conclude that this difference is the cause of the problem. The brain difference may result from some other factor, which has not been controlled for, or may even be a secondary consequence of the problem.

In studies of brain function, as opposed to brain structure, we can conduct genuine experiments where we can be confident that the condition we have applied is the cause of the change in brain activity. For example, we can be sure that the sight of a face is the cause of brain activity seen in inferior temporal cortex. However, we cannot invert the logic and conclude that activity in inferior temporal cortex can cause the experience of a face. To justify such conclusions we need to manipulate brain activity directly with techniques such as transcranial magnetic stimulation (TMS) or direct electrical stimulation. These issues are discussed later in this chapter.

Brain Imaging Techniques

Structural MRI

MRI is the method of choice for visualizing the structure of the human brain. This method has largely replaced computed tomography (CT) scanning because it has better resolution and does not involve exposure to harmful radiation. By placing the brain in a strong magnetic field and passing harmless, low-frequency radio waves through it, the density of hydrogen (i.e., water) at any point in the brain can be measured. Because the density of water varies systematically between the different components of the brain (white matter, gray matter, cerebral spinal fluid), this measurement builds up an image of the brain with a resolution of approximately 1 mm, which approaches the quality of a photograph of a postmortem brain slice. Such images can be obtained in approximately 15 minutes and can be used to detect changes in volume or shape in specific brain structures as well as to measure the volume of gray and white matter.

The more recently developed technique of diffusion tensor imaging (DTI) visualizes the diffusion of water molecules along white matter tracts. This method permits the tracing of long-range connections between cortical areas and can thus be used to measure anatomical connectivity (Croxson, Johansen-Berg, Behrens et al., 2005). However, the technique only reveals approximate connectivity of bundles of white matter rather than single neurons. Currently, questions about the direction of flow of signals can only be answered from animal studies.

EEG and MEG (see chapter 17)

There are many methods for measuring human brain function, each with particular advantages and disadvantages. It has long been known that the basic units of brain function – the neurons – generate and propagate electrical impulses. The electroencephalograph (EEG) measures this electrical activity directly via electrodes attached to the scalp. This technique can track neural events at very short time intervals, but cannot tell very precisely where in the brain these events take place. Magnetoencephalography (MEG) measures the changing magnetic fields associated with the electrical activity of neurons using detectors placed close to the head. This technique also has very good temporal resolution and somewhat better spatial resolution than EEG, particularly for sources close to the detectors. However, the interpretation of data gathered through both techniques suffers from a fundamental problem. For any pattern of electrical or magnetic activity measured
at the scalp there are many different possible sources of this activity within the brain. This is known as the inverse problem. Methods for solving this problem are currently under development (Mattout, Phillips, Penny et al., 2006). The problem of localizing the source of brain activity does not arise with functional MRI (fMRI).

**PET, fMRI and NIRS**

These techniques use indirect methods for detecting changes in neural activity. They capitalize on the fact that, when neurons become active, they consume oxygen carried by hemoglobin in red blood cells from local capillaries. The oxygen uptake in the blood vessels can be made visible in the scanner, and this uptake reflects neural activity. The more oxygen is detected in a particular region, the greater the neural activity.

The local response to this oxygen utilization is a local increase in blood flow to regions of increased neural activity, occurring after a delay of approximately 1–5 seconds. The precise mechanism by which neural activity causes an increase in blood flow (the hemodynamic response) is unknown. Recent work suggests that most brain energy is used to power postsynaptic currents and action potentials rather than presynaptic activity. Furthermore, the hemodynamic response seems to be driven by neurotransmitter-related signaling and not directly by the local energy needs (i.e., oxygen consumption) of the brain (Attwell & Iadecola, 2002). PET measures changes in blood flow directly via injection of a radioactive tracer. Because of the risk associated with radiation, this method is rarely used with children. In contrast, fMRI is considered safe as it measures changes in blood flow without the need for any tracer. This is possible because the blood flow increase is associated with a change in the ratio of oxyhemoglobin to deoxyhemoglobin with the blood becoming more oxygenated. These two forms of hemoglobin have different magnetic properties so changes in their ratio can be detected by MRI (blood oxygenation level dependent contrast; BOLD). Studies of animals have shown that there is a good correspondence between changes in neural activity and changes in the BOLD signal (Logothetis, Pauls, Augath et al., 2001).

The two forms of hemoglobin also differ in color: red as in arteries and blue as in veins. This color change can be measured by near-infrared spectroscopy (NIRS) using light transmitters and detectors close to the scalp. The value of this methodology for brain imaging is currently being established (Huppert, Hoge, Diamond et al., 2006). NIRS has the advantage of being much cheaper and less cumbersome than fMRI and may prove to be particularly useful in the study of newborn infants because their thin skulls cause less attenuation of the light signal (Bartocci, Bergqvist, Lagercrantz et al., 2006).

EEG/MEG and fMRI are complementary measures in that EEG/MEG tells us where things are happening, but not precisely where they are happening, while fMRI tells us where things are happening, but with a crude time scale of seconds rather than milliseconds. Although technically demanding, it is now possible to acquire data simultaneously in these two imaging modalities. This approach is particularly relevant in the field of epilepsy (Salek-Haddadi, Diehl, Hamandi et al., 2006), because EEG can detect the abnormal epileptic activity and fMRI can localize its source in the brain. However, more frequently, the two techniques are used consecutively in the same participants performing the same task. In general, fMRI can be used to locate the source of the signals, such as spikes, evoked potentials or oscillations detected by EEG/MEG. Temporal resolution is particularly important if we want to understand neural mechanisms and address questions of control when it is vital to know whether activity in one region occurs before or after activity in another region (Bar, Kassam, Ghuman et al., 2006).

**Connectivity**

Until recently, the majority of brain imaging studies have been concerned with localization of function (functional specialization or brain mapping). However, in the long run, understanding how the brain works will depend on revealing the mechanism by which different brain regions interact with one another (functional integration). By measuring correlations across time between neural activity in different brain regions it is possible to show that certain regions are functionally connected. This pattern of connectivity will change depending upon the task being performed by the subject (Sakai & Passingham, 2003). More sophisticated analysis techniques are currently being developed that not only show that regions are functionally connected, but also assess the direction of causality associated with this interaction (Penny, Stephan, Mechelli et al., 2004).

**Chemical Imaging**

The transmission of signals between neurons depends upon chemical messengers (neurotransmitters) rather than electrical signals. Through the use of appropriate radioactive tracers, PET can be used to measure neurotransmitter release and receptor occupancy. This technique has been of great value in the study of disorders, such as Parkinson disease, in which there is a specific loss of the neurotransmitter dopamine (Au, Adams, Troiano et al., 2005). However, the use of radioactive tracers is too risky a technique to apply to children. MRI spectroscopy (MRS) cannot replace PET for the study of neurotransmitters, but it can be used to study other chemical markers of brain abnormality (Frangou & Williams, 1996). For example, the concentration of N-acetylaspartate (NAA) can be measured in brain tissue. This substance is thought to be a marker that decreases in processes where neurons die. MRS has been used to detect metabolic changes associated with abnormal aging (Pettegrew, Panchalingam, Moossey et al., 1988) and also to monitor effects of drug treatment (Satlin, Bodick, Offen et al., 1997). The spatial and temporal resolution of MRS is lower than those of fMRI, and the technique has still to prove itself (Gujar, Maheshwari, Bjorkman-Burtscher et al., 2005). Nevertheless, interesting results concerning developmental disorders are already beginning to emerge (Sun, Jin, Zang et al., 2005). In the future, this technique will undoubtedly provide important new data for the understanding of abnormal brain development.
CHAPTER 11

Genomic Imaging
There is increasing interest in studying genetic factors in brain function by looking at correlates of allelic variation (see chapter 23). For example, different forms of the serotonin (5-HT) transporter gene, (5-HTT), have been found to relate to individual differences in traits related to negative affect, leading to the suggestion that genotype might be associated with variation in amygdala activation. Canli, Omura, Haas et al. (2005) showed that 5-HTT genotype was indeed associated with functional activation of the amygdala, and also with structural variation in frontal cortical regions, anterior cingulate and cerebellum. A particularly exciting possibility for the future is the imaging of local changes in gene expression. This would be an enormously powerful adjunct to the study of brain development, but it is not yet available for studying the human brain (Dijkhuizen, 2006).

To finish with a note of caution, despite claims to the contrary, all the techniques discussed above are still primarily of interest to researchers rather than clinicians, except in individual cases of gross structural abnormalities (see chapter 22). Although there is the potential for major breakthroughs in diagnosis and treatment, these are yet to be realized. Perhaps the area where these techniques have the most immediate practical value is in monitoring the effects of treatment on the brain. For example, studies of patients with obsessive-compulsive disorder (OCD) have shown that brain changes occur with psychological therapies as well as drug therapies (Brody, Saxena, Schwartz et al., 1998). Imaging also has the potential to distinguish between brain changes brought about by treatment and changes relating to the natural course of the disorder (Casey & Durston, 2006).

Analysis of Imaging Data
Some fundamental problems of analysis of brain images apply to both structure and function. First, there is the problem of aligning brains from different individuals. One solution is to choose regions of interest (ROIs). For example, the amygdala can be identified and measured in each brain, and then these measurements, whether volumes or activity, are put together for analysis. The disadvantages of this approach follow, first, from the need to define the regions of interest and, second, from throwing away all the data outside the regions of interest.

At the opposite extreme are techniques such as statistical parametric mapping (SPM) in which brains are first normalized to a template and then comparisons are made on a voxel by voxel basis. A voxel is the basic element of spatial resolution, typically a cube with sides of approximately 2 mm. Such a voxel typically contains approximately 500 K neurons and several million synapses. In the case of structural images this technique is known as voxel-based morphometry (VBM). This technique is suitable for looking at fairly small-scale changes in structure, but is not applicable for large-scale changes (Ashburner & Friston, 2000). This is because each brain is first normalized to a standard template, thus eliminating large-scale differences between individuals. Techniques for identifying large-scale changes in brain structure, which are essentially differences in shape, are currently being developed but have yet to be routinely applied (Ashburner, Hutton, Frackowiak et al., 1998).

Second, there is the problem of multiple comparisons. Analysis of a whole brain involves thousands of comparisons. Unless there are well-justified a priori hypotheses, strict levels of significance corrected for multiple comparisons must be applied.

The colorful brain images associated with fMRI studies must always be interpreted with caution. They are not direct reflections of brain activity, but typically show differences in brain activity between one state and another rather than absolute activity. They are usually maps of statistical differences rather than absolute measures. Thus, the brighter the block, the greater the difference between the conditions or the people that are being compared.

Difficulties in Using Brain Scanning Techniques with Children
Before the scan begins the researcher or clinician must explain the procedure to the participants and make sure that they are free of all metallic objects. Prior practice in a “mock-up” scanner can be particularly helpful.

Even though it is non-invasive, there is no denying that having an MRI scan is not a pleasant experience. Not only does the head have to be put into a small and confined space, but the scanner produces a very loud noise. This noise is audible even through the routinely used and constantly improved earphones. Even some adults who volunteer for scanning may discover that they are claustrophobic when lying in the scanner.

Perhaps the greatest limitation as regards children is the requirement to lie completely still in the scanner. Unfortunately, keeping completely still for at least several minutes at a time is a requirement for MRI. While a structural scan can be completed in about 10–15 minutes, a functional scan could last for anything between 20 and 60 minutes or more. With young children sedation has been used in some studies. This means that the psychological tasks that are used when investigating brain activity and demand fully waking attention cannot be performed. Interestingly, very small babies can be swaddled so that they are calm and lie very still in the scanner (Dehaene-Lambertz, Dehaene, & Hertz-Pannier, 2002). Unfortunately, because of concerns with as yet unknown risks that might conceivably be associated with exposure to magnetic resonance, studies with newborns or infants have been carried out only rarely. While structural studies are increasingly applied to children from age 4 onwards (Giedd, Blumenthal, Jeffries et al., 1999; Gogtay, Giedd, Lusk et al., 2004), functional studies have only rarely been conducted with children under the age of 8 years. This is frustrating because it is in the earlier years that the most interesting and important developmental changes in cognitive processes take place.

Brain Function and Cognitive Architecture
It is often stated that it is only by recording the activity in single neurons that we can come to an understanding of the
mechanisms of brain function. Such recording is not really feasible in the human brain. The only exception occurs in cases of severe epilepsy where electrodes are sometimes implanted, typically in medial temporal cortex (Kreiman, Koch, & Fried, 2000) to allow precise location of seizure activity prior to surgery. Brain imaging as currently used means we see activity averaged across thousands, if not millions of neurons. Thus, relative to single cell recording, brain imaging techniques must appear extremely crude. However, given that the brain contains 100 billion neurons, there is clearly a place for studies at a much coarser grain in which activity across the whole brain can be observed. MRI studies can provide important guidance as to where to place electrodes for subsequent single neuron recording (Tsao, Freiwald, Tootell et al., 2006). The coarse grain of brain imaging studies is also more appropriate for current levels of theorizing about cognitive processes. The language of cognition is critical for making the link between, on the one hand, physiological processes in the brain and, on the other hand, mental activity and behavior. The wealth of information available even from a coarse brain imaging study can be too much to be explained by extant cognitive theories. Studies of the mechanisms by which brain regions interact typically involve not more than three or four different brain regions (Meyer-Lindenberg, Hairi, Munoz et al., 2005).

Whether activity is measured in the firing of a single neuron or indirectly from millions of neurons throughout the brain using EEG or fMRI, such studies are essentially correlational. Because we can reliably observe activity in, for example, the fusiform gyrus when subjects observe faces, this does not prove that this region is necessary for perceiving faces. Studies of the effects of brain lesions are an important complement for brain imaging studies, because lesion studies can show whether a brain region is necessary for a particular function. It is now possible to produce short-lived “lesions” in healthy volunteers with the use of TMS, in particular the repetitive version (rTMS). This procedure can reduce cortical excitability for some minutes after application. The precise mechanism of this effect is not clear, but it may result from changes in synaptic efficacy. While the exact location of the “lesion” induced by this technique is difficult to establish, the technique does provide an important experimental alternative to the study of patients with lesions (Cowey & Walsh, 2001). However, TMS is not suitable for the study of children. Although it is considered a safe method for the study of healthy adult volunteers, there is a risk of eliciting seizures, and it is not known what effects rTMS might have on the developing brain.

**Brain Changes in Typical Development**

The need for normal developmental information on typical brain and cognitive development is obvious, not only for its own sake, but also because we need a baseline for knowing what constitutes an abnormality (i.e., what lies beyond normal variation). All developmental scientists would agree that cross-sectional data are less informative than longitudinal data (Kraemer, Yesavage, Taylor et al., 2000). The collection of data on the same child at key points in time is highly desirable, but it makes heavy demands on research time and effort. Fortunately, some examples of such studies exist already, although the timespan covered is still relatively narrow. For the reasons discussed above, it is impractical to subject healthy children to lengthy scanning procedures before middle to late childhood. Ideally, one would like to start studying the development of the brain, in terms of structure and function, straight from birth at frequent intervals. This study is still very new, but reviews of human brain maturation based on structural neuroimaging techniques, which require only brief scanning sessions, are beginning to appear (Toga, Thompson, & Sowell, 2006).

**Structural Studies**

Lenroot and Giedd (2006) provide a comprehensive review of studies of structural brain changes during normal development from approximately 5 years onwards. However, the most systematic studies concern brain development during adolescence (Blakemore & Choudhury, 2006; Paus, Collins, Evans et al., 2001). MRI studies demonstrate that in prefrontal cortex (PFC) there is an increase in the density of gray matter (the layer of cortex that contains neurons) up to the onset of puberty followed by a subsequent rapid decrease in gray matter density from just after puberty and throughout adolescence, continuing into early adulthood. At the same time, there is an increase in the density of cortical white matter (the layer of cortex that contains the connections between neurons) from puberty throughout adolescence and into adulthood. The dorsolateral prefrontal cortex is notably late in reaching adult levels of cortical thickness. Complex patterns of change related to gender are observed in specific structures such as the amygdala and hippocampus. Such findings are difficult to interpret without a theory of what the observed changes mean.

One interesting area of speculation concerns ideas about brain reorganization at different ages. Results of earlier post-mortem investigations of human brain development suggest that the cortical changes seen in MRI mainly reflect two cellular processes occurring during infancy and adolescence: first, synaptogenesis followed by synaptic pruning, and, second, axonal myelination (Benes, 1989; Huttenlocher, 1979; Huttenlocher, de Courten, Garey et al., 1982; Yakovlev & Lecours, 1967). Myelination speeds up nerve conduction and the associated cognitive processes. It has been hypothesized that synaptogenesis and pruning fine-tune neural circuitry in the PFC and other cortical regions, and thus increase efficiency of the cognitive systems they subserve. It is important to distinguish two types of neuron: feedforward or driving neurons, which carry information about the outside world, and feedback or modulatory neurons, whose function is to modulate the driving neurons. Feedforward connections run from primary sensory areas carrying sensory signals to higher level association cortex. Feedback connections run in the opposite direction and modulate the effects of the sensory signals at earlier stages of processing. Recent studies in animals

---

137
have shown that the process of refining connections through synaptogenesis and pruning applies to lateral and feedback connections, but not to feedforward connections, which are established much earlier (Price, Kennedy, Dehay et al., 2006).

As Paus (2005) comments, developmental studies of structural changes during adolescence are as yet at a preliminary stage and the meaning of gray matter increases or decreases is still a matter for speculation. However, through a combination of structural and functional studies it may be possible to obtain indices of critical variables such as synaptic density (Marcar, Strassle, Loenneker et al., 2004).

**Functional Studies**

Interpretation of changes in brain activity associated with development is an order of magnitude more difficult than the interpretation of structural changes. In part, this problem springs from the lack of a framework for the understanding of the development of brain function. One of the burning questions in developmental psychology is to what extent there is regional specialization of brain functions from birth. It is generally assumed that programmed brain maturation interacts with modification by experience. Perhaps development proceeds along a path of differentiation of brain function with initially more global and more diffuse cognitive abilities being replaced by more specific and spatially localized functions. These ideas could be explored by scanning young children at those critical stages when behavioral and cognitive changes are most conspicuous.

A result that highlights very early specialization for cognitive functions, in this case speech processing, comes from a pioneering fMRI study by Dehaene-Lambertz, Dehaene, & Hertz-Pannier (2002). These researchers exposed swaddled 3-month-old infants to speech and non-speech noises. Remarkably, the left-lateralized brain structures known from adult studies to be activated preferentially by speech were also active in the babies’ brains when they heard speech.

Schlaggar, Brown, Lugar et al. (2002) studied single word processing in 7- to 10-year-old children and adults and found differences in circumscribed frontal and extra-striate regions. Some of these differences were dependent on age rather than performance, suggesting maturational effects.

There is also evidence for changes in brain structure and function solely in response to environmental input in studies with adults. For example, Draganski, Gaser, Busch et al. (2004) observed a transient increase in gray matter in regions concerned with the analysis of motion in people who practiced juggling for 3 months. Paulesu, McCrory, Fazio et al. (2000) observed subtle differences in brain activity associated with reading, between English and Italian participants, presumably as a consequence of exposure to English or Italian orthography, respectively.

Thus, in adults at least, the learning of novel tasks is associated with a shift from activity in many areas concerned with general problem-solving (including frontal cortex) to activity in a few specialized areas (Jenkins, Brooks, Nixon et al., 1994). Similar changes can be observed during development. In a simple arithmetic task, Rivera, Reiss, Eckert et al. (2005) found that younger subjects showed greater activity in prefrontal cortex, while adults showed greater activity in inferior parietal cortex, suggesting increased functional specialization in this area for mental arithmetic. Durston, Davidson, Tottenham et al. (2006) observed similar shifts with age towards increased focal activation in a cognitive control task. Passarotti, Paul, Russiere et al. (2003) studied face and location processing in 10- to 12-year-old children. Here again the children showed a more distributed pattern of brain activity than adults.

**What Can Brain Imaging Reveal About Abnormal Development?**

At first glance it seems a simple step from finding a brain abnormality to finding the cause of a neurodevelopmental disorder. But can we be sure that the abnormality we find is a cause of the disorder rather than merely a correlate or marker? Is the abnormality we find actually the way the plastic brain compensates for a developmental derailment at an earlier stage, now invisible?

Spelke (2002) points out the usefulness of functional neuroimaging methods in discovering the neural signatures of cognitive processes and by implication their change or persistence over development. The term neural signature is neutral as to whether the brain activations seen while the volunteer engages in a particular mental process are a correlate, cause or consequence of this process. Imaging techniques also provide the possibility of finding differences in this signature in children whose development is atypical. However, there are many pitfalls in explaining the cause of a disorder of development.

For instance, Morton (2004) reviewed a range of developmental disorders and showed in detailed examples that performance on psychological tests does not map in one-to-one fashion to underlying cognitive processes and by implication to underlying brain processes. Thus, when interpreting activations obtained from scanning studies, analyses have to be carried out at different levels simultaneously of behavior, cognition and brain. This is essential for understanding abnormalities of brain function when individuals are compared who may show the same performance on behavioral tests but different patterns of brain activation. We would infer that they perform the task in a different way. For the same reason, findings from brain imaging studies cannot be mapped directly to the behavioral manifestations of a disorder, but should be mapped to abnormalities in the specific neurocognitive processes that are thought to give rise to the behavior.

Success in distinguishing different developmental disorders requires a degree of specificity, but at what level should this specificity apply? For example, abnormalities of the developing brain are always likely to involve abnormal connectivity because it is connectivity that is modified by maturation and experience. In this case the specificity lies in precisely where the abnormal connections occur. Understanding of brain
function at this level of detail will require considerable development in techniques for measuring connectivity and in mechanistic theories of cognition.

Compensation
It has long been thought that extensive damage that in adulthood would result in marked neuropsychological deficits, is associated with only mild deficits in children. This has been taken to mean that the developing brain is more plastic and better able to cope with brain injury than the mature brain, possibly by adapting brain systems unaffected by the injury. In the case of focal brain damage from birth or early infancy, brain regions tend to take over functions that are not normally carried out by this region (Krageloh-Mann, 2004; Stiles, Reilly, Paul et al., 2005). Examples are changes in the organization of visuospatial and language processes (Lidzba, Staudt, Wilke et al., 2006). Furthermore, these compensatory processes are enhanced through teaching. Thus, remedial teaching of reading strategies can change the pattern of brain activity in dyslexic children when reading (Shaywitz, Shaywitz, Blachman et al., 2004) and similar results have been found for adult dyslexics (Eden, Jones, Cappell et al., 2004).

Abnormality or Compensatory Adaptation?
Compensatory adaptations make the study of the abnormal brain extremely complicated. First, the same overt behavior may be achieved by different cognitive processes and associated brain systems. Brain imaging has an important role in revealing these hidden differences. An interesting example of what it means when a brain “abnormality” reflects adaptation rather than being the prime cause of the developmental abnormality comes from a study of Tourette syndrome (see chapter 44). The tics that characterize this disorder are probably caused by pathology in the basal ganglia (Peterson, Thomas, Kane et al., 2003). However, abnormalities in the volume of dorsolateral prefrontal cortex (DLPFC) have also been observed. Plessen, Grüner, Lundervold et al. (2006) have speculated that these changes in DLPFC reflect an adaptation enabling children to suppress their tics in social situations. Thus, abnormally high activity in PFC found in this group, far from being a sign of primary abnormality, is instead a sign of high demands for inhibition. This is also a striking example of compensation during brain development.

Cause or Consequence?
Abnormal brain changes could also be a consequence rather than the cause of an abnormality. For example, a number of studies suggest that people with autism show a lack of specific activity in response to faces in the fusiform gyrus. However, this may not be a primary abnormality. Schultz (2005) has proposed that this is a consequence of a more basic lack of understanding in social stimuli, which in turn may be a result of faulty amygdala functioning. A lack of social interest might plausibly cause a failure to develop expertise in face processing, and therefore might result in the absence of a specialized face processing area in the fusiform gyrus.

Clearly, in these examples, group differences in brain activations found in fMRI studies may not be a guide to the cause of the disorder, but merely reveal changes that are secondary consequences of the disorder and of compensatory changes that occurred, or the remedial actions that have been taken. These examples also remind us of the artificiality of separating structure and function in brain imaging studies. This is most obviously the case when an abnormality of structure, such as a lesion, leads to a compensatory change in function. There is a general consensus that whenever an abnormality of brain function is observed there must be an associated abnormality of structure. Of course, this abnormality need not be as obvious as a space-occupying lesion, but could be a subtle alteration in connectivity or could be manifest in neurochemical changes that might only be seen at the microscopic level of the synapse. Studies of developmental abnormalities benefit greatly from investigating both structural and functional changes. One of the advantages of MRI is that structural scans are routinely obtained in the course of functional studies. We present an example combining these techniques in the next section.

Can Neuroimaging Studies of Adults With Developmental Disorders Give Useful Information About Underlying Abnormalities?
We have mentioned a number of practical and ethical limitations that make neuroimaging studies of children rather difficult. However, we do not have to wait around for the improvement in techniques, nor do we have to rely on EEG-based approaches only, to study the neural causes and correlates of these disorders. Developmental disorders do not cease when children become adults or when behavioral problems are no longer manifest. Many useful studies of developmental disorders have been conducted with adults. An example is developmental dyslexia.

Dyslexia (see chapter 48)
Many adults with developmental dyslexia have learned to read and write to a high level of accuracy and sometimes cannot be detected by conventional reading tests. However, their problems remain manifest in slow reading and poor spelling. Dyslexia also exists in other languages. In Italian there is a highly transparent writing system that allows largely unambiguous mapping of sounds and letters. As a result, children with dyslexia who would have severe problems in learning to read English may not manifest obvious problems in learning to read Italian. Still, as adults, Italian individuals with dyslexia read significantly more slowly than their peers, just as in the case of English.

In a PET study by Paulesu, Demonet, Fazio et al. (2001), university students in three countries (England, France and Italy), those with developmental dyslexia and those without dyslexia, were exposed to print, which they either read aloud
or perceived only as a background to another task. The difference between the groups in each of the three countries was significant in one brain region, the left posterior fusiform gyrus, sometimes referred to as the visual word-form area (Cohen & Dehaene, 2004). This region is active when people read words. For participants with dyslexia, this region was less active. A subsequent voxel-based investigation of the whole brain showed that anatomical differences between the groups, again in each of the three countries, were present in precisely this region of the cortex (Silani, Frith, Demonet et al., 2005).

There were two kinds of differences, increases and decreases in gray matter density relative to control subjects. However, it was the increases in density that were significant. This was shown by their correlation with reading performance in the dyslexic groups, again observed for each country. The more gray matter in the critical region, the worse the reading impairment. Given that the decreases in gray matter density were seen in a region immediately next to the increases, the authors offer the speculative hypothesis of a failure in neural migration: some neurons ended up where they should not be, and these unwanted neurons disrupt the functioning of the word-form area. The more such neurons are present, the more the functioning is impaired. While this hypothesis is extremely speculative, it has some support from traditional neuropathological studies. The idea of migration failure in developmental dyslexia was first proposed by Galaburda, Sherman, Rosen et al. (1985), who found ectopic cells in the perisylvian region of the left temporal lobe when studying postmortem tissue of dyslexic brains under the microscope. Chang, Ly, Appignani et al. (2005) found an association with impairment in reading skills in a sample of 10 patients with epilepsy who showed neuronal migration disorder of periventricular nodular heterotopia.

However, only extremely high-field scanners would be able to detect ectopias, and the theory remains to be tested in the future, if such instruments become available for the study of human brains. In addition, for a full understanding of the behavioral and brain abnormalities in dyslexia, genetic studies would be essential. In the next section we discuss an example where such convergent evidence already exists.

Brain Imaging Studies Require Converging Evidence from Other Disciplines

We have emphasized throughout this chapter that the application of brain imaging to developmental disorders will not be informative unless interpretation of the results can be supported by convergent evidence from several other sources: evidence about causes from genetic and neuropathology and evidence about consequences from behavioral testing and cognitive theory.

Williams Syndrome

Williams syndrome (WS), also known as Williams–Beuren syndrome, is important as an example of a developmental disorder caused by a specific genetic anomaly (a microdeletion of approximately 21 genes on chromosome 7q11.23; see chapter 24). Its incidence has been estimated as 1 in 7500. In a recent comprehensive review, Meyer-Lindenberg, Mervis, and Berman (2006) summarized findings from several disciplines and pointed out the convergence of behavioral and neuroimaging studies. The genetically complex deletions on chromosome 7q11, 23 that characterize the syndrome are associated with quite specific consequences in brain structure and function. In this field, volunteers in scanning experiments are frequently adolescents or adults, as it is clear that the disorder does not go away with age.

The most obvious advantage of knowing the genetic cause of the disorder is that the study group can be defined by a genetic test. Furthermore, variations in the form and severity of the disorder can be linked to the size or location of the deletions.

Starting with anatomical abnormalities of the brain of individuals with WS, van Essen, Dierker, Snyder et al. (2006) reported cortical folding abnormalities, while Thompson, Lee, Dutton et al. (2005) also found cortical abnormalities when looking at cortical complexity and thickness. However, these rather pervasive structural abnormalities are not sufficient to explain the cognitive abnormalities that are present in WS. The behavioral abnormalities associated with WS have been studied intensively and the pattern of cognitive impairments has been well charted (Farran & Jarrold, 2003). While being associated with mild to moderate intellectual disability, WS is characterized by a distinctive cognitive profile with severe impairment in visuospatial construction tasks alongside relative strength in verbal short-term memory and language.

fMRI studies of high-functioning adult cases of WS performing visuospatial construction tasks have revealed reduced activity in the parietal lobe just in front of the intraparietal sulcus. This observation is consistent with the proposal that the visuospatial impairments in WS result from abnormalities in the dorsal visual processing stream (Atkinson, Braddick, Anker et al., 2003). Structural investigations of the same WS cases, using VBM, revealed symmetrical reductions of gray matter volume in the intraparietal sulcus (Meyer-Lindenberg, Kohn, Mervis et al., 2004). This observation has been confirmed in younger and more typical WS cases (Boddaert, Mochel, Meresse et al., 2006). The structural abnormality revealed by these studies is immediately adjacent to the parietal region showing reduced activity during the performance of visuospatial tasks. Thus, the structural abnormality might serve as a “roadblock” preventing information flowing from visual cortex to parietal regions concerned with the representation of space. Consistent with this idea, Meyer-Lindenberg et al. (2004) demonstrated reduced connectivity between visual areas and parietal cortex in WS cases.

The intraparietal sulcus is not the only region of structural abnormality identified in WS. An abnormality has also been found in orbitofrontal cortex. This abnormality may be linked to the social disinhibition typical of WS (Meyer-Lindenberg et al., 2005).
These studies of Williams syndrome illustrate the importance of combining brain imaging studies of structure, function and connectivity with detailed behavioral testing and cognitive analysis.

**Disorders of Connectivity**

Locating lesions will never be sufficient to understand abnormal brain function and the resulting cognitive and behavioral abnormalities. We need to know about how different brain regions interact with one another. A lesion will alter the way the remaining regions interact with one another (Price, Warburton, Moore et al., 2001). In many developmental disorders there may not be a lesion, but rather an abnormality in the way in which brain regions interact. The development of methods for detecting abnormalities of structural and functional connectivity is at an early stage, but influential speculations have been presented about certain disorders, such as dyslexia (Pugh, Mencl, Shaywitz et al., 2000) and schizophrenia (Stephan, Baldeweg, & Friston, 2006), as fundamentally disorders of neural connectivity.

Another example concerns psychopathy (see chapter 51). It has been proposed that this disorder is characterized by a lack of connectivity between the amygdala and orbitofrontal cortex leading to impaired stimulus-reinforcement learning (Mitchell, Fine, Richell et al., 2006). This proposal relies on combining evidence from non-human primate studies (Baxter & Murray, 2002), human lesion studies (Mitchell et al., 2006) and brain imaging studies (Gottfried, O’Doherty, & Dolan, 2003).

**Autism**

Autism (see chapter 46) is a prime example of the recent increase in interest in disconnection as opposed to regional abnormalities. As yet there are few structural studies of connectivity, although abnormalities of white matter have been observed (Hendry, De Vito, Gelman et al., 2006). However, the convergence of data from different functional imaging studies suggesting atypical connectivity as an underlying brain abnormality in autism is impressive. Just, Cherkassky, Keller, et al. (2004) found indications of underconnectivity between two language areas during performance of a sentence comprehension task, and underconnectivity between frontal and parietal areas during performance of a typical executive function task (Just, Cherkassky, Keller et al., 2007). Villalobos, Mizuno, Dahl et al. (2005) observed reduced connectivity between V1 and inferior frontal cortex. Courchesne and Pierce (2005) suggest that connectivity within the frontal lobe is excessive, while connectivity between frontal cortex and other brain systems is poor. Castelli, Frith, Happe et al. (2002) used PET to study individuals with high functioning autism and Asperger syndrome while they watched the movements of animated triangles, which normally compel observers to attribute mental states. The people with autism showed reduced activation in the previously established mentalizing system, comprising medial prefrontal cortex (MPFC), superior temporal cortex (STS), basal temporal regions and temporal poles. At the same time, they showed enhanced activation in extra-striate visual regions. This might be because the STS region, which is specialized for the analysis of intentionally moving agents, is failing to get the information from the regions earlier in the visual processing stream, which are specialized for analyzing more general characteristics of movement. In line with this suggestion, weak connectivity was observed between the active visual regions V3 and STS in the autism group.

While all these studies show evidence of reduced connectivity in autism, it is striking that the location of the abnormal connectivity differs from one study to another and probably is determined by the task used to elicit brain activity. It seems unlikely that there is a different abnormality for every task. Furthermore, it is not at all clear what precise form the lack of connectivity might take in physiological terms.

Schulz (2005) has proposed that in autism relevant visual information may not properly reach the dedicated face processing area (FPA) because of weak feedback connections between the amygdala and fusiform gyrus. He proposes that from early on in life the amygdala fails to send emotionally enhanced signals and that this may be the primary cause of disconnection. This line of reasoning was also considered by Castelli et al. (2002). They proposed the hypothesis of a top-down failure of feedback signals reaching STS from the anterior components of the mentalizing system. Top-down feedback is believed to alter connectivity. For example, when subjects attend to a particular visual feature, such as motion, connectivity between V1 and the visual motion area V5 is enhanced. This enhanced connectivity is under the control of top-down signals from parietal cortex (Friston & Buchel, 2000). Frith (2003) suggested that the reduced connectivity in autism might be caused by a lack of this top-down modulation. Anterior brain regions, such as amygdala and prefrontal cortex, normally enhance attention towards the signals being processed (e.g., by increasing connectivity between STS and earlier regions in the visual processing stream) and are thus able to signal their social significance. This top-down modulation might be faulty in autism.

This hypothesis was tested by Bird, Catmur, Silani et al. (2006) with a paradigm where houses and faces were presented simultaneously, but attention was directed at a single spatial location. This paradigm, introduced by Vuilleumier, Armony, Driver et al. (2001), had established that attentional amplification of FFA could be induced when faces appeared in the attended location, while amplification of activity in the parahippocampal place area (PPA) occurred when houses appeared in the attended location. As predicted by their hypothesis, Bird et al. found that in autism the amplification of activation in FFA by attention was significantly weaker than in controls. At the same time, the amplification in PPA, although reduced, was not different from normal. Faces are normally salient social stimuli, but seem to be less salient to individuals with autism. The study offers an explanation through the proposal of a failure in top-down processes.
Thus, there would be a transmission failure between basic perceptual information and higher level interpretation of the social significance of the perceptual input.

While these various studies offer different proposals for the reasons of underconnectivity, the top-down modulation hypothesis has the advantage of parsimony as it suggests a common pathology.

Failures of connectivity have also been postulated in other disorders. It remains to be seen whether the precise location and type of the disconnection can distinguish between different disorders. Clearly, if neural signatures can be identified in terms of lack of connectivity and can be related to specific disorders, then this could be helpful in the clinical diagnosis. However, we are just as far from knowing the necessary detail of the critical differences in neural connectivity as we are in knowing the critical differences in cognitive processes. This highlights the continuing importance of cognitive models in the interpretation of imaging data.

Conclusions: The Age of Pioneering rather than Definitive Studies

The examples given demonstrate that brain imaging can teach us much about the development of brain and mind as well as its disorders, even though its full potential has yet to be realized. We have mentioned a number of reasons why developmental neuroscientists have not yet been able to use neuroimaging techniques to the full. In fact, the neuroimaging studies available must still be considered pioneering rather than definitive. Nevertheless, we believe that just as in the investigation of basic neurocognitive processes in healthy adults and neuropsychological patients, huge progress can be made in our knowledge of the developing brain and its disorders. The studies we have reviewed confirm that there is exciting potential even though this potential has not yet been fully realized.

New methods are still evolving, in particular statistical methods for the analysis of the masses of data that can be obtained from activations in cortical areas and in the connections between them. There are continuous improvements in engineering, which means that pictures of increasingly higher resolution can be obtained. At the same time, efforts are being made to improve the administration of the techniques, with noise being reduced and space opened up and the ability to compensate for spontaneously occurring head movement. These technical improvements will benefit studies of children in particular.

When reviewing neuroimaging studies in disorders such as autism, attention deficit/hyperactivity disorder (ADHD), Williams syndrome and dyslexia, one is struck by the number of inconsistent findings. These can to some extent be put down to the typical use of small numbers of participants and poor matching procedures. There are warning examples when divergent results have been obtained when clinical and typical developmental groups were matched for diagnosis but not for IQ. Often, as in behavioral studies, group difference can be accounted for by IQ differences. However, poor designs are also to blame for apparent inconsistencies, because the importance of appropriate control tasks is not always realized.

Sometimes, inconsistencies arise from differing statistical thresholds used for analysis. If thresholds are set too low, then unreliable findings will swamp the literature. On the other hand, it is important to be cautious about setting thresholds too high. Findings from studies using stringent thresholds cannot be taken to mean that they have identified the only abnormality in a clinical group. While the strict statistical procedures used allow confidence in the presence of such an abnormality, they do not rule out that other differences, currently below the threshold, are not also of importance.

Finally, it is not necessarily the methods that are to blame for inconsistent findings. The heterogeneity of developmental disorders makes it very hard to avoid noise in empirical data, be they behavioral or physiological.

Given the ethical and practical considerations, it is particularly important that neuroimaging studies in children should get the most out of the limited opportunity to see the living brain in action. Here, a combination of methods from different disciplines can optimize designs and these need to be guided by hypotheses from cognition and from genetics. Fishing expeditions, where the only question is “what does the active brain look like?” cannot be justified. Studies in children, even more than adult studies, need to be constrained by theory.

Further Reading

References

The field of developmental psychopathology is a relatively new discipline, launched slightly more than two decades ago by the publication of two papers, one by Sroufe and Rutter (1984) and another by Cicchetti (1984). As these authors eloquently pointed out, the disciplines of developmental psychology and abnormal psychology have historically traveled along parallel rather than convergent paths. However, our understanding of child mental health would improve dramatically if we adopted a true developmental framework. It was with this goal in mind that this new field of developmental psychopathology was created, and it has clearly taken root, with whole conferences and journals devoted to it. Yet imbuing the study of developmental psychopathology with biology (be it neurobiology or molecular biology) has only recently begun to gain traction (Cicchetti & Posner, 2005; Dahl & Spear, 2004; Nelson, Leibenluft, McClure et al., 2005; Rutter, 2006; see also Nelson, Bloom, Cameron et al., 2002). The failure to consider the linkages between developmental psychopathology and biology is unfortunate for several reasons, not the least of which is the observation that many mental health disorders have a strong genetic basis (Rutter, 2006), and the fact that mental disorders are inherently brain disorders.

This leads us to ask, why have those studying typical or atypical child development been so hesitant to consider the biological bases of development? Several possible explanations come to mind. First, the training involved in becoming a psychologist, psychiatrist or neuroscientist is long and arduous, and to master the methods and models of multiple disciplines is difficult. Second, through at least the first two-thirds of the 20th century, Freudian theory and, later, some strains of attachment theory (Sroufe, 1986; Sroufe, Carlson, Levy et al., 1999; Warren, Huston, Egeland et al., 1997) had a dominant influence on many aspects of developmental psychopathology. These theories focused more on the importance of environment and upbringing in development, and therefore underplayed the impact of biological factors. Additionally, investigators in that period believed that genetics seemed overly deterministic, and argued that to attribute the cause of mental disorders to atypical neural processes deflected attention away from the assumed root cause – bad parenting, adverse early experiences, and so forth.

As has been the case for child development and neuroscience (Nelson & Bloom, 1997), most contemporary views of child psychopathology are more inclusive, and few investigators would now argue that biology (be it genes or brain) is unimportant. In this chapter we sound the contemporary theme that mental processes (normal or abnormal) have their basis in neural activity. To illustrate this perspective, we begin our chapter with a tutorial on brain development. Here we include summaries of neurulation, cellular proliferation, migration and differentiation, followed by discussions of synaptogenesis and myelination. Next, because some forms of psychopathology have their origin in abnormal early experiences (e.g., abuse, neglect), and because much is known about the role of experience in brain development and brain function, we turn our attention to a discussion of neural plasticity. Finally, having laid the ground-work for how errors in brain development might contribute to psychopathology, we turn our attention to the neurobiological origins of developmental psychopathology. We begin with a general review of the link between early pre- and perinatal insults and subsequent psychopathology. We then focus this discussion on a specific developmental disorder – autism. We argue that children with classic autism and some children with histories of institutionalization share features in common, a phenotypic overlap, if you will. We consider the mechanism by which such a final common pathway can emerge despite very different etiologies and early beginnings. This brings us back to the original struggle between the influence of biology versus environment in developmental psychopathology.

**Brain Development**

Brain development is a protracted process. It begins after conception, and is essentially complete by the time an individual reaches his or her mid-20s. We illustrate these remarkable changes in Plate 12.1, in which the surface development of the brain is shown from just a few weeks after conception through adulthood.

How does this miracle occur? We can approach an answer to this question at multiple levels: the action of genes (the molecular level), the action of synapses (the physiological level), the functions subserved by specific structures (the anatomical
CHAPTER 12

level) and the combination of all of these, in which diffuse networks of millions of neurons work synchronously in the service of behavior (the systems level).

Basic Embryology
Beginning shortly after conception, the primitive zygote undergoes multiple cell divisions that eventually lead to the formation of the blastocyst (a mass of cells), which contains an inner and an outer layer. The former will give rise to the embryo proper, whereas the latter will give rise to support structures (placenta, umbilical cord, amniotic sac). After several more cell cycles have been completed, some time between the first and second prenatal week, the inner layer subdivides out into three layers. Here the inner layer (endoderm) will give rise to most of the internal organs of the body, the middle layer (mesoderm) will give rise to support structures (e.g., bone) and the outer layer (ectoderm) will give rise to the nervous system.

Although brain development is a continuous process that begins with the formation of the neural tube and ends when the basic architecture of the brain becomes adult-like (approximately two decades later), we organize our review of brain development into those events that occur prenatally and those that begin prenatally and continue postnatally.

Prenatal Development

Neurulation
The formation of the neural tube, which is derived from the ectoderm, is considered by most to be the first stage of brain development (Plate 12.2). As cells that line the ectoderm multiply, the ectodermal layer thickens to form a pear-shaped neural plate. This plate gradually begins to fold over onto itself, forming a tube. This tube, in turn, gradually closes at the bottom and then the top, a process that is complete by roughly the end of the third week of gestation. Cells trapped inside the tube will lead to the formation of the central nervous system (CNS), whereas those trapped between the outer layer and the ectodermal wall will give rise to the autonomic nervous system (ANS).

As illustrated in Plate 12.3, the neural tube rapidly becomes a three-vesicle structure, and then a five-vesicle structure. The rear-most (caudal) portion of the tube will give rise to the hindbrain (rhombencephalon), which will consist of the medulla oblongata (which regulates basic bodily functions; importantly it is the medulla that connects the rest of the brain to the spinal cord), pons (which relays sensory information between the cerebrum and cerebellum) and cerebellum (which will subserve a variety of motor functions). The middle vesicle gives rise to the midbrain (mesencephalon), which caudally connects to the pons and rostrally connects to the diencephalon (a forebrain structure that consists of the thalamus and hypothalamus). Finally, the most rostral (top) portion of the tube will give rise to the forebrain (prosencephalon), which in turn will subdivide into the telencephalon (cerebral hemispheres), the diencephalon and the basal ganglia.

Proliferation
Once the neural tube has formed, cells that line the innermost portion of the tube (the ventricular zone) proliferate at a logarithmic rate. As cells in the ventricular zone multiply, a second zone is formed, the marginal zone, which contains axons and dendrites. This proliferative stage continues for some time, ultimately leading to the newborn brain having many more neurons than the adult brain. The overproduction of neurons is eventually compensated for by a second normative process referred to as apoptosis, or programmed cell death. Apoptosis is responsible for the pruning back of these neurons to adult numbers.

Cell Migration
The cortex proper – the several millimeters thick covering of the brain – is formed through a process of cell migration. Postmitotic cells that originate in the ventricular zone will migrate through the intermediate zone (essentially a zone that lies between the ventricular zone and the cortical plate), eventually reaching their final destination. These postmitotic cells move in an inside-out direction, with the earliest migrating cells occupying the deepest cortical layer, with subsequent migrations passing through the previously formed layer(s). Six months after conception, all six layers of the cortex have been formed.

Cell migration takes place using radial and tangential migratory patterns. The former refers to the propagation of cells from the deepest to the most superficial layers of the cortex. Approximately 70–80% of migrating neurons (primarily pyramidal neurons) and most glia (including oligodendrocytes and astrocytes) use this radial pathway. In contrast, cortical interneurons and nuclei of the brainstem adopt a tangential migratory pattern.

Most cell migration is complete by approximately the 25th prenatal week. Once a cell has completed its migratory journey, it can differentiate, the process we discuss next.

Differentiation
Once a neuron has migrated to its target destination, it generally proceeds along one of two roads: the cell can differentiate and develop processes (axons and dendrites) or it can be retracted through apoptosis. Current estimates place the number of neurons that are subsequently retracted at 40–60% (Oppenheim & Johnson, 2003). The development of axons is facilitated by growth cones, small structures that sit on top of an axon. The growth cone directs an axon towards some targets and away from others. This is accomplished by using a combination of molecular guidance cues (e.g., cell adhesion molecules) as well as anatomical structures that sit atop the tip of the axon (e.g., lamellipodia and filopodia).

Recent work has indicated that the gene calcium-regulated transcriptional activator (CREST) has an important role in the development of dendrites (Aizawa, Hu, Bobb et al., 2004). Early dendrites appear as thick processes with few spines (small protruberances that occupy the length of the dendrite) which extend from the cell body. As dendrites mature, the number
and density of the spines increase; this, in turn, increases the chance that a dendrite will make contact with a neighboring axon. The first dendrites appear approximately 15 weeks after conception, which is about the same time the first axons reach the cortical plate. At 25–27 weeks’ gestation dendritic spines greatly increase in number, on both pyramidal and non-pyramidal cells.

**Pre- and Postnatal Development**

**Synaptogenesis**

A synapse is the point of contact between two neurons, frequently between an axon and a dendrite. Depending on the neuron in question, the action of a synapse can be excitatory (promoting the likelihood of an action potential) or inhibitory (reducing the likelihood of an action potential).

The first synapses are generally observed by about 23 weeks gestation (Molliver, Kostovic, & Van der Loos, 1973), although the peak of production does not occur until some time in the first year of life. As is the case with neurons, there is a massive overproduction of synapses which is followed by a gradual reduction. In the visual cortex, a synaptic peak is reached between approximately 4 and 8 postnatal months (Huttenlocher & de Courten, 1987), whereas in the middle frontal gyrus (a region of the prefrontal cortex) the peak synaptic density is not obtained until after 15 postnatal months (Huttenlocher & Dabholkar, 1997).

The process of reducing the number of synapses (pruning) is dependent in part on the communication between neurons. Following the Hebbian principle of use and disuse, the more active synapses tend to be strengthened and less active synapses tend to be weakened or even eliminated (Chechik, Meilijson, & Ruppin, 1999). An elegant example of this can be found in a paper by Le Bé and Markram (2006) who, using 12- to 14-day-old rat neocortical slices, demonstrated that pyramidal neurons spontaneously connect and disconnect from each other, and that adding an excitatory neurotransmitter (glutamate) increases the number of connections that are formed. Importantly, the adjustments that are made in the pruning of synapses can either be quantitative, with a reduction in the overall number of synapses, or qualitative, with a refinement of connections such that silent or abnormal connections are eliminated.

The process of synaptic pruning varies by brain area. For example, in the human occipital cortex the peak number of synapses occurs at 4–8 months of age, and is reduced to adult numbers by 4–6 years. Synapses in the middle frontal gyrus of the human prefrontal cortex reach their peak closer to 1–1.5 years of age, and adult numbers are not obtained until mid to late adolescence (Huttenlocher, 1979, 1994; Huttenlocher & Dabholkar, 1997; Huttenlocher & de Courten, 1987).

**Myelination**

Myelin is a lipid–protein substance, which, when wrapped around an axon, tends to increase the conduction velocity, or speed at which neuronal impulses travel. *Oligodendroglia* produces myelin in the CNS, whereas *Schwann cells* produce myelin in the ANS. Myelination in the peripheral nervous system, motor roots, sensory roots, somesthetic cortex, and the primary visual and auditory cortices begins prenatally. During the first postnatal year, regions of the brainstem, cerebellum and the splenium of corpus callosum myelinate. By 1 year of age myelination of all regions of the corpus callosum is under way.

In contrast to most other aspects of brain development, myelination can be studied non-invasively using magnetic resonance imaging (MRI). The attractiveness of this tool is that one can repeatedly study the same individual across time, yielding impressive developmental data. Previously, of course, all such data were obtained pathologically, through cross-sections of brains of autopsy specimens.

Although the application of MRI in the study of typical development is still quite novel, this tool has been used to examine brain anatomy, gray and white matter development, myelination and the development of white matter tracts across a range of ages. While ultrasound is most useful for the diagnosis of gross abnormalities (e.g., intraventricular or intraparenchymal hemorrhage, or major structural malformation) and can be used to view some additional details of cortical development, MRI is the gold standard for visualization of the posterior fossa, and for viewing sulcation and myelination. Prenatally, a rather accurate estimate of gestational age can be made by the pattern of sulcation seen on MRI. For instance, at 16 weeks only the parieto-occipital and calcarine sulci have been formed but, by 30 weeks, the occipito-temporal, superior and inferior frontal, and superior-temporal sulci have also appeared (Van der Knaap, van Wezel-Meijler, Barth et al., 1996).

Degree and location of myelination can be accurately measured by level of signal intensity on T1 and T2 weighted MRI studies. As shown by MRI, myelination begins in the fifth fetal month with the cranial nerves, and then continues through the first two decades of life. In general, the process occurs in a caudal to cephalad and dorsal to ventral pattern. Furthermore, in any specific portion of the brain, the posterior region myelinates first. Myelination progresses most quickly in areas of the brain that are used in early life. For instance, in the brainstem, the regions needed for tactile sensation and proprioception sensation are myelinated at birth, whereas regions necessary for motor input into the cerebellum do not myelinate until later in infancy. These patterns have been consistently documented using MRI and, postnatally, the level of brain maturation is estimated based on degree and location of myelination (Barkovich, 2005a).

Gilmore and colleagues have conducted an elegant series of studies of typically developing newborns and young infants using a relatively high-field magnet (3 Tesla). They have reported that males in general have larger intracranial volumes than females, and (in an unpublished study) that in contrast to the adult, there are no sex differences in white matter in newborns (Gilmore, Zhai, Wilber et al., 2004, Gilmore, Lin,
CHAPTER 12

Knickmeyer, 2006). This same group has also been studying 1- to 2-year-old typically developing infants. From this work they report that there is a large increase in intracranial volume in the first year, and that by age 1 year intracranial volume is about 75% of adult volume, and at 2 years it is 80% (Gilmore et al., 2006).

Moving beyond infancy, there are now a number of longitudinal studies that have examined the course of myelination from early childhood through early adulthood (for a recent review see Toga, Thompson, & Sowell, 2006). A summary of these findings suggests that there is a linear increase in white matter until 20 years of age, and non-linear changes in gray matter during this same time period. Regarding gray matter, Giedd, Blumenthal, Jeffries et al. (1999) have shown that there is an increase in gray matter up until about the age of 12 years in the frontal and parietal lobes, thereafter followed by a decrease. In the temporal lobes, the increase occurs until age 16, and then again is followed by a decrease.

Collectively, changes in gray and white matter continue across the first two decades of life, with gray matter reaching its peak around the age of 12, and myelination reaching its peak around the age of 20 years. Unfortunately, relatively little work has been carried out on relating these changes to behavior. One exception is recent work by Sowell et al. (2004). Drawing on longitudinal data collected between 5 and 11 years of age, Sowell et al. (2004) have shown that among these typically developing children, the cortex thins by 0.15–0.30 mm per year, particularly in the frontal and parietal regions; such thinning also occurs in the temporal and frontal regions (specifically those that are related to language functions). Intriguingly, cortical thinning in the left dorsal frontal and parietal lobes correlated with improvements in performance on a general IQ test. The authors speculated that such thinning represents a plastic process, likely driven by experience (for another example see Shaw, Greenstein, Lerch et al., 2006).

**Postnatal Neurogenesis**

The process of neurogenesis begins shortly after the neural tube has been formed, and continues through much of gestation. For most of the 20th century it was commonly believed that our full complement of neurons is complete at or around the time of birth, and that we do not make new neurons after that, not even in response to injury. One exception to this rule was the olfactory bulb, where there were reports of postnatal neurogenesis occurring through much of life. However, the assumption of “no new neurons” began to be questioned in earnest by a number of investigators during the 1990s. Initially it was demonstrated that a region of the hippocampus – the dentate gyrus – continues to make new neurons through at least middle age (for a review see Barinaga, 2003). Such data have been replicated multiple times, so there is little reason to question their veracity.

However, far more controversial is whether other regions of the brain, the cortex in particular, also continue to make new neurons postnatally. For example, Gould and Gross (2002) have reported postnatal neurogenesis in the cingulate gyrus and segments of the parietal cortex, and Bernier, Bédard, Vinet et al. (2002) have reported postnatal neurogenesis in the amygdala, piriform cortex and inferior temporal cortex. However, other authors have failed to replicate these findings (for discussion see Rakic, 2002). In a seminal paper published by Bhardwaj, Curtis, Spalding et al. (2006) employing 14C and BRDU (DNA methods that permit one to examine the birth of a cell), it now appears that the cortex does not enjoy the same privilege as the dentate gyrus: that is, all the cortical neurons we will ever have are typically present by birth, and no new neurons are made after that. Accordingly, it now appears that postnatal neurogenesis may be limited to the dentate region of the hippocampus (Kozorovitskiy & Gould, in press).

An intriguing observation about postnatal neurogenesis is that these new neurons have a relatively short half-life, and typically die within a few weeks of birth. Equally intriguing is the fact that, despite their short lifespan, these neurons differentiate (develop axons and dendrites, express neurotransmitters and possess all the functional properties of a “typical” neuron, and they are influenced by experience (Gould, Beylin, Tanapat et al., 1999; Mirescu, Peters, & Gould, 2004). For example, when mice or rats are placed in contexts in which demands are placed on learning and memory, or in which exercise is encouraged, there is an increase in the number of cells produced in the dentate gyrus; importantly, this effect can be obtained among aged mice, not just young mice. For example, van Praag, Shubert, Zhao et al. (2005) demonstrated that when young and aged mice were housed with a running wheel, both groups showed an increase in neurogenesis in the hippocampus and a corresponding improvement in spatial memory.

In contrast to complex (or so-called “enriched”) environments, stress in adulthood appears to reduce the number of postnatally derived neurons in the rat dentate gyrus. Moreover, in unpublished work by Gould (2003), when rodents are housed together, dominance hierarchies develop. Within these hierarchies, the dominant animals tend to produce more new neurons than the non-dominant animals. Interestingly, if these same animals are then housed in complex environments, there is an increase in the number of neurons born in the dentate, although the dominant animals continue to fare better than the non-dominant animals. Perhaps most intriguingly, although environmental enrichment up-regulates postnatal neurogenesis, these cells are not involved in spatial learning (Meshi, Drew, Saxe et al., 2006; but see van Praag et al., 2005). Collectively, experience appears to have an influence on postnatal neurogenesis, although it is unknown what role these new cells have in brain function.

Because the area that benefits from the process of postnatal neurogenesis lies in the hippocampus, and because the hippocampus is deeply involved in memory, some have speculated that postnatal neurogenesis will functionally benefit memory processes. This has led Aimone, Wiles, and Gage (2006) to speculate that newly born cells and prenatally
Nelson and colleagues have discussed this topic extensively over the past decade, and in the context of development, neural plasticity changes to psychopathology. Clearly, more research is needed to explicate changes in brain development during the adolescent period, and to relate such changes to psychopathology. Changes during puberty that many forms of psychopathology really take root in, and that such hormones affect brain structure and function remains elusive (although headway has been made in animal models; for a recent overview on adolescent brain development see Dahl & Spear, 2004). This is unfortunate, as it is during puberty that many forms of psychopathology really take root (e.g., in the case of depression) or manifest themselves for the first time in obvious ways (e.g., schizophrenia). Moreover, it is also during puberty that sex differences in psychopathology first emerge (again, the case of depression comes to mind). Clearly, more research is needed to explicate changes in brain development during the adolescent period, and to relate such changes to psychopathology.

Neural Plasticity

The topic of neural plasticity has received considerable attention over the past decade, and in the context of development, Nelson and colleagues have discussed this topic extensively (Black, Jones, Nelson et al., 1998; Cline, 2003; de Haan & Johnson, 2003; Nelson, 1999, 2000; Nelson & Bloom, 1997; Nelson, de Haan, & Thomas, 2006). In its simplest terms, plasticity refers to the brain’s ability to be molded by experience. Of course, because experiences can be good or bad, this means that plasticity “cuts both ways” (Greenough, personal communication). Thus, good experiences can lead to “good” brains and bad experiences can lead to “bad” brains. Moreover, experience is not merely something to which the organism is passively exposed; rather, the effects of experience on development represent a complex interplay among:

- The developmental status of the brain at the time of exposure;
- The nature of the experience;
- The degree of experience (e.g., a great deal of early stress vs. limited exposure to early stress);
- The organism’s involvement with the experience, and, very likely;
- The individual’s genetic background.

Some of these factors can be illustrated by the following example. Francis, Szegda, Campbell et al. (2003) cross-fostered two strains of mice with one another. One was cross-fostered prenatally (here, embryos from one strain that were just a few hours old were implanted in the mothers of another strain) and the other postnatally (newborn pups from one strain were raised by mothers of the other strain). Control animals consisted of the two original (non-cross fostered) strains. All animals were tested at 3 months of age. The authors reported that the control animals differed reliably from one another on four dimensions:

1. Differences in exploration of an open field;
2. Relative time on the open arms of a plus maze;
3. Latency to find a hidden platform in the Morris water maze; and

Cross-fostering animals prenatally or postnatally did not exert any effects on the expected phenotype. However, mice that had been prenatally and postnatally cross-fostered exhibited the same behavioral phenotype as the adopted strain, despite differing genetically from the adopted strain. The fact that mice that had been cross-fostered prenatally and postnatally did not show this effect supported the contention that the effects of the combined cross-fostering must be a result of non-genetic factors, namely the powerful role of experience on gene expression. This study illustrated the dynamic interaction between genes, brain and behavior.

Sensory and Perceptual Development

In the context of developmental psychopathology, it is important to stress that the impact of experience on the brain is not constant throughout life. As the brain develops and matures, its sensitivity to experience changes. As we discuss below, there is now a plethora of examples of adult plasticity but, suffice to say, the functional properties of the
 CHAPTER 12

developing brain are such that they are more experience-dependent than the adult brain. Below we provide examples of both developmental and adult plasticity (for a more extensive treatise on this topic in the context of development see Nelson, de Haan, & Thomas, 2006).

Developmental Plasticity
The classic examples of developmental plasticity are generally drawn from early sensory and/or perceptual development. For example, we know that between 6 and 12 months of age, the ability to discriminate phonemes from languages to which an infant is not exposed declines dramatically (for a review see Saffran, Werker, & Werner, 2006; Werker & Vouloumanos, 2001). With that said, it appears that the door does not shut completely on retaining the ability to discriminate non-native contrasts. For example, if before 12 months of age infants are given additional experience with speech sounds in a non-native language, this ability is retained (Kuhl, Tsao, & Liu, 2003).

A similar phenomenon occurs in the visual domain; specifically, in the domain of face processing. Pascalis, de Haan and Nelson (2002) have reported that 6-month-olds, 9-month-olds and adults are all equally good at discriminating two human faces, but only 6-month-olds can also discriminate two monkey faces. However, it is also the case that if 6-month-olds are given 3 months’ experience viewing monkey faces, they retain this ability (Pascalis, Scott, Kelly et al., 2005). Thus, as is the case with speech, face processing also appears to go through a developmentally sensitive period, although one that can be extended with specific experience.

A similar phenomenon exists for visual acuity. Maurer, Lewis, Brent et al. (1999) have reported that among infants born with cataracts that are removed and new lenses placed within months of birth, even just a few minutes of visual experience can lead to a big improvement in visual acuity. However, the longer the cataracts are left untreated, the less favorable the outcome.

In the broad domain of visual function, we know that among Braille-reading individuals who lost their sight after age 16, activation of area 17 of the visual cortex is absent, whereas such activation is present among those who lost their sight before age 16 (Sadato, Pascual-Leone, Grafman et al., 1998). Such findings are also consistent with a sensitive period for visual function.

Effects of Early Focal Lesions on Language Development
The extent to which language represents a special modular function that is hard-wired into the nervous system or represents a domain-general function that becomes domain-specific with experience continues to be debated. One element of the language literature that is particularly relevant to this debate concerns the effect of early brain injury on the development and neural organization of language. In what way is this literature relevant? If there are such things as language modules, then there should be relatively little plasticity in language systems, as other systems should be unable to absorb the functions subserved by language-dedicated areas. On the other hand, if language (speaking broadly) reflects an experience-expectant system that is heavily activity dependent, then there should be considerable plasticity in the system – although such plasticity is likely to be bounded by a sensitive period. As a result, children experiencing early damage to language-related areas should develop reasonably normal language, assuming they are reared in a language-typical environment. As we shall see below, that is exactly what happens.

Building on earlier work by Lenneberg and others (e.g., Lenneberg, 1969), the late Elizabeth Bates led a longitudinal study concerned with language development in children experiencing focal brain damage. In their project (for a review see Bates & Roe, 2001), children who experienced a stroke immediately prior to birth or in the immediate postpartum period were studied. In some cases the stroke was unilateral and in others bilateral. As the infants developed, they were studied using a battery of tasks designed to evaluate a range of language functions.

The most consistent finding reported by these researchers was that relative to typically developing controls, by school age, children with unilateral brain damage fell within the normal range on measures of productive language, and that no differences in productive language were observed between children experiencing left vs. right hemisphere damage. When compared with adults with damage to the left hemisphere, children who experienced focal brain injury were superior in all measures of language production. A virtually identical pattern of findings was obtained on measures of language comprehension.

Bates and colleagues interpreted these findings to suggest that the left hemisphere is initially committed to language development. If development proceeds normally, this hemisphere will become specialized for language; however, when brain damage occurs (as with a pre- or perinatal stroke), the right hemisphere will subsume the functions of the left hemisphere. This pattern is very different from that observed in adults, in whom damage to language-related areas typically leads to significant and persistent deficits (i.e., there is much less plasticity in recovery from brain damage). These findings also suggest that the neural substrate for language is not fixed but, rather, is simply biased in a particular direction. Should the typical trajectory be perturbed because of early brain damage, the brain’s plasticity makes it possible for other neural systems to subsume the functions of the original architecture.

Social and Emotional Development and Developmental Psychopathology
Moving away from the sensory, perceptual and linguistic domains, a rather dramatic example of the effects of early experience on development can be found in an ambitious project concerned with the effects of early institutionalization on brain and behavioral development. The Bucharest Early Intervention Project (BEIP) is a longitudinal study contrasting three groups of children. The institutionalized group comprised children who had lived virtually their entire lives in institutional settings in Bucharest, Romania. The foster care group
included children who were institutionalized at birth, and then following an extensive baseline assessment, placed in foster care (the mean age of placement was 22 months). Finally, the never-institutionalized group included children living with their biological families in the greater Bucharest community (for details see Zeanah, Nelson, Fox et al., 2003). The neuroscientific premise underlying this project is that the deficits and developmental delays that result from institutional rearing have their origins in compromised brain development. For the brain to wire correctly requires input; a lack of input leads to the under-specification of circuits and mismapping of circuits. Children living in institutions lack input (stimulation) on a grand scale, and thus, we expect such children to experience a range of problems as a result of “errors” in brain development. Finally, we know that some domains of function are more experience-dependent than others, and in the experience-dependent functions, the critical timing of the experience needed to ensure healthy development will vary. Thus, the efficacy of foster care should vary by domain (e.g., language, psychopathology) and duration of deprivation.

Our findings have been reported and reviewed in a variety of outlets (for a recent overview see Nelson, Zeanah, & Fox, 2007). For the purposes of this chapter, we briefly touch on our psychopathology data.1

First, it is important to note at the outset that the institutionalized group and foster care group were identical in all respects at baseline (i.e., before half the sample was placed in foster care). Second, we found that at 34 months of age, approximately 56% of the institutionalized group met criteria for an axis I disorder, whereas this figure dropped to 36% for the foster care group. If we break this down further, we see that 50% of the institutionalized group but only 22% of the foster care group met the criteria for any emotional disorder; however, in the domain of behavioral disorders, there were no statistically significant differences between the institutionalized group and foster care group (where the rates are 32% and 25%, respectively).

Naturally, we were curious about specific disorders, so we broke our data down further. Here several observations are worth noting. For depression, the incidence among the institutionalized group and the foster care group was 8.5% and 3%, respectively; for anxiety, these same figures were 44% and 20%. Thus, for emotional disorders generally, there was a very high incidence of anxiety overall, and foster care appears to be effective in reducing the burden of suffering for both anxiety and depression. The picture is quite different for disruptive symptoms. Here we found that the incidence of attention deficit/hyperactivity disorder (ADHD) was 25% in the institutionalized group and 19% in the foster care group (not a statistically significant difference). For oppositional defiant disorder/conduct disorder (ODD/CD), these figures were 15% and 14%, respectively. Thus, in contrast to emotional disorders, foster care has shown no beneficial effect (as yet) on reducing the symptoms of ADHD and ODD/CD.

Collectively, this project demonstrates that early psychosocial deprivation appears to be causally related to subsequent psychopathology, and that foster care is more effective in reducing symptoms of emotional disorders than disruptive disorders. This latter observation permits us to speculate that the neural circuits that subserve attention and emotion regulation (largely prefrontal) may be established in the first 2 years of life, prior to when the children were removed from the institution and placed in foster care. However, whether this represents a true sensitive period or not is impossible to say until we see the children at a later age (as we are currently doing). Collectively, these and other examples (for elaboration see Nelson, de Haan, & Thomas, 2006) demonstrate the role of early experience in development, and the concept of sensitive periods.

Adult Plasticity

It was once assumed that with the exception of a few isolated domains (e.g., recovery from stroke), the adult brain possessed little plasticity. However, studies by Rosenzweig and Diamond (e.g., Diamond, Lindner, Johnson et al., 1975) and later by Greenough, clearly proved this view incorrect. For example, over the past 30 years Greenough and colleagues have elegantly demonstrated that rats raised in complex laboratory environments perform many cognitive tasks better than rats reared in isolation. Some of the changes observed in the brain include the following:

1 Regions within the dorsal neocortex are heavier and thicker and have more synapses.
2 The number and length of dendritic spines and branching patterns increase.
3 There is increased capillary branching, thereby increasing blood and oxygen volume (for some specific examples and overviews see Black, Jones, Nelson et al., 1998; Greenough & Black, 1992; Kolb, Gibb, & Robinson, 2003).

Other examples of adult plasticity can be found in the motor and sensory domains. For example, Elbert, Pantev, Wienbruch et al. (1993) have reported that the somatosensory cortex representing the fingers of the left hand in highly proficient stringed instrument players is larger than: (i) the analogous area in the opposite hemisphere representing the right hand (used to bow vs. the left hand, which is used in more fine motor activity), and; (ii) than non-musicians. In addition, Draganski, Gaser, Busch et al. (2004) have reported that individuals who had been given 3 months to learn to juggle showed increased bilateral neural activation in certain brain regions (mid-temporal area and left posterior intraparietal sulcus). Importantly, 3 months after this group stopped juggling, there was a decrease in activation. Non-jugglers over the 6-month period showed no changes in brain activation.

Moving into more cognitive systems, Erickson, Jagadeesh, and Desimone (2000) presented adult monkeys with multicolored

---

1 Note: because the critical question being addressed in this project is the efficacy of foster care in ameliorating the negative sequelae of early institutionalization, we do not report the data from the Never Institutionalized Group (NIG). However, suffice to say, the incidence of psychopathology in this group is virtually identical to that of a US comparison sample.
complex stimuli (some familiar, some novel) while brain activity was recorded from the perirhinal cortex (an area known to be involved in episodic memory). The authors reported that after only 1 day’s experience viewing the stimuli, the performance of neighboring neurons became highly correlated during viewing of familiar stimuli; this was in contrast to novel stimuli, which revealed little correlated neuronal activity. The authors interpreted these findings to suggest that visual experience leads to functional changes in an area of the brain known to be involved in memory.

An even more dramatic example of how experience leads to changes in neural architecture is the now well-known study of London cab drivers. Maguire, Gadian, Johnsruide et al. (2000) obtained structural MRI scans from individuals with great expertise in navigating the streets of London (i.e., London cab drivers). The authors reported that, relative to non-cab drivers, the posterior hippocampus was larger; moreover, there was also a positive correlation between hippocampal volume and the amount of experience the drivers had. Alas, there is rather a chicken-and-egg problem with this work: specifically, it might be the case that individuals who choose to be cab drivers already have a larger hippocampus or possess more plasticity than non-cab drivers, thus making them more likely to show anatomical changes in response to experience. Clearly, this is an area ripe for future study.

Collectively, we now know that the adult brain is quite capable of being molded by experience. Over and above the examples provided, learning and memory represent the quintessential examples of adult plasticity. However, the behavioral domains that benefit from such experience are more limited than those that benefit from experiences earlier in development. This leads us to ask what the difference is between adult versus developmental plasticity.

What distinguishes adult plasticity from developmental plasticity?

There are a number of fundamental differences in the way plastic processes might work in the developing brain compared to the developed brain. First, at the physiological, anatomical and metabolic levels, the plastic processes that operate early in the lifespan differ from those that occur later in the lifespan. The newborn brain has more neurons and synapses than an adult brain, and many of these are not yet committed to particular circuits or functions. Thus, an axon that is growing towards its target has very different terrain to negotiate in the newborn brain than in the adult brain. Similarly, modifying synapses already committed to a particular circuit is quite different from committing synapses to a particular circuit for the first time. In other words, rewiring the brain is different from wiring the brain.

Another way to demonstrate the difference between developmental and adult plasticity is at a systems or behavioral level. For example, a goal of infant development is to establish neural circuits in the service of some behavior. However, these circuits are already in place in the adult brain, and must be retasked or reconfigured in order to serve another function; a case in point might be the difference in acquiring a first language versus learning a second or third language.

In summary, both the developing and developed brain are capable of being molded by experience, although there are many more constraints on changing the adult brain and the mechanisms that underlie plasticity likely differ between children and adults.

Biological Insults

Across developmental time the brain can be altered by experience. However, many organic insults can, and do, also alter brain development, and can sometimes lead to long-lasting damage. In this section we describe such pre- and perinatal insults, with emphasis on the fact that many different types of injury can result in similar developmental outcomes.

The central nervous system develops over a protracted course, beginning shortly after conception and continuing after birth, with refining processes (e.g., myelination and synaptogenesis) occurring throughout childhood and adolescence. As one would expect, the brain is susceptible to injury at each stage of development. Following the principles of neural plasticity outlined earlier in this chapter, we know that timing, duration, location, mechanism and extent of injury and initial clinical course all contribute to neurological outcome and extent of neurodevelopmental pathology. As we will show, the level of clinical impairment depends upon the interplay of the factors listed above (e.g., timing, extent and location of injury), with no one factor having a singularly dominant role in defining outcome.

Prenatal, or intrauterine, defects can result from malformation or destruction of brain tissue. Brain malformations can occur at every stage of prenatal development (Aicardi, 1998; Barkovich, 2005a; Swaiman, Ashwal, & Ferriero, 2006). Aberrant neural tube formation can lead to anencephaly (failed closure of the rostral end of neural tube, leading to incomplete formation of brain and skull), encephalocele (herniation of the brain outside of skull) or myelomeningocele (failure of closure of the caudal end of neural tube, leading to an open sac of spinal cord tissue). Later in development, abnormal segmentation and cleavage can result in holoprosencephaly (failure of the brain to divide into lobes), agenesis of the corpus callosum, or septo-optic dysplasia (underdevelopment of the optic nerve, hypopituitarism and absence of a midline structure called the septum pellucidum). Later still in development, disordered neuronal proliferation can cause microcephaly (small brain), macrocephaly (large brain) or can lead to abnormal neoplastic or benign cortical tumors. Disordered migration can result in lissencephaly (smooth brain) or cortical heterotopias (groups of neurons not fully migrated), while abnormal neuronal organization can result in schizencephaly (abnormal cortical clefts). Finally, defects in myelination result in disorders of the white matter such as white matter hypoplasia.

In addition, far beyond the scope of this chapter, there exist countless inherited metabolic, neurodegenerative and genetic
disorders that result in brain malformations and associated developmental psychopathology. Common examples include trisomy 21, fragile X and tuberous sclerosis (see chapter 24). Extensive research in the past two decades on the genetics of brain malformations has resulted in the isolation of genes for many of the above disorders, such as the DCX, LIS1 and RELN gene mutations found in the lissencephaly syndromes (Barkovich, 2005b).

The clinical outcome of brain malformations varies, and depends on both timing and extent of the area of brain involved. For instance, children with holoprosencephaly typically have intractable seizures, profound developmental delay and spastic quadripareisis, while those with small cortical heterotopias may only have focal seizures with no developmental disabilities. The level of impairment in children with lissencephaly depends on the extent of cortex affected, but typically children have profound neurological impairment in all realms of development.

Destructive processes, including infection, vascular injury and toxic exposures, also can occur in utero. With regard to infectious agents, the most common pathogens affecting the CNS include viruses such as cytomegalovirus (CMV), herpes simplex virus (HSV), varicella zoster virus (VZV), Epstein–Barr virus (EBV), human immunodeficiency virus (HIV) and rubella, parasitic infections such as toxoplasmosis, and, more rarely, bacterial infections. In utero infection with any of the above agents can result in significant neurological sequelae such as profound developmental delay, seizures, behavioral disturbances, autistic features, visual impairment, sensorineural hearing loss and spastic quadriparesis (Swaiman, Ashwal, & Ferriero, 2006; Volpe, 2001). Again, as with brain malformations, the extent of intraparenchymal involvement and timing of infection influence the severity of outcome. In some cases the earlier the exposure to the infectious agent, the more significant the neurological devastation. For example, a recent study compared children exposed to CMV infection in the first-trimester with those exposed later in gestation. Of the first-trimester group, 24% had sensorineural hearing loss, compared to 2.5% of the later-infection group. Of the first-trimester group, 32% exhibited at least one CNS sequela (intellectual disability, cerebral palsy, seizures) compared to 15% in the later group, and none of this later group had more than one sequela (Pess, 2006).

Moving on from infection, perinatal vascular injury usually occurs in the setting of hypoxia or ischemia, resulting from maternal disease, placental insufficiency or pathology intrinsic to the fetus. Pathologically, necrotic and cavitary lesions are most commonly seen with perinatal injury, especially lesions of the white matter such as periventricular leukomalacia (PVL). Diagnosis of these insults is often postnatal, and sometimes can be delayed for months in milder lesions. Outcome depends on extent and site of injury. For example, global hypoxia can cause profound intellectual disability and quadripareisis, while focal ischemia may result in only a mild motor impairment or seizures, depending on location of the stroke. Mild to moderate degrees of hypoxic injury, however, can sometimes exert their effects relatively selectively, leading, for example, to damage to the hippocampus, which in turn may lead to selective deficits in memory (de Haan, Wyatt, Roth et al., 2006).

Finally, toxic exposures to the fetus can lead to neurodevelopmental pathology, even in the setting of normal-appearing brain parenchyma. Toxins include therapeutic drugs such as antiepileptics, or recreational drugs such as alcohol, nicotine, marijuana or cocaine. As discussed in detail in chapter 30, fetal alcohol exposure is the most common preventable chemical cause of intellectual disability in the USA (Aicardi, 1998). Long-term follow-up studies of children with fetal alcohol syndrome (FAS) show significant deficits in visuospatial functioning, verbal and non-verbal learning, attention and executive functioning. They also have behavioral problems that further affect their daily functioning (Riley & McGee, 2005).

Perinatal injury, defined as insults during or just after birth, can also cause significant neurological sequelae. The most common examples include intracerebral hemorrhage, hypoxic ischemic injury, PVL and perinatal toxic or metabolic disturbances. With these insults, timing may be less critical, and more important become location, extent of injury and level of neurological dysfunction at the time of injury. Most perinatal insults occur within the first 10 days of life.

Intracerebral hemorrhage includes subdural, intraventricular, intraparenchymal and subarachnoid bleeding. Birth trauma is the major cause of subdural and subarachnoid hemorrhage, and often can fully resolve without neurological sequelae. Sometimes children will have seizures in the acute setting, and based on the location of the hemorrhage may have some motor deficits. Intraventricular hemorrhage occurs most commonly in the preterm infant, especially before age 32 weeks, when the germinal matrix still exists. Classically, hemorrhage is graded by the extent of ventricular blood and dilatation. Grade I is the mildest, with less than 50% of the ventricle filled with blood, with grade IV, or periventricular hemorrhagic infarction, resulting in both intraventricular and intraparenchymal blood. Factors that predispose the preterm infant to intraventricular hemorrhage include labile blood pressures, sepsis, certain medications and mechanical ventilation. The neurological outcome of intraventricular hemorrhage depends on the extent of hemorrhage and the neonate’s clinical status at presentation. Grade I hemorrhage often results in a normal outcome, whereas 75% of neonates with grade III–IV hemorrhage, if they survive, have profound spastic quadripareisis, intellectual disability and behavioral disturbances (Volpe, 2001).

Hypoxic ischemic encephalopathy (HIE) can occur as a result of perinatal vascular insufficiency, perinatal asphyxia, or postnatal hypoxia from respiratory failure, hypotension or other systemic illness. HIE occurs in up to 6 per 1000 live births, and results from two mechanisms: hypoxia (reduced oxygen supply to the blood), or ischemia (reduced perfusion of the brain). Both are caused by asphyxia, or hypoxia associated with hypercarbia (a build-up of carbon dioxide in the blood). The end result is a depletion of adenosine triphosphate (ATP) and a rise in lactate production in the brain, which ultimately causes brain edema and cell death. The pathology
CHAPTER 12

associated with HIE depends on the duration and extent of the asphyxia. Acute total asphyxia leads to bilateral lesions in the brainstem and thalamic lesions, while partial prolonged asphyxia causes more diffuse lesions with edema, mainly affecting the cortex and basal ganglia. In addition, HIE is often associated with PVL (bilateral necrosis of the white matter adjacent to the lateral ventricles). Sometimes these lesions can become hemorrhagic or cystic (Aicardi, 1998; Volpe, 2001).

Clinical impairments of HIE range from mild to severe based on the extent of pathology. Preterm infants tend to have poorer outcomes than term infants. In the milder cases, irritability and jitteriness prevail, whereas in more severe cases, obtundation and intractable seizures occur. Babies with diffuse involvement of the cortex can present in coma. When the brainstem is affected, babies may lose their ability to breathe, suck or swallow independently. The long-term prognosis depends on the severity of the clinical picture during the first days of life. Neurodevelopmental deficits are not seen if there are no initial clinical sequelae of HIE (Aicardi, 1998). In mild HIE, only some motor deficits may occur. In severe HIE, most children will have significant developmental delay along with cerebral palsy and seizure disorder.

Metabolic disturbances such as hyperbilirubinemia leading to kernicterus, or electrolyte abnormalities such as hypoglycemia or hypocalcemia can also lead to significant neurological sequelae after birth, initially with encephalopathy and seizures and ultimately with developmental delays, depending on extent and duration of exposure. Also, many inborn errors of metabolism present early in the neonatal period and lead to varying degrees of developmental delay and behavioral disturbances.

Perhaps the most common risk factor for subsequent morbidity concerns infants born prematurely and/or of low birth weight. About 55,000 children per year are born in the USA with birth weights less than 1500 g, defined as very low birth weight (VLBW) (Taylor, Minich, Klein et al., 2004). In these children, the incidence of major developmental disabilities (e.g., intellectual disability, cerebral palsy, epilepsy, blindness, sensorineural hearing loss) is in the range of 15–20%. In addition, more subtle disabilities such as learning disabilities, mild cognitive impairment, ADHD and behavioral problems occur in an estimated 50–70% of such children (Hack, Klein, & Taylor, 1995).

In the CNS, hypoxic ischemic injury, intraventricular hemorrhage, PVL and infection represent the primary pathology in children of VLBW. Both white and gray matter are vulnerable to injury, and hypoxic ischemic injury leads to multifocal cortical ischemia and necrosis, especially in the sensorimotor, parieto-occipital, temporal regions adjacent to the ventricles, hippocampus and other subcortical structures (Volpe, 2001).

Neuropsychological studies of VLBW adolescents have shown deficits in multiple cognitive domains, such as visual–motor skills and memory, independent of IQ. In a recent study by Taylor, Minich, Klein et al. (2004), long-term follow-up of children of VLBW was performed, with neuropsychological testing performed until age 16. Analysis revealed poorest outcomes in those with lower birth weight, lower weight for gestational age and longer period of oxygen requirement. The major impairments were in visual–motor skills, spatial memory and executive function. In studies of younger children, impairments in working memory and spatial planning are consistently found, and are thought to be predicted by the presence of intraventricular hemorrhage or PVL (Frisk & Whyte, 1994).

Overall, there seems to be a correlation between birth weight and level of impairment, with the lowest birth weight children having the most impairment. Associated factors that likely determine clinical outcome include medical and neurological complications in the neonatal period. Furthermore, there is evidence that environmental factors may also have a role, with sociodemographic status and family environment likely moderating the biological effects of being VLBW (Taylor et al., 2004). Therefore, like many of the other prenatal insults described in the above section, rather than one variable defining clinical outcome, it is likely the interplay of several critical factors that predicts the degree of impairment in children of VLBW. While degree of prematurity (with weight as a marker of gestational age) does have an important role, it is not clear that specific CNS pathology correlates consistently with specific neuropsychological deficits.

Summary

This brief review was designed to illustrate that many different mechanisms of biological injury can result in psychopathology, ranging from profound intellectual disability to mild developmental delay, behavioral problems or disorders on the autistic spectrum. We now discuss one specific neurodevelopmental disorder, autism, and consider how this clinical syndrome can result from many distinct biological entities (for a fuller discussion of autism see chapter 46). In this section, we use autism as a model for a discussion about biological and environmental mechanisms of developmental psychopathology. While many children with autism do not have a known underlying neuropathology, many children with the pre- and postnatal insults described earlier meet the criteria for autism; these include children with prenatal CMV infection, intracerebral hemorrhage and genetic syndromes such as tuberous sclerosis. In our discussion we illustrate that while much of the pathogenesis of this disorder remains unknown, there is adequate evidence to support underlying pathology at multiple stages of brain development.

Autism

Decades ago, it was believed that this disorder of behavior and cognition resulted from emotional deprivation in infancy. However, subsequent studies found a much higher incidence of abnormal electroencephalograms (EEGs), epilepsy and intellectual disability in children with autism, thereby arguing for a biological basis for the syndrome (Small, 1975). Because
of the variability in age of diagnosis, the timing of the insult or injury was not well characterized.

As discussed in chapter 46, in the past decade, studies in neuropathology, neuroimaging, morphometrics and early behavior of children with autism suggest that abnormalities in the nervous system occur at multiple stages of brain development, from the first prenatal months through early childhood. Changes in the brain occur long before atypical behaviors become apparent, and these changes continue over the course of a lifetime. These changes are likely not static, but progressive, and may evolve over the course of brain development. For example, it may be the case that an error in brain development that occurs prenatally will not be expressed until the area affected begins to mature and subserve function (Miller, Goldman, & Rosvold, 1973); a case in point may be the prevailing view that schizophrenia, which does not typically present until late in the second decade of life, likely has its origin in errors in cell migration, an event that occurred perhaps as much as two decades earlier (see chapter 45).

Given the mounting evidence that at least some signs of autism appear well before a formal diagnosis is made, the question then arises, when and how does this insult occur? Is there one critical time of development that results in the autistic phenotype, or are there many paths to one final common phenotype? Much speculation exists regarding the role of prenatal insults in the pathogenesis of autism. Retrospective studies have shown a higher incidence of many different perinatal and prenatal factors in children with autism, such as uterine bleeding, hyperbilirubinemia, early gestational age, early fetal distress and low Apgar scores, but none have been evaluated prospectively (Glasson, Bower, Petterson et al., 2004; Juul-Dam, Townsend, & Courchesne, 2001). Some argue that obstetric complications may, in fact, be an epiphenomenon or even a consequence, and not a cause, of neurodevelopmental disabilities such as autism. In other words, both autism and perinatal complications may be derived from shared risk factors, such as genetic or environmental susceptibility (Bolton, Murphy, Macdonald et al., 1997). More studies are needed to resolve these issues.

**Pre- and Postnatal Insults and Autism**

Associations exist between autism and certain prenatal insults, including fetal exposure to alcohol, valproic acid and thalidomide, as well as congenital infections including CMV and rubella (Arndt, Stodgell, & Rodier, 2005; Miller, Strömland, Ventura et al., 2005). It is also known that certain genetic syndromes, such as tuberous sclerosis, fragile X, Smith–Lemli–Opitz, and Cornelia de Lange, as well as some neurodevelopmental disorders, such as Möbius sequence and CHARGE association (colobomas, heart defects, choanal atresia, retarded growth/development, genital anomalies and ear anomalies/hearing loss) have a higher incidence of autism than the general population (Miller et al., 2005).

From a neurodevelopmental perspective, what is interesting is the fact that each of the above syndromes influences the brain at different stages of fetal development, with some insults clearly occurring early in gestation. For instance, in Möbius sequence and CHARGE association, children exhibit abnormalities in cranial nerves and facial structures (such as ear development) both of which develop in the first month of gestation. The teratogenic effects of valproic acid are thought to occur early in gestation as well, as the anomalies seen in exposed children indicate defects of neural tube closure, such as craniofacial abnormalities and defects in heart, genitalia, and limb structure (Arndt, Stodgell, & Rodier, 2005). In genetic syndromes such as tuberous sclerosis, where the incidence of autism is as high as 40%, benign tumors appear in multiple organ systems, including the heart, kidney and brain, throughout fetal development. Finally, in the case of congenital CMV or rubella, timing of infection is not as well correlated with outcome, as some children with evidence of infection as late as the second and third trimesters can ultimately show clinical signs of autism.

Furthermore, as reviewed in chapter 46, there are data from pathology and neuroimaging (functional imaging, morphometrics) that abnormalities exist that can be attributed to both pre- and postnatal development. It is clear that at least some of the dysregulation of neuronal growth must occur in the early prenatal period, but then likely continues through childhood and adolescence.

Work by Courchesne and colleagues has shown evidence of dysregulation of brain growth throughout development in children with autism. In their studies, the average head circumference in children with autism was slightly smaller than normal, but during the first year of life there was an abnormally accelerated rate of brain growth, so that by age 2 the brain of a child with autism was 10% larger than average (Courchesne, Carper, & Akshoomoff, 2003; Courchesne, Redcay, & Kennedy, 2004). MRI data have shown that the enlargement represents both gray and white matter, but most prominently cortical and cerebellar white matter (Courchesne, 2002; Herbert, Ziegler, Deutsch et al., 2005). Moreover, the overgrowth is consistently regional, with frontal lobes being most abnormally enlarged, while posterior regions of the brain such as the occipital lobes are normal in size. Furthermore, while the volume of brainstem and cerebellum was shown to increase with age, the overall sizes of regions of the brainstem as well as the cerebellar vermis were smaller than in the general population (Hashimoto, Tayama, Murakawa et al., 1995). The phase of cortical overgrowth was followed later in childhood by a phase of abnormally slow (or arrested) growth. By adolescence, the autistic child’s brain was only 1–2% larger than average. As with the localization of brain overgrowth, the growth retardation affects both white and gray matter, but most prominently cortical and cerebellar white matter (Courchesne, Redcay, Morgan et al., 2005).

While the principle of brain growth dysregulation in children with autism has been well accepted, the details of the data (such as cerebellar size and the fact that the brain returns to average size by adulthood) have not been confirmed by other studies. Nevertheless, these data do support the notion that changes in the brain may occur at different and continuing time points in children with autism.
CHAPTER 12

Through this discussion, one might conclude that autism is a biologically based disorder of brain development, and not a result of environmental deprivation. However, as we have emphasized throughout this chapter, brain development is affected by many factors, and there is likely an interplay of environment and biology. We now illustrate the fact that environment may also have a critical role in the development of the autistic phenotype, at least in some children. The monozygotic twin concordance rate in autism has been reported to be in the range 60–95% (Bailey, Luthert, Dean et al., 1998). The fact that the concordance is not 100% has been used as evidence for the important contribution of environment in the development of the final autistic phenotype (although of course variable expression of genes can also be due to stochastic effects).

What Environmental Factors are Associated with Autism?
The relationship between environmental deprivation and the autistic phenotype has been described retrospectively. Fraiberg (1977) found that children born blind developed behavioral abnormalities similar to autism, and defined them as manifesting an “autistiform syndrome.” More recently, several retrospective studies of Romanian children adopted into families after early institutionalization have been found to exhibit a similar autistic phenotype (Hoksbergen, ter Laak, Rijk et al., 2005; Rutter, Anderson-Wood, Beckett et al., 1999).

Rutter et al. (1999) evaluated a subgroup of Romanian children who were adopted from orphanages into homes in England. These children, most of whom were adopted by age 2, were reported to be severely deprived and malnourished. Their experience in the orphanages was described as ranging from “poor to appalling,” left in cots all day without much interactive play, verbal communication or physical interaction with others. The children underwent screening for autism at age 4 and then age 6 using the Autism Screening Questionnaire (ASQ). The Autism Diagnostic Interview (ADI-R) was also used to interview the adoptive parents about their children’s behaviors.

In their assessment, Rutter et al. (1999) found that 6% of these children at age 4 showed “a pattern of behavior that closely resembled childhood autism,” a pattern that Rutter defined as “quasi-autistic.” They had “poor reciprocity, a deviant style, poor appreciation of social cues, and a lack of normal social boundaries” as well as “indiscriminate friendliness.” They also demonstrated stereotyped preoccupations with certain types of play. However, unlike children with classic autism, they maintained a high degree of social interest and they did not manifest any repetitive movements such as rocking or spinning in circles. Furthermore, these children improved in all realms of behavior from age 4 to 6, quite unlike the typical child with autism. While there were no clear predictors of autism in this group, two correlates that emerged were degree of cognitive impairment and duration of institutionalization.

These findings were supported by Hoksbergen et al. (2005), who studied 80 children from Romania adopted in the Netherlands. Using parental interview only, they described a “Post-Institutional Autistic Syndrome” in 13 of the 80 children and also described some developmental improvement after adoption. Overall, according to these studies, children facing early environmental deprivation had a higher incidence of autism. The features of autism, however, were rather atypical. They also tended to improve with amelioration of their environment.

Conclusions

Earlier in this section we reported that a variety of disorders (e.g., fragile X, tuberous sclerosis) can present as classic autism, and that a number of pre- or perinatal insults increase the probability that a child will present with autism. We concluded this section of our chapter by also reporting that a subset of children experiencing early severe privation appear quasi-autistic although, intriguingly, the symptoms of this disorder are lessened or even disappear following placement into families. Therefore, using autism as an example of a neurodevelopmental disorder, we have shown that a similar phenotype can result from a purely biological and a purely environmental insult.

How do we reconcile the fact that frank biological insult (e.g., tubers that replace normal brain tissue, as in the case of tuberous sclerosis), toxic exposures (e.g., alcohol), and exposure to early psychosocial adversity can all lead to the same disorder? To address this question, we must return to the definition of the “disorder” itself. Autism, as defined by DSM-IV (American Psychiatric Association, 2000), is a summation of specific cognitive and behavioral traits, which together create a specific phenotype. Like many behavioral and developmental disorders, the definition is based purely on clinical criteria created by clinicians and researchers. The definition assumes no specific pathogenesis or etiology, but only describes the ultimate clinical outcome. Thus, the fact that multiple causes can produce the same phenotype does not undermine or confound the definition itself. However, it does support the contention that autism encompasses a number of different – although likely related – disorders, and that as we learn more about their neuropathology, these separate syndromes will emerge from the blanket diagnosis of “autism” as independent identities. Stated rather differently, the heterogeneity of autism may, in fact, reflect biologically distinct disorders.

One could argue that most clinically defined disorders, such as ADHD, bipolar disorder and schizophrenia, face a similar underlying heterogeneity. For example, some “strains” of ADHD or depression may have a much higher genetic loading than others, some may be largely attributed to a birth injury (e.g., an intraventricular hemorrhage that occurs as a byproduct of being born very prematurely) and still others may be triggered predominantly by environmental factors (such as the association between early maltreatment and depression). What we need to consider is that autism and all other forms
of psychopathology are inherently brain disorders, with alterations in neurochemistry, neural circuitry or neural anatomy causing the clinical phenotype.

The cause of these alterations is likely multifactorial. For example, alterations in specific genes or gene products at particular points in development can lead to changes in brain anatomy, circuitry or chemistry. Similarly, in some cases these genes may express themselves independently of experience, whereas in others it may well take an environmental trigger to alter gene expression. In still other cases, as among children who experience profound early privation, genes may play no part in the disorder. Instead, the pathogenesis can be attributed to the brain’s ability to be molded by experience – albeit molded abnormally. Ultimately, we could argue that brain development can be perturbed by both genetic and non-genetic factors, and that such perturbations can present in exactly the same way, despite different underlying causes.

Our only hope of unraveling the biological mechanisms that actually cause a disorder are to consider:
1. Both genetic and non-genetic factors simultaneously;
2. The exact timing of these factors; and
3. The degree to which these factors cause pathology (e.g., how many repeats of a given gene; the extent of early adverse experience).

We conclude our chapter with an additional recommendation for future research. If neuroscience is to shed light on psychopathology, it is imperative that we improve our phenotyping instruments. As behavioral neuroscientists have known for many years, the success in elucidating the neural underpinnings of a given behavior depends to a great degree on how carefully and specifically the behavior is described. For example, to say someone is anxious says little about the myriad of behaviors that collectively express themselves as anxiety. To improve the precision of diagnoses (by improved phenotyping), we need to improve our armamentarium of tools that permit us to look inside the developing brain. At present, the best functional tool we have to study the infant’s brain is EEG, as functional imaging (fMRI, PET) requires that a child be old enough to comply with the study. Ideally, we must develop a system of co-registering these measures in order to take advantage of the strengths of each tool. For completeness, we should use multiple measures combined with sensitive behavioral assays.

Ultimately, as we improve our ability to characterize accurately the neuropathology underlying behavioral disorders, the way we view and perhaps even treat these disorders will change. They will evolve from being definitions created by clinical observation to precise diagnoses validated by scientific data. This evolution will not only facilitate effective therapy, but also provide insight into the biology of behavior and, essentially, the mind.

If we accept at face value that all disorders of the mind are inherently disorders of the brain, and that genes and gene products have an integral role in brain development and brain function, it is incumbent upon us to train the next generation of developmental psychopathologists accordingly.

CHAPTER 12

Across the social and biological sciences, investigators are increasingly taking a life course perspective on the development of human health, behavior and disease (Elder & Shanahan, 2006). Psychiatry is no exception to this trend; as findings from long-term longitudinal studies proliferate, so it becomes increasingly clear that many adult disorders have origins very early in development, and that many childhood disorders have sequelae that persist to adult life. Knowledge of these long-term developmental linkages has cast new light on the etiology and course of many disorders, highlighted unexpected connections across the life course and raised key questions about the mechanisms – biological, psychological and social – that underlie both continuities and discontinuities in vulnerability over time.

Although there were earlier pointers (Rutter & Garmezy, 1983), the first clear evidence of the childhood origins of adult disorder came from large-scale surveys of adult mental health. Questioned about their first episode of disorder, many adults with histories of depression, anxiety and substance use dated the start of their difficulties before age 20 (Christie, Burke, Regier et al., 1988); analyses of peak hazard rates for a broader range of disorders set them too in childhood and adolescence (Burke, Burke, Regier et al., 1990). Since that time, epidemiological studies in childhood have clarified typical age at onset patterns for most disorders, and highlighted two broad age at onset groups. One, with onsets very early in childhood, includes what are now regarded as neurodevelopmental disorders (see chapter 3): autism spectrum disorders, specific language impairment, dyslexia and attention deficit/hyperactivity disorder (ADHD). All of these disorders have a strong male preponderance. The second group, with onsets in adolescence, includes disorders more common in women and girls: depression, eating disorders, social phobia and panic (Costello, Foley, & Angold, 2006). Separation anxiety, specific phobias and oppositional disorders also onset in childhood; substance problems typically emerge in the teens; and conduct disorders show two onset periods, one in childhood and the second in adolescence. Charting these onset patterns has provided an essential point of departure for the study of longer-term developmental trajectories.

Childhood studies have also highlighted other themes relevant to a life course view. First, although the point prevalence of childhood and adolescent disorders centers at around 10–12%, repeated assessments produce much higher estimates. In one community study, for example, annual assessments showed that over one-third of young people had met diagnostic criteria for disorder at some stage between the ages of 9 and 16 years (Costello, Mustillo, Erkanli et al., 2003). From this perspective, the childhood and adolescent “base” for later psychiatric morbidity is high. Second, persistence of disorder in childhood is also high. A 3-year follow-up of cases identified in the 1999 British Child Mental Health Survey (Meltzer, Gatward, Corbin et al., 2003), for example, found that more than 40% of young people who met criteria for disorder at first assessment also did so at follow-up. In many instances this reflected homotypic continuity – persistence or recurrence of the same disorder over time. Not infrequently, however, earlier and later disorders were of a different kind, highlighting the importance of sequential comorbidity or heterotypic continuity in the mental health domain. As these findings suggest, developmental models need to account for both continuity and discontinuity across the life course, and to identify factors that make for both stability and change.

Evidence for longer-term continuities in disorder comes from many sources. Some of the most persuasive are prospective studies of unselected birth cohorts, set up by far-sighted investigators many years ago (Coleman & Jones, 2004). As cohorts of this kind mature, their findings offer two complementary perspectives on connections between disorder in childhood and in adult life. First, looking forwards from childhood, longitudinal data provide estimates of the extent to which children and adolescents with mental health problems are at risk for disorder later in their lives. Second, looking backwards from adulthood, they highlight early roots of adult vulnerability. Some of the most compelling evidence for long-term continuities has come from this second approach. Recent reports from the Dunedin longitudinal cohort (Kim-Cohen, Caspi, Moffitt et al., 2003), for example, show that most young adults with a psychiatric disorder had diagnosable problems much earlier in life. Of those with treated mental health problems at age 26, half had first met criteria for disorder by age 15; by the late teens, that figure approached 75%.

What accounts for these long-term vulnerabilities? Although we are still far from definitive answers to this question, important pointers are beginning to emerge. This chapter draws
together recent findings in this area, using examples from contrasting disorders and early risks to highlight key themes emerging from developmental research. Because long-term developmental studies pose particular challenges, we begin with an overview of the methodological issues that arise in long-term longitudinal research, and the strengths and limitations of the differing strategies that investigators have used to examine continuities and discontinuities in psychopathology. Next, we explore patterns of child–adult links in a series of specific disorders, and in relation to early risks, to illustrate the varying mechanisms now thought to contribute to continuities and discontinuities over time. Finally, we consider the implications of these long-term developmental findings for clinical practice.

Methodological Considerations

There are many ways in which evidence on continuities and discontinuities between psychopathology and experiences in childhood and adult life may be informative. From a methodological perspective, however, three main topics may be differentiated. First, there is the need to determine the outcome of childhood disorders and, most especially, the factors associated with variations in outcome and course. If comparisons can be made among outcomes of different disorders, findings may also contribute to the validation of diagnostic distinctions.

Second, the interest may lie in the possibility that one form of psychopathology creates a risk for another. This arises, for example, with respect to the suggestion that antisocial behavior predisposes to substance abuse, or that anxiety in childhood predisposes to depression after puberty. Here, the research requirements differ from the study of prognosis mainly in terms of the crucial need to study the timing of transitions in psychopathology over its developmental course.

Third, investigators have examined the effects of risk factors in childhood (whether individual characteristics or risk experiences) and psychopathology in adult life. Here, the starting point has to be in terms of postulated risks (rather than the presence of a diagnosed disorder); outcomes must be examined in terms of those who do not, as well as those who do, suffer from the sequelae of risk; and there must be the possibility of examining the effect of later experiences in ameliorating or mitigating the effects of early stress or adversity. Especially for this last topic, but also for the first two, longitudinal data and longitudinal analyses will usually be needed to provide definitive answers to developmental questions.

Almost always, however, it will be desirable to precede longitudinal studies with other research strategies to develop relevant hypotheses. As one of the father figures of developmental studies, Baldwin put it: “A longitudinal study is the last, not the first step, in a research program. It is an absolutely essential research method if we are to get firm knowledge of psychological change, but paradoxically it is to be avoided whenever possible” (Baldwin, 1960). Because longitudinal studies are extremely costly and time-consuming, they need to be saved for use at the point when appropriate ground clearing research has been undertaken to articulate the questions to be examined. Moreover, as we will outline, longitudinal data in themselves do not provide a sufficient answer to developmental questions: in addition, they must be used in the context of appropriate designs and with appropriate methods of data analysis (Rutter, 2007; see chapter 9).

Historically, quite a diverse range of research strategies has been used to examine continuities and discontinuities over the lifespan (Rutter & Garmezy, 1983). Early researchers were innovative in building on existing records to “fast-track” their coverage of developmental time, and much early research focused on clinic-referred rather than general population groups. More recently, prospective studies of representative samples – now regarded as the gold standard in the field – have become increasingly available.

Case–Control Designs and Related Strategies

In many ways, the strategy that involves the least resource consists of bringing together existing record data on the same individuals in childhood and in adult life. That approach was usefully employed by Zeitlin (1986), investigating individuals who had been patients as both children and adults in the same postgraduate teaching hospital. His aim was to compare continuities across different diagnostic groups. The findings were informative, but they were inevitably heavily reliant on the representativeness of the individuals who were both child and adult patients. Many findings proved similar to those of prospective epidemiological studies, but those on the childhood features associated with depression in adult life have turned out to be somewhat misleading.

A different approach was provided by taking an adult patient group as the starting point and looking back to childhood using contemporaneous records. Watt (1974) used this strategy to great effect by using school records to examine childhood precursors of schizophrenia. Because the records were inevitably lacking in precision by current research standards, there is limited specificity in what was found. Nevertheless, the overall pattern of the findings has proved substantially similar to that gained from prospective longitudinal research. The main limitation was that the focus on a single disorder could show how schizophrenia differed from normality, but could not distinguish differences among different adult diagnostic groups.

The least satisfactory strategy has been to rely on retrospective recall for the assessments of childhood. Several studies used this approach to examine relationships between autism in childhood and adult schizophrenia, using the latter as a starting point (Howells & Guirguis, 1984; Petty, Ornitz, Michelman et al., 1984). Continuities were claimed, but prospective studies of children with autism have shown that the conclusions were mistaken. Schizophrenia is indeed preceded by language and social abnormalities in childhood, but prospective studies of individuals with autism have been quite consistent in showing that there is not a raised rate of schizophrenia in adult life (Howlin, Goode, Hurton et al., 2004; Volkmar &
Follow-up Studies of Clinical Groups
The standard for follow-up studies of clinical groups was first set by Robins’ research-based adult follow-up of children who had been seen at a child guidance clinic in middle America in the 1930s (Robins, 1966). Robins traced and interviewed these young people in adulthood, gaining a broad picture of strengths as well as difficulties in their later lives. She used a general population comparison group from the same geographic area to assess how far outcomes were specific to those with childhood disorder, and paid careful attention to differences among psychopathological groups. The findings proved hugely influential: diagnostic criteria for antisocial personality disorder were largely shaped by her findings, and the study generated numerous other developmental hypotheses that have stood the test of time.

Other researchers have used variations on this strategy to study outcomes of specific disorders. This applied, for example, to Rutter, Greenfeld, & Lockyer’s (1967a,b) follow-up of children with autism, and to Harrington, Fudge, Rutter et al. (1990) follow-up of childhood depression. Both used clinical samples, but both were innovative in using as comparisons not general population controls, but rather children with other forms of psychopathology. The findings of both studies were striking in showing a surprising degree of diagnostic specificity in outcomes, findings that have also stood the test of time. In both cases, there were, however, inevitable limitations arising from the reliance on clinic samples and – in these particular instances – samples that lacked early research-based measures.

Prospective Studies of Clinically Defined Groups
Prospective studies of clinically defined groups differ from record-based follow-ups in three key respects. First, they have the major advantage of research-based assessments for their starting point. As a result, differentiation of the qualities of childhood psychopathology that may affect later outcomes is likely to be much more satisfactory. Second, because prospective studies can involve multiple waves of assessment, they allow better tests of the timing and patterning of symptoms as they unfold over time. Third, for the same reason, there are also better opportunities to test focused hypotheses on possible causal mechanisms.

Numerous studies have now used this strategy; many have highlighted previously quite unexpected effects. Laub and Sampson’s (2003) follow-up of a juvenile delinquency sample to age 70 constitutes much the longest follow-up of this kind. It has been especially informative on the role of adult experiences, showing how developmental trajectories continue to be influenced by both negative and positive turning points well into in adult life. Clegg, Hollis, Mawhood et al. (2005) follow-up of children with specific language impairment involving severe comprehension difficulties constitutes a rather different example, in which one of the major findings was the very high frequency of social impairments in adulthood – impairments that did not follow traditional psychiatric diagnostic categories.

Prospective Studies of General Population Epidemiological Samples
Prospective studies of general population samples have all the advantages of prospective studies of clinically defined groups, but some key additional strengths: they provide a stronger basis for generalizability, they can examine effects of environmental risk factors, and they can also study outcomes of traits or behaviors in childhood that fall short of full diagnostic criteria. The extensive insights that have emerged from the Dunedin study (http://dunedinstudy.otago.ac.nz/) and Christchurch longitudinal studies in New Zealand and the US Children in the Community study (http://nyspi.org/childcom) well illustrate the powerful strengths of this design. Its one important limitation, however, is that – unless based on extremely large samples – general population studies are typically in a weak position to examine effects of extreme patterns, and may only include small numbers of individuals who meet full diagnostic criteria for disorder. As a result, there is much to be said for combining general population epidemiological and/or longitudinal studies with prospective studies of more extreme groups. The former have the advantage of avoiding possible biases associated with clinical referral, while the latter have the advantage of being able to examine the effects of more extreme patterns.

Prospective Studies of High-Risk Groups
None of the above designs are particularly good for the study of more subtle abnormalities that may constitute important precursors of later psychopathology. Here, studies of groups likely to be at high risk because of genetic factors involved in familial loading come into their own. Weissman, Wickramaratne, Nomura et al. (2005) research into depression constitutes one good example here, illustrating the value of multiple measures over time and the utility of studying age at onset. Lyytinen, Ahonen, Eklund et al. (2004) prospective study of babies born into families with a familial loading for dyslexia constitutes another good example. Detailed cognitive and neurophysiological measures were obtained from early in the children’s development, making it possible to explore how far at-risk children show hypothesized precursor deficits very early in development, well before they are exposed to the demands of learning to read. Owen and Johnstone’s (2006) study of a high-risk schizophrenia sample, again beginning before the onset of disorder, has been similarly informative.
about the specifics involved in the prodromata of schizophrenia. The major limitation of this design, however, lies in uncertainties over the extent to which findings are specific to individuals with a high familial loading. In that connection, it is important to be able to combine the high-risk strategy with data from general population samples that can tap at least some of the features thought to constitute precursors of adult psychopathology.

High-risk designs can also be used to assess outcomes of hypothesized environmental risks. The longitudinal study of children experiencing profound institutional deprivation in Romania and who were subsequently adopted into UK families constitutes an example of this kind (Croft, Beckett, Rutter et al., 2007; Kreppner, Rutter, Beckett et al., 2007; Rutter, Colvert, Kreppner et al., 2007). In this case, the main interest is not so much in testing hypotheses about environmental risk mediation (although designs of this kind do allow that), but rather in examining factors contributing to variations in outcome within a high-risk group. As with all studies of developmental pathways, it is crucial to check the representativeness of the samples being studied. In that connection, when the frequency of the postulated risk factor is sufficiently high, there is much to be said for embedding a high-risk sample within an epidemiological design. The study of children born to teenage mothers, as part of the Moffitt & the E-Risk Study Team (2002) environmental risk study, constitutes an example of this kind.

**Retrospective and Prospective Measures**

Whenever possible, contemporaneous measures of childhood behaviors or experiences are almost always to be preferred over measures based on retrospective recall, especially when the aim is to examine the relative timing of events or onsets. People are much better at remembering whether something happened than when it occurred, and memories of the temporal ordering of events or behaviors – often required to test causal hypotheses – are especially open to bias associated with later outcomes. Because temporal sequence is particularly important for the study of environmental risk mediation, prospective measures are ordinarily much to be preferred. Nevertheless, for memorable, easily defined and well-conceptualized happenings (e.g., parental divorce), retrospective recall may be useful for the assessment of whether particular experiences have occurred, but not for timing of when they took place (Hardt & Rutter, 2004). To date, evidence suggests that deliberate falsifications of adverse experiences are uncommon. Rather, findings suggest that the main source of bias lies in the tendency of people who are functioning well in adulthood to forget or under-report early risk experiences, rather than those with psychopathology exaggerating negative experiences in the past. Two further points need to be made about retrospective recall. First, some events – such as exposure to sexual or physical abuse within the family – cannot readily be assessed prospectively in non-referred samples because parents are unlikely to agree to their children being asked about such happenings, and ethical committees often constrain questioning. Second, even “prospective” studies will usually involve some degree of retrospective reporting, covering the periods between study contacts. Accordingly, although – other things being equal – prospective data are to be preferred, it is important not to exaggerate problems of retrospective recall. The problems are serious with respect to time sequences and also for value judgments such as severity of punishment or quality of relationships. On the other hand, retrospective reports may be more satisfactory for experiences that are prolonged, memorable for their impact and likely to have been discussed subsequently. For any experiences that are less striking than that, under-reporting will be common and retrospective reports will not provide an accurate estimate of frequency or prevalence.

**Testing Causal Hypotheses**

When studying causal hypotheses, longitudinal analyses focusing on within-individual change are almost always to be preferred over between-group comparisons. Nevertheless, it is essential to appreciate that longitudinal analyses alone are not adequate for testing causal hypotheses. However, they are extremely useful in sorting out the likely direction of the causal arrow – an important consideration, for example, in differentiating between child effects on the environment and environmental influences on the child (Bell, 1968). Even so, caution is needed before assuming that earlier behaviors necessarily cause later ones. Many studies have shown, for example, that anxiety in childhood constitutes an important precursor to depression later in life, leading to the proposal that anxiety is part of the causal process. However, an alternative possibility is that at some stages in the life course this temporal sequence is simply a function of maturational processes whereby anxiety manifests itself earlier than depression. It is relevant, therefore, that in adult life depression both precedes and follows anxiety (Rutter, Maughan, & Kim-Cohen, 2006a).

Four main alternatives to causal influences have to be considered when drawing inferences from statistical associations between postulated risk factors or precursor conditions and psychopathological outcomes (Rutter, 2007). First, both may reflect the same underlying liability. Thus, crawling precedes the onset of walking and babbling precedes the onset of spoken language, but it is most unlikely that crawling causes walking or babbling causes language. Rather, both are likely to constitute part of the same process. In the same way, the association between early conduct problems and later substance misuse is at least partially likely to reflect the same underlying liability.

The second possibility is that associations with environmental risks may reflect social selection rather than social causation. Environments are not randomly distributed, and variations in risk exposure may be a consequence, at least in part, of individuals’ own behavior, rather than reflecting an independent environmental influence. Processes of this kind are likely to be widespread in psychopathology, and call for particular attempts to examine the origins, as well as the effects, of postulated environmental risks.
Third, statistical associations between later outcomes and prior risks or disorders may reflect effects of confounding. Environmental risks rarely occur in isolation, and comorbidity among disorders is high; as a result, associations with any individual early risk or prior disorder may in practice be attributable to the effects of other correlated risks. Reports from the Christchurch Health and Development study have paid particular attention to the problem of confounding. Examining early adult sequelae of adolescent depression, for example, Fergusson and Woodward (2002) reported initial associations with a wide range of adverse outcomes including depression and anxiety, suicidal behaviors, problems in employment and early parenthood. Adolescent depression was also associated with numerous other childhood and adolescent adversities. Controls for these correlated difficulties markedly refined conclusions on later outcomes: while associations with later depression and anxiety remained strong, links with all other problems in adult functioning were spurious, and reflected the effects of confounding.

The final possibility is that, although the risk effect is real, it is, at least in part, genetically rather than environmentally mediated. Thus, the association between, say, harsh discipline and child psychopathology may partially reflect genetic factors involved in the liability to use severe disciplinary strategies as well as effects of harsh discipline on the child. Twin and adoption studies provide well-accepted designs that “pull apart” influences of this kind; in addition, a much larger variety of “natural experiments” can serve much the same purpose (Rutter, 2007; Rutter, Pickles, Murray et al., 2001). With ingenuity, some purchase can be gained on most causal questions.

As is implicit in the whole of this methodological discussion, the research focus has changed over time from attention to the extent of continuities to attempts to understand the causal mechanisms involved. In the remainder of the chapter, we consider some examples.

**Developmental Findings**

We begin by examining developmental findings in relation to a number of individual disorders or disorder groups. Detailed discussions of each of these disorders are presented in later chapters. Our aim here is a rather different one; to use emerging findings to illustrate the more general developmental issues, principles and questions that emerge in relation to differing patterns of childhood–adult continuity.

**Neurodevelopmental disorders**

We begin with the group of what has come to be known as neurodevelopmental disorders (see chapter 3): autism spectrum disorders, specific language impairment (SLI), dyslexia and ADHD. Although differentiated in important ways, these disorders also share key features in common: they are diagnosed early in development, involve delay or deviance in maturationally influenced psychological features, along with some degree of cognitive impairment (specific or general), and all show relatively strong genetic liabilities. They are all also much more common in boys than in girls.

At this stage, knowledge of the long-term prognosis for individuals with these disorders is highly variable: prospective follow-ups of ADHD samples have been reported for many years, but data on adult outcomes in the other disorders remain much more limited. In each case, however, current findings suggest a clear persistence of impairments into adulthood (although often with some diminution of effects with age), but also considerable variability in adult functioning. In some instances, follow-up findings have highlighted quite unexpected features. Specific language impairment has traditionally been regarded as reflecting a relatively pure deficit in language, and follow-ups have, as expected, documented long-term sequelae in relation to both language functioning and literacy skills. In addition, however, quite unanticipated findings have emerged in relation to the later social functioning of individuals with unusually severe SLI. In one study (Clegg et al., 2005), the majority of males with SLI involving an impairment in receptive language had not achieved independent living by their 30s, many had faced problems in employment, few had established cohabitations and half had impairments in non-romantic friendships; performance on theory of mind tasks also suggested deficits in social cognition. Although outcomes were better among individuals with the least severe initial language impairments, associations with language skills were quite weak. Overall, the pattern of the findings raises important questions about the conceptualization of SLI. Because it is unlikely that such extensive social impairments emerge solely in response to early language problems, it may be that, rather than being viewed as a pure deficit in language skills, SLI should more appropriately be regarded as involving much broader social and/or cognitive deficits from the outset.

Variability in long-term outcomes has been noted across the neurodevelopmental disorders: some individuals continue to show marked impairments in adulthood, while others function relatively successfully. At this stage, the basis for these variations is poorly understood. In autism, for example, IQ is clearly of importance: outcomes are universally poor in individuals with IQs below 50, and more positive adult functioning is very largely concentrated in groups within the normal IQ range. Among individuals with IQs of 70 or higher, however, specific IQ levels are of little or no prognostic value (Howlin, Goode, Hutton et al., 2004), and it remains unclear whether variations in functioning within this group are predominantly attributable to the severity of the basic biological handicap, or reflect effects of the adequacy of services received either in childhood or in adult life (Mawhood & Howlin, 1999). Social factors clearly impact on outcomes in dyslexia: although underlying literacy problems are highly persistent, effects on educational and occupational outcomes are considerably mitigated for young people from more socioeconomically advantaged homes, and appropriate “niche-picking” – the selection of adult environments where literacy demands are limited, or can be
met in other ways – is a clear feature of the histories of individuals with more successful later outcomes (Maughan, 1995). Finally, heritable factors are also likely to influence outcome and course. In the case of SLI, for example, heritability seems substantially greater for children with persistent language impairment than for those with more transient language delays (Bishop, Price, Dale et al., 2003), and in ADHD polymorphisms in the DRD4 and DAT1 genes have been shown to be associated with variations in both IQ and later adult functioning (Mill, Caspi, Williams et al., 2006).

On both clinical and theoretical grounds, a life course approach to the neurodevelopmental disorders requires knowledge not only of adult outcomes but also of early precursors. Although all of these disorders are typically diagnosed early in childhood, it is of considerable importance to know how early they can be detected, and whether reliable indicators of presumed underlying deficits are evident before major impairment appears. In the case of autism, marked difficulties do not typically emerge until around 18 months of age, and reliable diagnoses are often only possible at or after age 2; analyses of home movies, however, suggest that some children show evidence of abnormalities as early as the first year of life (Rutter, Le Couteur, & Lord, 2003). In ADHD, diagnostic criteria require that symptoms are present before age 7 but clinical evidence clearly shows that ADHD-related behaviors often result in major impairments well before children reach school age. Diagnosing ADHD in preschoolers has long been recognized as challenging, but systematic studies of preschoolers are beginning to show that both rates and psychosocial correlates of preschool ADHD are closely comparable to those found in school-age samples (Egger & Angold, 2006). In addition, preschool children with ADHD have been found to show deficits in executive functioning and delay aversion, now regarded as core features of the disorder (Sonuga-Barke, Dalen, & Remington, 2003), providing further pointers that the liability to ADHD is present early in development.

Probably the most extensive data on early precursors are available in the dyslexia field. Although, by definition, developmental reading problems can only become manifest once children are exposed to reading instruction, current models assume that core linguistic and cognitive deficits are present well before children begin to read. Preschoolers who go on to develop reading difficulties are now known to show delays in oral language, a lack of interest in books and reading materials, and problems in pre-reading and related cognitive skills. Studies of high-risk groups (Lyytinen et al., 2004) show some differences from controls in brain responses to speech sounds even in infancy. Measures of expressive and receptive language became increasingly differentiated across early childhood, with stronger associations with later reading in the family high-risk group than among controls. Overall, the findings suggest that the cognitive and language deficits found in dyslexia are indeed evident earlier in development, but are not sufficiently distinctive to be useful at an individual diagnostic level.

Finally, mention must be made of the high rates of comorbidity with conduct and oppositional disorders found in both ADHD and dyslexia in childhood, and their implications for outcomes later in life. ADHD and dyslexia themselves show strong overlaps, largely genetically influenced. As a result, we might anticipate that associations with antisocial behavior would also show much in common. Perhaps surprisingly, current evidence is somewhat against that view. ADHD is strongly comorbid with oppositional disorders in childhood, and conduct disorders often develop from this base. Follow-up studies suggest that these risks persist: ADHD is associated with increased rates of antisocial personality disorder and substance abuse in adult life, even in the absence of marked conduct/oppositional symptomatology earlier in development, although the increase in adult psychopathology is much greater when there were conduct problems in childhood (Manuzza, Klein, & Moulton, 2003; Manuzza, Klein, Abikoff et al., 2004). A variety of factors might contribute to these links. Genetic influences are strongly implicated in comorbidity in childhood, and almost certainly contribute to risks of persistence; family and peer influences seem salient, perhaps in interaction with genetic risk; and evidence also points to the importance of severe and pervasive ADHD symptomatology, especially when combined with low cognitive abilities, as a key element in the clinical picture associated with persistence. Reviewing this evidence, Thapar, van der Bree, Fowler et al. (2006) drew attention to the complexities involved in any more precise specification of risk pathways at this stage: despite a plethora of evidence on putative risks, current findings leave it uncertain which factors predict, which mediate and which moderate the links between ADHD and antisocial outcomes. Given the clinical and public health significance of these progressions, more detailed studies testing competing hypotheses about the key developmental pathways are clearly a major priority.

Findings in relation to dyslexia differ in several ways. First, although developmental reading problems have long been known to be associated with conduct disorder in childhood (Rutter, Tizard, & Whitmore, 1970), the mechanisms involved have remained obscure. Findings on the mediating role of inattentiveness are mixed (Maughan & Carroll, 2006), but recent twin data suggest that, in contrast to ADHD, comorbidity between dyslexia and childhood conduct problems is best explained by reciprocal phenotypic causation: conduct problems impede reading acquisition, while reading failure exacerbates disruptive tendencies (Trzesniewski, Moffitt, Caspi et al., 2006). Long-term follow-ups of representative samples of poor readers remain limited. Available evidence suggests, however, that – again unlike findings in ADHD – poor readers show few increased risks of criminality or other indices of antisocial behavior in early adult life (Maughan, Pickles, Rutter et al., 1996); rather than the persisting vulnerability associated with ADHD, comorbid conduct problems in dyslexia may thus reflect more time-limited responses to school failure. Although comparisons of long-term trajectories across disorders are only now beginning to be possible, examples of this
kind suggest that they should prove increasingly informative for our understanding of intervening mechanisms.

**Childhood Origins of Schizophrenia**

Arguably, developmental findings have made the most major change to conceptualizations of disorder in relation to schizophrenia (Keshavan, Kennedy, & Murray, 2004; Murray & Lewis, 1987; Weinberger, 1987). Traditionally seen as a psychosis beginning in late adolescence or early adulthood, schizophrenia is now increasingly regarded as a developmental disorder, with roots traceable to very early vulnerabilities (Walker, Kestler, Bollini et al., 2004a). This change of view has largely been prompted by follow-back findings from longitudinal studies that show mild deficits in social, motor, and cognitive functioning in children and adolescents, and even infants, who go on to display psychotic symptoms. Susceptibility to schizophrenia has also been associated with a range of prenatal and perinatal risks that have the potential to affect neurodevelopmental processes. Early insults of this kind, perhaps in interaction with genetic predispositions, are now thought to lay the groundwork for vulnerable neuronal circuits whose effects can compromise brain structure and function. Not all individuals with these vulnerabilities go on to show disorder; indeed, although neuropsychological and neurodevelopmental measures differentiate high-risk individuals from healthy controls, it is schizotypal symptoms and cognitions that offer the best differentiation within high-risk groups. Final illness expression is thus likely to depend on later developmental processes (such as those associated with adolescent neuromaturational, or enhanced sensitivity to the effects of later stress.

These findings raise a series of key developmental questions. First, what is the meaning of the associations with childhood and adolescent characteristics? Although some features (in particular, delays in early motor development, and impairments in receptive language and cognitive functioning) show some diagnostic specificity with later schizophreniform disorder, childhood socioemotional disturbances clearly do not. Distinctions are often drawn between precursors to a disorder (thought to constitute risk factors) and prodromal features, seen as early manifestations of the disorder itself. Although the distinction is probably a useful one, in the case of schizophrenia over half of individuals with prodromal features do not go on to develop the disorder (Drake & Lewis, 2005), raising uncertainties over the meaning of a prodromal phase (Cannon, Kendell, Susser et al., 2003). As we shall see, this pattern of clear and consistent, but far from necessary or specific, associations across development arises in a range of disorders.

That being so, a second key question concerns the factors or processes that lead to the translation of precursors and/or prodomata into overt disorder. In the case of schizophrenia, three main possibilities have been considered to date. First, developmental changes in brain structure and function in late adolescence may be crucial (Keshavan, Kennedy, & Murray, 2004), although once again it is unclear how such general developmental processes contribute to disorder onset in just a small minority of individuals. Second, certain types of social adversity (such as migration and social isolation) may also contribute (Broome, Woolley, Tabraham et al., 2005). Third, consistent evidence now implicates heavy early adolescent use of cannabis with a substantial increase in risk (Arsenault, Cannon, Witton et al., 2004; Henquet, Krabbendam, Spauwen et al., 2005; Moore, Zammit, Lingford-Hughes et al., 2007). Here, some degree of specificity does seem apparent: the risk applies mainly to individuals who have shown either precursors or prodomata of schizophrenia spectrum disorders, and is confined to those with early and heavy cannabis use. Molecular genetic findings (Caspi, Moffitt, Cannon et al., 2005) suggest that it is a function of the valine allelic variation in the catechol-O-methyltransferase (COMT) gene. Even so, this gene–environment interaction can only account for part of the population variance in the transition to schizophrenia: most individuals with the specific allelic variation, and who use cannabis heavily, do not develop schizophrenia, while many of those who do develop disorder have not shown heavy cannabis use. Although we are beginning to identify factors important in the transition to disorder, we are far from having achieved a complete account.

Finally, it remains possible that, in addition to early neurodevelopmental abnormalities, further changes in both cognitive function and brain structure and function take place during the course of the disorder, either as a result of the disease process, or of the drugs used in its treatment (Keshavan, Kennedy, & Murray, 2004). The evidence so far is not decisive, but does suggest that further changes may take place after the development of the psychosis that may be relevant to its later course.

**Depression**

As in research on schizophrenia, so developmental studies have markedly changed concepts of depression in recent decades. Prior to the 1970s, depression was viewed as a predominantly adult disorder: pre-adolescent children were thought incapable of experiencing adult-like depressions, and low mood in adolescence was thought to reflect little more than “normal” adolescent mood swings. Research since the 1980s has radically changed that view. Both clinical and epidemiological studies have confirmed the reality of childhood and adolescent depressive disorders; indeed, recent evidence suggests that (with age-appropriate modifications to diagnostic criteria) depression is also seen in some preschoolers, although the high rate of comorbidity with other disorders leaves it unclear whether depressive symptom clusters at these very early ages are phenotypically similar to depression at later ages (Egger & Angold, 2006). Age and sex trends – other key features of the developmental picture – have also been clarified. Depressive disorders are rare in childhood, but rates rise markedly from the early teens (Glowinski, Madden, Bucholz et al., 2003), probably associated with the hormonal changes of puberty (Angold, Costello, & Erkanl et al., 1999b), related changes in brain physiology and social information processing (Nelson, Leibenluft, McClure et al., 2005) and possibly...
an increase in gene–environment correlations (Rice, Harold, & Thapar, 2003). The female predominance typical of adult depression also emerges at this stage, to be maintained throughout the childbearing years. Much adolescent onset depression is preceded by childhood anxiety; later in development, depression can form part of more complex progressions, both preceding and following adult anxiety, and is a not uncommon outcome of both anti-social disorders and substance use.

Developmental studies of depression have explored a variety of issues, beginning with the question of whether – despite similarities in symptomatology – childhood, adolescent and adult onset depressions do indeed reflect the same underlying disorder. Medicine provides many examples – diabetes being perhaps the best known – where, despite similar clinical features, disorders with differing ages at onset show quite distinct patterns of neurobiological correlates. A variety of evidence now points to rather similar possibilities in depression. Jaffee, Moffitt, Caspi et al. (2002), for example, found that while “juvenile onset” depression (with onset prior to age 15) was associated with high rates of family psychopathology and disruption, neurocognitive impairments, and with a broad spectrum of emotional and behavioral problems in childhood, adult onset cases (aged 18 years and older at first reported episode) were not; indeed, the only “adverse” childhood factor clearly evident among adult onset cases was exposure to sexual abuse. Studies have also shown that neurobiological correlates of depression differ in adult and earlier onset disorders, and there are well-documented variations in response to tricyclic medication (for a review see Kaufman, Martin, King et al., 2001). It remains unclear at this stage whether these differences reflect developmental variations in the maturation of relevant neurobiological systems, stage of illness factors or heterogeneity in the underlying nature of the disorder.

Second, longitudinal data have shown that, at least between adolescence and adulthood, continuities in depression are strong. Risks are elevated at least twofold (and often considerably more so) by contrast with rates in non-depressed controls; are increased in sub-threshold groups, as well as in young people meeting full diagnostic criteria for depression (Pine, Cohen, Cohen et al., 1999); and remain increased when other comorbid disorders and associated childhood risks are taken into account (Fergusson & Woodward, 2002). By contrast, childhood onset samples (Harrington et al., 1990; Weissman, Wolk, Wickramaratne et al., 1999) show little or no increased risk for adult depression by comparison with non-depressed controls, and are at lower risk of recurrence than their adolescent onset peers. If further replicated, evidence of this kind provides additional pointers to the possibility that childhood depression differs in important ways from its later onset counterparts.

Third, investigators have highlighted a range of mechanisms that may be implicated in risk for the recurrence of depressive episodes across developmental periods. Among these, genetic factors seem almost certain to be involved. Genetic influences on depressive phenotypes are low in childhood, but rise in adolescence to levels broadly similar to those found in adult samples (Rice, Harold, & Thapar, 2002). To date, longitudinal data from genetically sensitive designs have only been reported across relatively short follow-up periods, and often in samples spanning quite wide age ranges. Rearing these limitations in mind, findings suggest that genetic factors do contribute to stability in depression scores across adolescence and early adulthood, but that new genetic and non-shared environmental influences also arise across this age period (Lau & Eley, 2006). Interplay between genetic predispositions and environmental exposures is also likely to be involved. Studies have confirmed, for example, that specific gene variants affect susceptibility to adverse life events in both adolescence (Eley, Sugden, Corsico et al., 2004) and early adulthood (Caspi, Sugden, Moffitt et al., 2003), and that both depressed children (Rudolph, Hammen, Burge et al., 2000) and adults (Hammen, 2003) behave in ways that increase their likelihood of exposure to interpersonal stress.

Early adversities – spanning both severe exposures such as abuse and maltreatment and more chronic difficulties such as lack of adequate maternal care – have long been recognized as risk factors for adult depression. Over time, a variety of pathways have been proposed to mediate these links. As more immediate precipitants, depressive episodes are often provoked by acute or chronic stressors; one route for the effects of early adversity may thus be to increase exposure or vulnerability to these more proximal risks (Harris, Brown, & Bifulco, 1990). Childhood adversity is also associated with later difficulties in close personal relationships, and they too are implicated in risk for depression. In a retrospective study, Hill, Pickles, Burnside et al. (2001) found intriguing suggestions of specificity in mechanisms here: while good adult love relationships did nothing to reduce risks of depression following child sexual abuse, they made a substantial difference to risk following neglect or poor maternal care. The authors speculated that these findings may in turn reflect differential responses to differing types of adversity: while the chronic nature of neglect may affect self-views, the fright and trauma associated with abuse may have wider effects, impacting both affect regulation and neurobiological pathways (Grossman, Churchill, McKinney et al., 2003).

Finally, as suggested in a number of models, cognitive factors may also have a role in long-term vulnerability to depression, and the experience of an initial episode may itself bring about changes that affect recurrence risk. Depressogenic cognitive biases have now been identified in children as young as 3 years of age (Murray, Woolgar, Cooper et al., 2001), and appear to function both as outcomes and as risks for depression in childhood (Nolen-Hoeksema, Girgus, & Seligman, 1992). Such biases are moderately stable, and contribute to the risk for recurrence of depression (Abramson, Alloy, Hankin et al., 2002); at this stage, however, we still await direct longitudinal evidence of their persistence across extended developmental periods. In terms of recurrence risk, the role of precipitating stressors changes across episodes in adulthood (Kendler, Thornton, & Gardner, 2000), with vulnerability becoming increasingly autonomous from overt and severe...
precipitants as the number of episodes increases. Although
effects of this kind have typically been interpreted as reflect-
ing processes akin to “kindling” (Post, 1992), recent com-
mentaries have highlighted ambiguities in that view: although
illness-related factors may increase sensitivity to ever more minor
stressors, the empirical evidence is also consistent with a
model of reduced sensitivity to stress (Monroe & Harkness,
2005). Further studies are needed to clarify these competing
interpretations, and to determine whether similar effects are
seen in depressions beginning in adolescence.

Eating Disorders
In many respects, eating disorders represent the form of psy-
chopathology that would most seem to require a developmental
psychopathology perspective. Overt eating disorders arise for
the first time in the teens, and show a highly variable long-
term course; to date, however, very little is known about
key childhood precursors of disordered eating, or predictors
of better or poorer later outcome. In addition, core questions
remain about associations among different types of eating
disorder, and continuities with more common eating-related
problems. Dieting and dissatisfaction with body shape and size
are extremely common in adolescent girls and, on the face of it,
seem to constitute a lesser variant of the much rarer overt
eating disorders. However, the huge disparity in prevalence
raises the possibility of an essentially qualitative discontinu-
bility between the two. Comparable questions arise over contin-
uities and discontinuities within the domain of overt eating
disorders. Both clinic and community samples show that by
far the rarest syndrome is anorexia nervosa (AN), with a rate
well below 1% even within adolescent girls; the next rarest
is bulimia nervosa (BN), with a prevalence in young adults
of 1–2%; but much the most common is eating disorders
not otherwise specified (EDNOS; Fairburn & Bohn, 2005;
Fairburn, Cooper, Doll et al., 2005; see also chapter 41). Over
time, there is some movement across these groups, suggesting
that all three may constitute variants in the manifestation of
the same basic disorder. On the other hand, BN has a sub-
stantially later average age of onset than AN (early adult life,
by contrast with mid-adolescence), and twin studies suggest
that genetic factors are more influential in AN than BN (see
chapter 41). Finally, AN typically begins in the immediate
postpubertal years, but the meaning of this association
remains unclear. Is onset causally associated with the hormonal
changes of puberty; or is it provoked (in societies that value
thinness) by adverse effects on body image and satisfaction
associated with the increase in adiposity that accompanies
puberty; or is the adolescent timing rather a function of the
effect of depression, which rises markedly in frequency in
girls at about the same time? Many of these issues were first
raised in a heavily cited paper by Attie and Brooks-Gunn (1989)
-nearly two decades ago. Their small-scale 2-year longitudinal
study of adolescent girls suggested that negative attitudes
to body size and/or shape constituted the most important
predictor of eating problems, with puberty an initial stimulus
but not an enduring influence. As they recognized, however,
the rarity of eating disorders meant that a much larger
sample would be required to provide proper answers.

In principle, occupations with a particular pressure for
thinness provide an additional window on the development
of eating disorders. Szumukler, Eisler, Gillies et al. (1985),
following Garner & Garfinkel (1980), drew attention to the
high frequency of severe dieting in ballet dancers and the
probable increase in overt AN. However, they also noted
the generally good outcome among dancers, and the relative
infrequency of more obviously psychopathological features
such as induced vomiting or laxative abuse. They emphasized
the difficulties in diagnosing eating disorders when there is
a strong occupational pressure to be thin, and the dangers
of drawing false psychopathological inferences. Surprisingly,
there have been few attempts to examine these issues further.
Neumärker, Bettle, Neumärker et al. (2000) found that an
excessive concern with dieting, a drive for thinness and a pre-
occupation with weight were all more frequent in female (but
not male) dancers, but found no instances of either binge eat-
ing or self-induced vomiting. Somewhat similarly, Santonastas,
Mondini, & Favaro (2002) found that although fashion
models weighed significantly less than controls, few used
unhealthy methods to control their weight. The database is
decidedly thin, but the tentative conclusion would seem to be
that although occupational pressures may provide a risk for
eating problems, the risk for overt disorder is very low.
In order to examine possible continuities in the general
population, it is necessary to turn to the very few large
samples with longitudinal data spanning adolescence to early
adult life. Kotler, Cohen, Davies et al. (2001), in a childhood–
early adult follow-up, found high stability in bulimic symp-
toms between early adolescence and adult life, but the
number with AN was too small for analysis. Despite this, the
authors noted that it seemed that, although eating conflicts
in childhood predicted AN symptoms, they did not predict
BN. Leon, Fulkerson, Perry et al. (1999), in a 3–4-year
longitudinal study of adolescents, found that negative affect
and attitudes were the only robust predictors of eating dis-
orders (mostly EDNOS); Johnson, Cohen, Brook et al. (2002)
found that the main predictor of eating disorders was depres-
sion; and Measelle, Stice, & Hoganson (2006) reported a
unidirectional relationship from depressive symptoms to
eating pathology across the teens. In sum, although existing
evidence is not entirely consistent, the tentative conclusion
may be drawn that emotional disturbance in early adolescence
constitutes the main risk factor for later eating disorder. The
evidence on the putative risks stemming from eating conflicts
in childhood is unconvincing.

With respect to possible continuities within the domain of
overt eating disorders, the best data are provided by Fairburn
and Bohn (2005). Out of a potential community sample of
some 10,000, they focused on some 3000 currently dieting.
Within the latter, there were 45% with a possible eating dis-
order, of whom 104 were found on the basis of more detailed
study to have disorder (10 AN, 19 BN and 75 EDNOS). There
was no follow-up of individuals who were not dieting, but
the figures indicate a likely increased risk for the development of eating disorder. The most important finding concerned the risk factors for eating disorders among the dieters. In addition to low body mass index, seven stood out: frequent binge eating, eating in secret, a preoccupation with food and eating, a desire to have an empty stomach, frequent purging, a fear of losing control and a preoccupation with shape or weight. Taken together with other evidence, the tentative inference is that, whereas there is very little continuity between “ordinary” dieting and body weight and/or size dissatisfaction in adolescence and overt eating disorder, there is continuity (involving an extension outside overt disorder) when body dissatisfaction is associated with these more unusual features.

It cannot be claimed that the key developmental questions regarding eating disorders have been answered but, despite the sample size challenges, it is clear that they warrant more detailed study than they have received up to now.

**Antisocial Behavior**

Key aspects of the developmental profile of antisocial behavior have been known for many years. Four decades ago, Robins (1966) highlighted the pattern that has since been confirmed in numerous follow-up and follow-back studies: most severely antisocial adults have been antisocial children, but, at most, half of antisocial children go on to show marked antisocial behavior in their adult lives. Alongside this life-course picture, criminologists have also noted a highly consistent pattern of age-related change in “participation” in offending; official crime rates are low in late childhood, rise sharply in the teens, then fall back again across the adult years. Taken together, these two sets of observations suggest that any developmental account of antisocial behavior needs to “explain” at least three key phenomena: first, strong childhood-adulthood persistence among some individuals; second, the marked rise in antisocial involvement in the teens; and third, a general pattern of desistance in at least more overt markers of antisocial behaviors from late adolescence or early adulthood.

These developmental variations strongly suggest heterogeneity within the antisocial population. Among the many models advanced to account for this, Moffitt’s (1993) developmental taxonomy has been perhaps the most influential. This taxonomy (see chapter 35) highlights age at onset as the key distinguishing marker, and proposes that early onset conduct problems are distinct from adolescent onset delinquency in both etiology and course. In brief, early onset conduct problems – male-dominated, and associated with both individual and environmental risks – are especially likely to show poor long-term outcomes. Adolescent onset problems – largely prompted by social influences, and with a less marked sex ratio – are assumed to be relatively transient, and to remit once individuals assume the responsibilities and experience the benefits of moving into adult roles. As Moffitt (see chapter 35) outlines, extensive evidence has now accumulated to support key elements of this model, although persistence of adolescent onset antisocial behavior has proved to be greater than originally anticipated.

In addition, developmental findings point to other potentially salient markers of heterogeneity. As we have seen, comorbid ADHD carries a strong risk for persistent antisocial behavior (Thapar et al., 2006) and psychopathy and related callous/unemotional traits (Viding, 2004) may also be markers of poor long-term outcome; it is unclear at this stage how far these reflect differing facets of a single high-risk subgroup or separable associated risks. In addition, a number of studies have now identified subgroups with early onset conduct problems where adult outcomes are also poor, but where the pattern of later difficulties is of a markedly different kind. For these young people – estimated in some studies as approaching half of the childhood onset population – the sequelae of early conduct problems are marked not by persistence in antisocial difficulties, but by poor social functioning, social isolation, avoidance of close relationships and increased risks for emotional difficulties later in life (Moffitt, 2006). Very little is known at this stage about the early risks or later maintaining factors that differentiate young people who follow this avoidant “childhood-limited” pathway from those whose difficulties follow a more persistent “externalizing” course.

Outcome studies have also consistently highlighted a further striking feature of the sequelae of childhood conduct problems: the wide spectrum of adverse outcomes faced by young people with disruptive behavior disorders later in their lives. Fergusson, Horwood, & Ridder (2004) found that conduct problems at ages 7–9 years conveyed risk for poor educational and occupational achievements; for problems in sexual and partner relationships (including exposure to domestic violence); for early parenthood; and for elevated rates of substance use, mood and anxiety disorders and suicidal acts, as well as for crime and antisocial personality disorder. Educational and occupational difficulties seemed largely attributable to correlated early risks. For all other outcomes, the severity of childhood conduct problems continued to be associated with an increased risk after the effects of a broad spectrum of potential confounders had been taken into account. Kim-Cohen et al. (2003), exploring psychiatric sequelae of a range of childhood disorders, found a similar picture: alone among childhood disorders, conduct problems were associated with increased risks of all the adult disorders surveyed, including anxiety, depression, schizophreniform disorders and mania as well as substance abuse.

These findings raise key questions about the early risks and intervening mechanisms that contribute to this broad spectrum of adult difficulties. We focus here on possible pathways in persistence in and desistance from antisocial behavior, and effects on poor social functioning in adulthood; heterotypic continuities to other disorders are considered in a later section. First, genetic liabilities are almost certain to be implicated. Pervasive early onset antisocial behaviors – likely to carry high risks of persistence – are also known to be strongly heritable (Arseneault, Moffitt, Caspi et al., 2003). As in depression, genetic effects may be as important in contributing to exposure or vulnerability to environmental adversities as in any direct “main effects” way (Rutter, Moffitt, & Caspi, 2006b). Genetic factors...
have been found to moderate vulnerability to childhood family adversity and maltreatment, with effects evident on measures of both childhood–adolescent conduct problems and on personality features and violent offending in adult life (Casp, McClay, Moffitt et al., 2002). In addition, genetically influenced traits may influence exposure to adverse environments. Childhood disruptive behaviors have long been known to evoke negative maintaining responses from parents (Anderson, Lyttton, & Romney, 1986; Patterson, Reid, & Dishon, 1992). Recent evidence suggests that processes of this kind may be set in train very early in development (Boivin, Perusse, Dionne et al., 2005). Later, genetically influenced traits are also likely to play a part in selecting antisocial young people into deviant peer groups (Fergusson, Swain-Campbell, & Horwood, 2002) and intimate partnerships (Woodward, Fergusson, & Horwood, 2002) that reinforce early difficulties, stabilizing maladaptive behaviors and interactional styles, and restricting opportunities for involvement in more positive functioning.

Cumulating consequences of this kind – also referred to as chains or cascades of risk – seem likely to be key mechanisms in the persistence of early onset conduct problems (Maughan & Rutter, 2001). Where adolescent onset antisocial behavior is followed by poor adult outcomes, similar processes also seem likely to be implicated, although this remains to be directly tested at this stage. Questions also remain over the extent to which the poor long-term prognosis for childhood onset conduct problems is at least in part attributable to more extended exposure to the cumulating consequences of early behaviors – that is, to age at onset per se – or whether effects are primarily driven by associated early risks or variations in mediating mechanisms. In addition, antisocial young people may vary in the extent to which they have access to, or perhaps can benefit from, positive later experiences associated with desistance from delinquency and crime. Stouthamer-Loeber, Wei, Loeber et al. (2004) found that desistance from serious delinquency was most common among young adult males with good job skills, positive earlier relationships with peers, awareness of the risks of offending and who were actively engaged in either education or employment. In a similar way, Laub and Sampson (2001, 2003; Rutter, 1996) have highlighted the role of adult “turning point” experiences in desistance, underlining the importance of adult social attachments – arising both from work involvement and supportive marital relationships – in promoting desistance from crime. While almost all offenders eventually desist, these findings – along with models suggesting the cumulative nature of many intervening risk mechanisms – provide important pointers for intervention, suggesting that chains of risk can be broken and that later opportunities can, to some extent at least, offset the effects of earlier risks.

**Substance Use**

Although a great many young people are involved in experimental and recreational drug use, far fewer progress to abuse or dependence (Fergusson & Horwood, 2000; Kandel, Yamaguchi, & Chen, 1992). Adolescent substance use is implicated in a nexus of other disorders across development, strongly predicted by externalizing disorders in childhood and comorbid with, and predicting to, both antisocial outcomes and affective disorders later in life. Many early psychosocial risks for drug and alcohol use overlap with family-based adversities implicated in risk for other disorders; as a result, there are major difficulties in determining how far later adverse outcomes are specific to drug-related problems or operate primarily via effects on other disorders. However, twin studies provide a most useful means of testing alternative mechanisms (Kendler & Prescott, 2006; see also chapter 2).

We take up issues associated with heterotypic continuities with other disorders below; here, we focus on the role of age at onset as a potential predictor of later adverse outcomes. Throughout the history of epidemiological studies of substance use, early initiation of drug and alcohol use – in general, before the mid-teens – has been identified as a strong marker both for progression to later stages in substance abuse pathways and for more global difficulties in adult functioning. As in the case of antisocial behavior, these findings raise the key question of whether early initiation per se contributes to these effects, or whether it functions primarily as a marker for more severe, and possibly more generalized, liability to subsequent difficulties. As will be apparent, answers to this question carry major implications for policy and practice, as well as for theoretical understanding (Rutter, 2005b). Although current evidence is not entirely unequivocal, there are increasing pointers that early onset of a range of “problem behaviors” tends to co-occur. McGue and Iacono (2003) found strong evidence for a generalized risk for early onset problems, encompassing delinquency and early sexual behaviors as well as alcohol and drug use, before age 15. Young people with this multiple problem cluster of early behaviors were at exceptionally high risk of both externalizing disorders and depression at follow-up at age 20. This in turn suggests that shared risks (genetic and environmental) underlying a general tendency to early onset difficulties may have a key role in later outcomes. Twin findings confirm the importance of shared genetic influences in this multiple problem cluster (Kendler & Prescott, 2006). Although early initiation may, in itself, carry a minor additional facilitating effect, most of the increased risk for poor functioning later in development appears to lie in shared early risks of this kind. This has been shown most clearly through discordant twin designs (Kendler & Prescott, 2006). Twins as a group show the same association between early alcohol use and later alcoholism found in singletons. However, when twins differ in their age of starting drinking they do not differ in their alcoholism outcome. The apparent early onset effect is largely an artifact of shared genetic liability.

**Heterotypic Continuity and Psychopathological Progressions**

As we have seen, developmental data leave no doubt that many child psychiatric disorders represent early manifestations of
instances where one disorder or its logical progressions has been used to refer to processes of this kind. Continuity the same underlying liability: in general, the term some connections may reflect age-varying manifestations of as underlying these varying developmental sequences. First, the emergence of widespread problems in social functioning difficulties need to be considered in this context, along with later disorders; and between anxiety and depression have empirical support: progressions from ADHD to later anti-grouping disorders are high at all stages of development, and clearly more common in girls than in boys. Anxiety to postpubertal depression. In some instances the impairments involved are clearly closely related, so that associations across development can be expected to be high. In others, mechanisms contributing to continuities are less clear. In relation to schizophrenia, for example, although there is relative specificity in some of the developmental linkages observed, childhood precursor deficits are much more common than eventual psychotic outcomes, raising key questions over the mechanisms involved in the translation of early vulnerabilities into subsequent disorder.

Developmental progressions in anxiety and depression have attracted particular attention. Associations between these two disorders are high at all stages of development, and clearly reflect shared genetic risks (Kendler, Prescott, Myers et al., 2003). The order of emergence of these phenomena does, however, appear to vary systematically across development. Between childhood and early adolescence – around the time of puberty – anxiety typically precedes depression, and the degree of diagnostic overlap between the two disorders increases strongly over the following years (Wittchen, Kessler, Pfister et al., 2000). From later adolescence onwards, the temporal sequence runs in both directions: anxiety predicts to depression, but depressive disorders also predict to later anxiety (Pine, Cohen, Gurley et al., 1998). To an extent, of course, the apparent specificity of the childhood-adolescent transition may simply reflect typical ages at onset of the two disorders: anxiety is common in childhood, but there is a sharp increase in depression in the early teens (Glowinski et al., 2003; Hankin, Abramson, Moffitt et al., 1998), whether preceded by anxiety or not. In addition, there seems little doubt that childhood anxiety does constitute a risk factor for depression (Wittchen, Beesdo, Bittner et al., 2003); and possibly an age-dependent expression of the same underlying disorder (Weissman et al., 2005). Twin study data lend support to this position, suggesting a common genetic etiology, and developmental findings point to a variety of possible mediating factors, including the role of pubertal hormones (Walker, Sabuwalla, & Huot et al., 2004b), increased exposure to stressful life events (Silberg, Pickles, Rutter et al., 1999) and negative cognitions (Nolen-Hoeksema, Girms, & Seligman, 1992), and adolescent changes in brain functioning (Nelson et al., 2005). While the presence of any childhood anxiety disorder is associated with increased depression risk (and the

Distinct condition. Some of the examples documented to date fail relatively straightforwardly under one or other of these headings, while others raise more queries.

**Heterotypic Continuity**

Several of the patterns of continuity outlined above seem well captured by the notion that there is meaningful continuity in the course of individual disorders, but that their manifestations change with age. This is likely to be the case, for example, in relation to the associations between neurodevelopmental impairments early in childhood, psychotic-like features later in childhood and the eventual development of schizophrenia; and in the progression from prepubertal anxiety to postpubertal depression. In some instances the impaired associations are closely related, so that associations across development can be expected to be high. In others, mechanisms contributing to continuities are less clear. In relation to schizophrenia, for example, although there is relative specificity in some of the developmental linkages observed, childhood precursor deficits are much more common than eventual psychotic outcomes, raising key questions over the mechanisms involved in the translation of early vulnerabilities into subsequent disorder.

To date, childhood–adult studies have not yet reported analyses involving comprehensive controls for co-occurring prior disorders in this way, although individual studies have done so in relation to particular later outcomes. As a result, some of the disorder progressions reported to date may prove to be epiphenomenal. However, many have unequivocal empirical support: progressions from ADHD to later antisocial disorders and substance use; from substance use to depression (Rutter, 2002); from CD/ODD to a spectrum of later disorders; and between anxiety and depression have all been confirmed in numerous studies. In addition, associations between schizophrenia and earlier emotional/behavioral difficulties need to be considered in this context, along with the emergence of widespread problems in social functioning identified in the adult outcomes of children with SLI.

To date, two rather different processes have been proposed as underlying these varying developmental sequences. First, some connections may reflect age-varying manifestations of the same underlying liability: in general, the term heterotypic continuity has been used to refer to processes of this kind. Second, some links may more properly reflect psychopathological progressions – instances where one disorder or its associated impairments function as risk factors for a second,
presence of multiple anxiety diagnoses seems especially salient),
generalized anxiety disorder (GAD) appears to show the high-
est individual risk (Wittchen et al., 2003).

As noted earlier, progressions from ADHD to later anti-
social disorders also seem likely to reflect shared underlying
liabilities, as do progressions from CD to substance use. Here,
however, associations are not simply unidirectional: although
CD is a strong predictor of adolescent substance use, both alco-
hol and cannabis use, early in adolescence, predict later delin-
quency, and alcohol dependence later in the teens seems to
“ensnare” some young men into persisting antisocial behav-
or (Malone, Taylor, Marmorstein et al., 2004). Mediating
mechanisms also vary at different stages of substance use
involvement. Twin data suggest that early in the teens, when
symptoms of alcohol problems are rare, associations with
conduct problems are almost entirely mediated by shared
environmental influences (Rose, Dick, Viken et al., 2004). By
late adolescence, however, shared genetic liability is by far the
strongest influence on the covariation of alcohol dependence
and antisocial behavior in males (Malone et al., 2004), likely
reflecting shared risks in personality features such as impuls-
vity, risk-taking and lack of behavioral restraint (Krueger,
Hicks, Patrick et al., 2002). Once established, substance use
problems may affect persistence in antisocial behavior
through somewhat different routes, including the disinhibit-
ing effects of alcohol, psychosocial factors associated with peer
influences and adverse effects on family relationships, and the
need for money to support drink and drug habits.

Alongside evidence of such heterotypic continuities, we
should also note instances where clinical assumptions about
progressions in disorder do not appear to be borne out by
empirical findings. One such example concerns the long-held
view that separation anxiety in childhood constitutes a pre-
cursor to panic disorder later in life. Three separate large-scale
prospective studies have now failed to find evidence for
associations of this kind (Costello, Foley, & Angold, 2006).
Although much remains to be learned about developmental
variations in the manifestations of anxiety, this widely anti-
ipated progression seems not – on current evidence at least –
to be supported by empirical findings. In a rather similar
way, the strong associations between depressed mood and use
of a range of substances in both adolescence and adulthood
have long been assumed to reflect efforts at self-medication.
At least in adolescence, longitudinal evidence has cast doubt
on that view: studies of teenage cannabis use find no direct
effects of depressive symptomatology (Rey, Martin, & Krabman,
2004), and follow-ups of depressed samples show little elevated risk for later drug or alcohol use (Fombonne,
Wostear, Cooper et al., 2001). As ever more complex pro-
gressions are identified in the sequencing of many disorders,
disconfirmations of this kind are of particular importance in
redefining our models of potential mediating mechanisms.

**Psychopathological Progressions**

While some developmental associations in disorder seem likely
to reflect varying expressions of the same underlying liability,
others are probably best conceptualized as psychopatholo-
gical progressions, where the experience of one disorder con-
tributes, directly or indirectly, to risk for another. The broad
spectrum of psychiatric sequelae of childhood conduct prob-
lems probably includes examples of both kinds. In relation
to depression, for example, origins of the increased risk in
conduct-disordered samples may arise in part from shared roots
in temperamental features. Zoccolillo (1992) has argued that
conduct disorder should be seen as a disorder of multiple
dysfunction, involving emotional as well as behavioral dys-
regulation. In childhood, findings from a number of studies
are beginning to highlight ODD as a central focus for much
comorbidity (Angold, Costello, & Erkanli, 1999a), and for
progressions to affective as well as antisocial outcomes (Burke,
Loeb, Lahey et al., 2005). To date, most longer-term follow-
ups have not differentiated outcomes of CD and ODD, leaving
it uncertain how far early temperamental difficulties
indexed by oppositional diagnoses may contribute to con-
tinuities currently attributed to more directly antisocial traits.
In addition, psychosocial mediating mechanisms seem likely
to be involved in transitions to depression. As we have seen,
childhood conduct problems frequently select individuals into
adverse environments (both physical and relational) later in
the life course, which in their turn are likely to increase
exposure to stress (Champion, Gooldall, & Rutter, 1995). In
addition, school failure and relationship difficulties may con-
tribute to the development of negative cognitions and self-views
(Capaldi, 1992); and for some previously conduct disordered
individuals, the pharmacological effects of substance use may
constitute further independent risks for depression. As our
knowledge of developmental pathways becomes clearer, so
equally complex linkages may emerge in relation to a range
of disorders.

**Long-term Effects of Early Experience**

In addition to tracing continuities in disorder, the expanding
longitudinal database has also underscored the long-term
effects of early experience on later psychological functioning.
Numerous studies have now confirmed associations between
a spectrum of early adversities – prenatal as well as post-
natal, and both chronic and acute – and increased risk for
disorder later in the life course. The specifics of these findings
are considered in detail in chapters 25–31; we focus here
on the more general issues that need to be borne in mind
in interpreting associations of this kind, and on current
evidence on the mechanisms that may underlie such long-
term links.

Several rather different trends are evident in recent research
in this area. First, studies have continued to demonstrate
statistical associations between adverse experiences in child-
hood and later psychopathological outcomes, using a range
of increasingly sophisticated designs. Where much early work
rested on retrospective reports of childhood circumstances, many
associations have now also been demonstrated in prospective studies; where retrospective reports continue to be needed (as, for example, in studies of sexual or physical abuse, where ethical constraints preclude prospective questioning in non-referred samples), important efforts have been made to establish the reliability of retrospective reports (Hardt & Rutter, 2004). Collectively, this work has demonstrated the broad spectrum of psychopathological sequelae that follow from the more severe forms of childhood adversity, and the substantial contribution that exposures such as childhood sexual abuse have on the overall burden of mental disorder in both childhood and adult life (Andrews, Corry, Slade et al., 2004). In addition, there has been a growing interest in the role of prenatal as well as postnatal exposures. Maternal smoking in pregnancy, for example, has attracted extensive attention as a risk for antisocial behavior in offspring across the life course (Wakschlag et al., 2002), and evidence is also accumulating for associations of later emotional/behavioural difficulties with maternal stress in pregnancy (O’Connor, Ben-Shlomo, Heron et al., 2005), and for links between prematurity/low birthweight and risk for subsequent depression (Patton, Coffey, Carlin et al., 2004).

Alongside these increasingly well-replicated statistical associations, commentators have also drawn attention to the need for appropriate caution in interpreting the meaning of such links. Several different issues are of concern here. First, because early risks frequently cluster, tracking the effects of any specific early exposure inevitably presents major challenges. Prenatal smoking provides an especially telling example here. Numerous studies have now confirmed links between maternal smoking in pregnancy and antisocial outcomes in offspring (Wakschlag et al., 2002), and preclinical studies provide clear and biologically plausible models for effects of nicotine exposure on development of the fetal brain. Despite these persuasive findings, uncertainties over the causal role of pregnancy smoking still remain, in part at least because prenatal smoking co-occurs so strongly with factors such as young maternal age, low maternal education, antisocial traits in parents and depression in mothers, all of which are also well-established risks for childhood conduct problems (Wakschlag et al., 2002). Against that background, passive observational studies alone are unlikely to be able to identify the key pathogenic factors; instead, planned or natural experiments capable of teasing out specific smoking-related effects are needed to take the causal argument forward.

Confounding of this kind typically presents fewer difficulties in relation to postnatal exposures, but problems of interpretation may nonetheless arise. In some instances, these relate to accurate identification of the key elements of risk; in others, to their mode of operation. In relation to the first point, studies have shown that associations with relatively “distal” risk factors such as family poverty in childhood are largely mediated through more proximal indicators of family functioning or the quality of parent-child relationships (Conger, Ge, Elder et al., 1994). Although poverty is indeed implicated in the risk process, its effects on child outcomes are largely indirect. In relation to the second point, genetically informative studies have been important in offering correctives to unquestioning assumptions that associations with apparently “environmental” risk factors do indeed point to environmentally mediated effects (Rutter, 2005a). Harsh parenting – well known to be associated with a plethora of adverse outcomes for children – provides a simple case in point. Although adverse parenting may indeed carry environmentally mediated risk, extensive evidence also points to two alternative possibilities: that genetically influenced child characteristics evoke negative responses from parents, and that styles of parenting are correlated with parental characteristics that also convey genetically mediated risks. Once again, passive longitudinal studies of individuals – the designs most commonly used thus far in tracking long-term developmental sequelae of early adversity – are rarely capable of disentangling these differing effects. However, more appropriate designs are now becoming available. D’Onofrio, Turkheimer, Emery et al. (2005) have recently used the additional leverage offered by studying the children of twins to demonstrate that environmental influences associated with parental divorce do indeed account for the higher rates of drug and alcohol use, and behavioral and emotional problems, shown by young adult children in divorcing families. Although empirical examples of the use of such designs are still limited, over time they promise important advances in our understanding of the key influences underlying exposure to early risks.

Several other general issues are also worthy of note. First, although especially severe early adversities are associated with poor outcomes in many exposed individuals (and effects of multiple adversities are typically most deleterious), most evidence also highlights individual differences in response, with some individuals apparently protected against, or resilient to, later adverse outcomes. In relation to sexual abuse, for example, current findings suggest that although the majority of affected young people show some psychiatric sequelae in adulthood, up to one-third do not (Fergusson & Mullen, 1999). In addition to variations in severity of risk exposure, positive adaptation following abuse appears to reflect interactions among heritable factors, individual characteristics (ranging from biological factors such as stress-reactivity to cognitive and personality features) and later life course experiences (including the availability of emotionally responsive parenting and positive and supportive peer relationships and intimate partnerships). However, discordant twin designs show that the strong effect of sexual abuse in childhood on later depression and later alcoholism is not explicable on the basis of shared genetic liability that spans both the experience and the outcome (Kendler & Prescott, 2006). The twin experiencing serious sexual abuse is the one more likely to have the psychopathological outcomes. Second, although some early theoretical discussions assumed specificity in the psychopathological sequelae of particular types of early adversity, empirical findings if anything suggest diversity in adverse outcomes; although the evidence base is too slim for firm conclusions at this stage, there are some pointers that mediating mechanisms, rather than
CHAPTER 13

phenotypic outcomes, will prove to show more specificity. Third, although some recent discussions have appeared to support early claims that the major effects of adverse experiences arise in the earliest years of life, when brain development is at its most rapid, the evidence is clearly against that view. Although very early adversities do indeed show long-term impacts, and some apparently sensitive period effects have been reported in relation, for example, to the effects of severely depriving early institutional care (Rutter & O'Connor, 2004), it is also clear that experiences across childhood and adolescence, and indeed in adult life, can function as risk factors for psychopathology.

Mediating Mechanisms

From both theoretical and clinical perspectives, delineating the mechanisms that contribute to the long-term sequelae of early adversity clearly constitutes a major priority. To date, direct evidence on mediating mechanisms remains limited, but a number of possible processes have been proposed (Rutter, 2005a). In some instances these reflect the development of biological or psychological vulnerabilities in childhood that are activated by exposure to further risk later in development; in others, effects may run through more immediate precipitation of disorder in childhood or adolescence, which then heightens risk for recurrence; and in others again, effects may run through selection into later risk-prone environments. Psychological mediators include the development of negative cognitive sets and dysfunctional mental representations of self, others and relationships. Exposure to maltreatment, for example, is known to be associated with problems in social information processing, and the development of hostile attributions and biases that may mediate effects on intimate relationships in adulthood (Berlin & Dodge, 2004). Findings on the sequelae of sexual abuse are of particular interest here in suggesting delayed effects in some individuals, not apparent (at least in terms of overt psychopathology) until later in the life course (Jaffee et al., 2002). It has been proposed that exposure to traumatic early experience may evoke active coping strategies to regulate affect. The overgeneralized autobiographical memories reported in some depressed samples, for example, have been argued to reflect attempts to deal with painful memories associated with childhood trauma (Williams, 1996); although adaptive in childhood, such strategies may prove less functional in the context of intimate adult relationships (Hill et al., 2001).

Cognitive development (Richards & Wadsworth, 2004) and coping styles may also be affected, and styles of interpersonal interaction seem especially vulnerable. Many childhood adversities are associated with later difficulties in close relationships (Paz, Jones, & Byrne, 2005); these in turn may function both to deprive individuals of the benefits of positive adult relationships and to increase the likelihood of exposure to later stress. Despite their importance, the roots of these difficulties remain poorly understood. In addition to other aspects of parenting, it is clearly essential to consider the role of attachment here. From the outset, Bowlby (1969) argued that an infant’s early attachments may constitute the basis of all later social relationships, and would be crucial to later psychological development. Prospective studies of attachment from infancy to adulthood (Grossman, Grossman, & Waters, 2005) suggest that the pathways involved are likely to be complex. Alongside evidence that the sensitive supportiveness, acceptance of the child and challenging cooperation of both parents contribute to favorable models of close relationships later in life, it is also clear that taken alone, attachment security in infancy is only a weak predictor of global functioning in early adulthood; when combined with other social measures, prediction to later outcomes is strong (Sroufe, Egeland, Carlson et al., 2005). This suggests that early attachment experiences work with and through other experiences – including peer relationships, later family experiences, and eventually mature intimate relationships – to contribute to later functioning. Although early relationships with mothers are most influential, they are not determinative: the quality of attachments to fathers and to other caregivers may also have domain-specific effects, and no one attachment style will work best under all contextual circumstances. It remains to be clarified quite how dyadic relationships early in development become more generalized, individual features later in the life course, and whether parental sensitivity or ongoing commitment forms the key component.

In addition to these psychosocial pathways, there is also increasing evidence for physical effects of maltreatment, with adverse outcomes on physical health suggesting that chronic early stress has effects on the cardiovascular system, the immune system and on neurobiological functioning (Paz, Jones, & Byrne, 2005). Preclinical studies now provide elegant models for the ways in which a range of early social experiences influence the brain (Champagne & Curley, 2005). Prenatally, gestational stress has been shown to affect the behavior and neuroendocrine functioning of offspring, and deprivation of maternal care in infancy has emerged as central to the development of stress responsivity associated with disruption of hypothalamic–pituitary–axis functioning. Importantly, such effects are not confined to extremes of maternal care; in rats, for example, high levels of maternal licking and grooming in the post-partum period are associated with less fearful behavior in offspring, with attenuated corticosterone response to stress, and with increased levels of hippocampal glucocorticoid receptor expression. Recent evidence suggests that these effects may result from epigenetic changes in DNA methylation, providing a stable mechanism whereby the effects of early social experience persist across development. Equally important, preclinical studies also provide evidence of plasticity. Enrichment of the post-weaning environment, for example, is related to decreased corticosterone response to stress and reduced behavioral indications of anxiety among rats exposed to postnatal maternal separation, with these later social experiences apparently affecting brain development through differing, but equally stable, mechanisms (Champagne & Curley, 2005).

It is unknown at this stage how far these mechanisms are directly relevant to other species, or whether effects of early
environment on human behavior involve parallel epigenetic modifications. Existing evidence does suggest, however, that susceptibility to early adversity varies depending on the individual's genotype. In the Dunedin longitudinal study, a gene–environment interaction was found whereby associations between an index of early maltreatment/adversity and risk of both childhood and adult antisocial outcomes were dependent on variations in the monoamine oxidase A gene (Caspi et al., 2002); males with a lowactivity form of the gene were at high risk of antisocial outcomes when exposed to maltreatment, while those with the high-activity form appeared protected. In a similar way, gene–environment interactions have been reported in relation to risk for depression in the face of stress (Rutter et al., 2006b), suggesting that genetic risk largely operates through its effects on susceptibility to risk environments. As studies of this kind are extended they promise important advances in our understanding of individual differences in the effects of early risks.

**General Developmental Themes**

Taken together, the findings reviewed here underscore the major advances in our understanding of the development of psychopathology achieved through the application of life course concepts and perspectives to the rapidly expanding long-term longitudinal database in psychiatric research. As they make clear, development involves both continuity and change, and an ongoing interplay between individuals and their environments; although early experience strongly shapes later developmental outcomes, opportunities for change also arise across the life course, and individual differences in response are evident throughout.

Alongside the major advances in knowledge reflected here, many issues also remain to be clarified. Although relatively robust evidence now exists on the pattern of continuities in many disorders, for example, and on the long-term sequelae of early adversity, understanding of the mechanisms underlying these links remains much more rudimentary. Gene–environment interplay seems likely to be central to many of these effects, but as we have seen, effects are also likely to be carried forward through psychological mechanisms, through influences on developing brain and neurobiological systems and through connections among social experiences. Much of the later impact of early disorder and adversity seems likely to run through the lasting chains of effects that they set in train in these differing developmental domains. To date, studies have primarily been concerned to highlight the range of mechanisms that may potentially be involved; a key need in the future is to pit alternative hypotheses against one another, to provide more specific pointers to particular mechanisms of risk.

Other challenges also abound. Beginning early in development, we need to know more about how early in life behavior is predictive of later psychopathology, and why, in a number of domains, early onset of disorder appears to carry such deleterious long-term effects: is early age itself a contributory factor (so that, for example, delayed involvement could ameliorate later outcomes), or are age-related variations in onset largely markers for heterogeneity in underlying risk (Rutter, 2005b)? Moving forward in development, the biological changes of puberty and the socially defined changes of adolescence are clearly associated with major changes in risk for many differing types of psychopathology, but the basis for those effects is only now beginning to be understood. Finally, one further key challenge highlighted by existing findings concerns heterotypic continuities: changes in the expression of vulnerability to disorder across age – which seem as striking in many arenas as consistency in emotional and behavioral progressions. From a scientific perspective, the tools now exist to address many of these issues, and major advances can be expected in the coming years in many of these domains. Equally importantly, developmental findings require integration into clinical practice; we conclude by highlighting some of the key implications of existing findings for practice in both the childhood and the adult fields.

**Clinical Implications**

The evidence on lifespan continuities and discontinuities in psychopathology clearly underlines the value of the developmental psychopathology perspective for mental disorders in all age periods, and highlights a range of issues that are relevant for services. We focus here on implications for the timing of interventions; the need to take account of risks of recurrence, as well as current symptomatology; the implications of developmental variations in response to medication; the value of support for successful coping with stress; and, perhaps most importantly, the need for co-ordination and co-operation between services for children and those for adults.

Multiphase or multistage pathways operate over time with many disorders. Different causal factors are implicated at different points on these pathways, offering different targets for intervention. For example, substance abuse disorders start with experimental, recreational use of substances; in some individuals this leads on to much heavier, regular use; and this, in turn, may lead on to pharmacological or psychological dependency and adverse physical consequences. On the whole, environmental influences are much stronger at earlier points on this pathway than in the later points involved with dependency and overt disorder. Physiological responses to the substance also have a role. Thus, individuals who are able to tolerate high dosages of alcohol without marked ill effects are more likely to go on to become dependent than those who become intoxicated more readily. The models provided by peers, parents and others are also important in the early phases of substance use. The issue of whether one substance provides a “gateway” to the use of other substances has proved a controversial one. Nevertheless, most regular heavy drug users and abusers take many different substances, and both
CHAPTER 13

Longitudinal and genetic data suggest that regular cannabis use predisposes to the use of other substances (Rutter, 2007). It is not entirely clear why that is so. It could simply be that it brings the individual into contact with people who use other drugs, or it could mean the acquisition of an attitude of mind in which drug-taking is an accepted part of both a means of pleasure and a means of dealing with stress. Either way, the implication is that preventive measures would do well to focus on the early phases of substance use and abuse, without waiting for overt disorder to become manifest. It is also apparent that the effects of drugs may vary with age. Thus, for example, the schizophrenogenic effects of heavy cannabis use seem to apply largely or entirely to such use in adolescence, rather than adult life. An early study of stimulant drug effects (Rapoport, 1980) suggested that these tended to have a dysphoric effect in childhood in contrast to the usual euphoriant effect in adult life. This suggested that the likelihood of recreational use may be greater in adulthood than in childhood.

Somewhat different considerations derive from developmental evidence on schizophrenia. As we have seen, schizophrenia in adult life is frequently preceded by neurodevelopmental impairments in childhood. The pattern is not diagnostically specific, however, and as yet, there is no justification for intervention at this early stage – at least with respect to the use of medication that is beneficial for overt schizophrenia. The psychotic-like features that may be evident in later childhood or early adolescence are obviously much closer to the overt disorder. Even so, the base rate of these features is far higher than the rate of schizophrenia itself, and only a minority of individuals with such experiences will go on to develop overt schizophrenia. At present, it is not known which factors are involved in this transition, other than that the heavy early use of cannabis does seem to be an important predisposing factor in some cases. This means that individuals with such psychotic-like experiences are particularly vulnerable to the risks associated with early cannabis use. The clinical features described in terms of the prodromata of schizophrenia, arising in late adolescence or early adult life, are even closer to overt schizophrenia. Because there is fairly consistent suggestive evidence that the prognosis is worse when there has been a marked delay in initiating treatment, some clinicians have argued that treatment ought to be initiated at this prodromal stage. The dilemma once again is that prodromata are more common than overt schizophrenia, and not everyone with prodromata goes on to develop the disorder. The possibility of preventing progression has to be balanced against the risks associated with the possibly adverse effects of long-term psychotropic medication. At present, the weight of evidence suggests that preventive intervention should probably be restricted to individuals with a strong family history of schizophrenia and prodromata that are associated with current social malfunction. Nevertheless, the issues are far from resolved (Phillips, McGorry, Yung et al., 2005) and one obvious need is for the development of services that are particularly designed for young people (older adolescents and young adults) who appear to have these prodromal problems. Further research on this group is needed in order to decide how best to intervene.

The findings on the outcome of neurodevelopmental disorders such as autism, ADHD, dyslexia, and the more severe varieties of SLI indicate the high frequency with which these early onset child disorders lead on to substantial social impairment in adult life. Services for these individuals are particularly poor because most adult psychiatrists lack expertise in dealing with the later sequelae of such disorders, and few child psychiatrists provide ongoing care once the individuals cease to be children. The development of better services for young adults who have had neurodevelopmental disorders in childhood constitutes a priority.

The findings of the sometimes long-term effects of early adverse experiences such as physical and sexual abuse raise a somewhat different set of issues. The evidence is clear that there are important long-term effects in some individuals. It is not immediately obvious, however, how that should influence treatment strategies. In a previous era, most psychological interventions were exclusively focused on the past and it definitely would not be justified to return to that approach. Current real life experiences are of major importance. Nevertheless, it would be unrealistic to suppose that the early experiences can simply be ignored as features of the past that are best forgotten and ignored. Psychological interventions need to focus on the present but, equally, they need to pay attention to predisposing experiences when the individuals were younger.

The findings on depressive disorders bring out other considerations. Traditionally, in psychiatry and psychology, therapeutic attention has focused on the relief of current suffering and the alleviation of current symptoms. That is appropriate, but most psychopathological disorders tend to be quite strongly recurrent. It is crucial to have therapeutic interventions that bring a particular episode to a close, but it is equally important to consider what sort of interventions are likely to reduce the risk of recurrence in the years ahead (Scott, 2006). Part of the attraction of cognitive–behavior therapy has lain in its claimed potential to help individuals cope better with life stressors or challenges and, thereby, to reduce risks of recurrence. It is not clear as yet how far it does in fact do that, but the aim is an appropriate one.

Awareness of recurrence risk has also led to a change in approach to the use of antidepressant medication in adults, with the practice now being continuing medication for at least 6 months, and possibly longer, after relief of symptoms. With respect to children and adolescents, recent attention has focused on apparent age differences in responses to medication, and on the risk of side-effects. It has been a puzzle that although there are strong continuities between depression in childhood/adolescence and in adult life, tricyclic medication seems much less efficacious in young people than it is in adults. The evidence on selective serotonin reuptake inhibitors (SSRIs) is less conclusive. Controlled trials have indicated worthwhile benefits, but doubts have been expressed on the extent to which these are comparable to those found in adulthood, and
there has been much concern over the possible increased risks of suicidal responses. Opinions differ on the interpretation of the evidence and the jury is still out on the overall question. Nevertheless, what is clear is that there are likely to be important age-related differences in response to medication; gaining an understanding of these constitutes an important priority for research.

Across the age span, it is obvious that there are individual differences in response to stress and adversity. Gene–environment interaction constitutes an important part of the explanation for these differences (see chapter 23). Nevertheless, the findings on resilience (see chapters 25 & 26) indicate that other factors are also involved (Rutter, 2006). Thus, successful coping with stress or adversity may increase resistance to later stressors. In the past, preventive efforts have been mainly concerned with the avoidance of negative experiences; research findings now suggest that, although that is an important objective, equal attention should be paid to the strengths that may come from successful coping. It is also likely to be important how people interpret their adverse experiences and that may come from successful coping. Both considerations need to have a role in the planning of therapeutic interventions.

Perhaps most of all, the evidence on continuities and discontinuities in psychopathology over time emphasizes the need for better co-ordination and co-operation across services for children, adolescents and young adults than is usually available today. Clearly, special skills and experience are relevant for the provision of services for young people, and specialization is therefore needed. Also, there are good reasons for wanting in-patient services to be particularly adapted to the needs of different age groups. Ordinarily, it is not good practice to treat children on wards that are predominantly concerned with adults. Nevertheless, questions do need to be asked about the merits and demerits of focusing some services on particular psychopathological features, rather than on age groups. Thus, for example, should services for individuals with eating disorders subdivide into those for children and adolescents and those for adults, or would there be advantages to having services that span different age groups? Much the same considerations apply with respect to substance use and abuse. While endeavoring to maintain the real and important strengths of age-related specializations, we need to avoid the rigidities that can sometimes come with them and ask ourselves when they should predominate in planning services and when they should not.

CHAPTER 13

DEVELOPMENTAL PSYCHOPATHOLOGY: LIFE COURSE

CHAPTER 13

Personality traits refer to individual differences in the tendency to behave, think and feel in certain consistent ways. The goal of this chapter is to describe these differences and to document how they shape children’s lives. This chapter is divided into five sections. The first section describes a taxonomy of measurable individual differences in temperament and personality. We present evidence about how to organize and describe the most fundamental personality differences between children and adolescents. It is important to bear in mind that a personality taxonomy is an evolving classification system whose purpose is to integrate and guide research. This also means that any such system must be open to empirical refutation and modification. In this sense, there are historical parallels between the use of structural models in personality psychology and the use of a standardized model for describing and diagnosing mental illness in psychiatry. For example, prior to the advent of the Diagnostic and Statistical Manual of Mental Disorders III (DSM-III; American Psychiatric Association, 1980), clinicians and researchers did not have available explicit criteria to define the boundaries of diagnostic categories (see chapter 2). Clinical diagnoses were difficult to compare and cross-sample replications were hard to conduct. The development of DSM-III was a big improvement because it provided a common language with which clinicians and researchers could communicate about the disorders they were treating or investigating. DSM-III had its share of problems, and subsequent modifications testify to the need for a flexible and evolving system that can accommodate new empirical information, as do recommended modifications in anticipation of DSM-V (Kupfer, First, & Regier, 2002). We can similarly hope that the use of a generally accepted trait taxonomy will help to impose structure on research findings and advance the study of personality development across the life course.

Using this taxonomy, we move on to discuss the development of personality. The second section discusses the developmental processes by which early emerging temperamental differences are elaborated into personality traits that influence how individuals organize their behavior to meet environmental demands and new developmental challenges. The third section reviews evidence about personality continuity and change across the life course. Next we review evidence about the effects of personality traits on behavioral outcomes in different developmental contexts. We go on to discuss the links between personality traits and psychopathology, with special emphasis on contrasting models of the relations between “normal” personality variants and psychiatric disorders. Finally, we discuss the assessment and treatment relevance of personality traits.

Temperament and Personality Traits in Childhood and Adolescence

Definitional Issues

Before describing current research on children’s individual differences, it is important to address the issue of what is meant by the terms temperament and personality, because these terms are used in such varied ways by different people. According to most contemporary perspectives, temperament includes individual differences in affect, activity, attention and self-regulation; although such early emerging traits have a biological basis and are in part shaped by heredity; experience and maturation also play an important part in their development (Rothbart & Bates, 2006). Although this relatively broad definition is widely accepted, it is important to note that some researchers argue for a more narrow definition of temperament. For example, Kagan and Snidman (2004) have suggested that temperament should be considered as individual differences in the reactivity of basic neural systems; this more narrow definition leaves out the self-regulatory dimensions included in other temperament models and puts the emphasis squarely on the biological basis of individual variation.

Personality is typically seen as including a wider range of individual differences than is temperament. Personality differences include personality traits such as extraversion and neuroticism, but they also encompass goals, coping styles, defensive styles, motives, attachment styles, life stories, identities and various other processes (McAdams & Pals, 2006). Although it can be useful to make distinctions between temperament and personality, particularly when considering aspects of personality beyond traits, research has demonstrated that traits from the two domains have much in common. Personality traits are like temperament traits in that they involve variations in emotion and regulation, and personality

182
is likewise shaped by the interplay of heredity and experience (Caspí & Shiner, 2006; Nigg, 2006). Sometimes, child psychologists and psychiatrists shy away from using the term “personality” to describe individual differences in children, because of understandable but incorrect assumptions about the nature of personality traits. Although personality is often assumed to be extremely stable across time and situations and essentially unchangeable, more recent work suggests that personality differences, in transaction with environmental circumstances, organize behavior in dynamic ways over time (Caspí & Shiner, 2006). Because of the significant commonalities between temperament and personality traits, we discuss them together throughout this chapter.

**Structure of Temperament and Personality Traits in Childhood and Adolescence**

As all observers of the human condition know well, children and adults vary strikingly in their day-to-day patterns of thinking, feeling and behaving. An important starting point for temperament and personality research has been describing how these patterns are structured: what are the reliable patterns of covariation of behaviors or traits across individuals? Arriving at some consensus about the basic structure of temperament and personality traits is a crucial task. Although debate continues about the best ways to parse the various traits in childhood and adulthood, considerable consensus has been achieved for both temperament and personality traits.

During infancy and early childhood, children display a more limited range of traits. Temperamental differences in infants and toddlers include three higher-order traits identified by Rothbart and Bates (2006). First, *surgency/extraversion* taps young children’s tendencies toward high activity, a rapid approach style, expressions of positive emotions, and pleasure and excitement in social interactions. Second, *negative emotionality* taps children’s tendencies toward sadness, fear, irritability and frustration, and difficulty with being quieted after high arousal. Third, *orienting/regulation* in infancy includes soothability, cuddliness, ability to sustain attention and pleasure in low intensity situations. In the toddler years, this factor also includes more sophisticated self-regulatory abilities, such as the ability to sustain attention over time and persist at tasks.

As children’s motor, cognitive, emotional and language abilities develop, the range of traits they can express similarly expands; thus, by later in childhood, children display a wider range of individual differences. Research over the last two decades has demonstrated that the basic five-factor structure of personality traits is fairly similar from childhood through adulthood. These comprise the *big five* traits of *extraversion*, *neuroticism*, *conscientiousness*, *agreeableness* and *openness to experience*, with weaker support for openness in youths than for the other four traits (Caspí & Shiner, 2006). Rothbart and Bates’ (2006) work on the structure of temperament in preschoolers and school-age children has yielded evidence for three higher-order traits of surgency, negative affectivity and effortful control, as well as a trait of affiliativeness in adolescence (although these traits are not identical to the big five traits, they are conceptually similar to extraversion, neuroticism, conscientiousness and agreeableness, respectively). Thus, youths and adults manifest a remarkably similar range of individual differences, albeit with some significant changes as development proceeds. It is important to note that the big five traits tend to be correlated with each other in particular patterns that replicate across samples of children and adults (DeYoung, Peterson, Séguin et al., 2006). Specifically, at a higher level of analysis, conscientiousness, agreeableness and neuroticism (reversed) cohere to form an overarching trait, as do extraversion and openness. De Young et al. (2006) have argued that the former “meta-traits” tap the tendency to maintain stability, whereas the latter taps the tendency toward exploration.

Some readers may be more familiar with other temperament models, specifically those of Thomas and Chess and of Cloninger. Because of widespread interest in these models, it is useful to note their links and discrepancies with the models described here. Thomas, Chess, Birch et al. (1963) identified nine traits in infancy and childhood in their New York longitudinal study. As discussed later in this chapter, some of these traits have proven to be very important for children’s development, particularly tendencies toward irritability and frustration and toward fearful withdrawal from new situations. However, the nine-trait structure Thomas et al. articulated does not accurately describe the structure of traits measured by questionnaires based on their model (Shiner & Caspi, 2003); rather, these questionnaires measure a smaller set of traits that are included in the models described in this chapter – irritability, fear and inhibition, activity level, and attention.

The model developed by Cloninger, Przybeck, Svrakic et al. (1994) in the temperament and character inventory (TCI) has also been a popular model, particularly in research on the biological basis of personality. According to this model, personality consists of four temperament dimensions, which are seen as moderately heritable and generally stable, and three character dimensions, which are viewed as more greatly shaped by experience and more malleable. Research reviewed later in this chapter has demonstrated that, contrary to the TCI model, all traits are moderately heritable, including those often considered to be influenced primarily by experience (e.g., traits associated with self-control, diligence, empathy, aggression and prosocial tendencies). Current neuroscience research also suggests that the TCI traits do not map onto the postulated underlying biological dimensions (Paris, 2005). The big five structure also appears to be more robust than that of the TCI dimensions (Markon, Krueger, & Watson, 2005). The TCI dimensions can be understood in terms of their primary links with the big five traits (Markon, Krueger, & Watson, 2005): extraversion (high reward dependence); neuroticism (high harm avoidance and low self-determination); conscientiousness (low novelty seeking and high persistence); agreeableness (high cooperativeness); and openness (high self-transcendence). Despite some of the limitations of this model,
it does converge in important ways with several dimensions of the big five model and with other personality models that include an approach domain manifested in positive emotions, an avoidance domain manifested in negative emotions and a constraint domain manifested as tendencies to inhibit or express emotion or impulse.

**Traits in Childhood and Adolescence: Descriptions and Underlying Processes**

One of the great benefits of a consensually agreed-upon taxonomy of traits is that it allows researchers to turn their attention to the ways temperament and personality traits express themselves in daily life and to the fundamental processes underlying variations in these traits. In this section, we first describe the traits and then review some of the most interesting current work on the psychological and evolutionary underpinnings of each trait. A more detailed description of the components of these traits is found in Caspi and Shiner (2006). Because relatively less is known about the processes underlying openness in children, we do not review this trait here.

**Extraversion**

Children vary in their tendencies to be vigorously, actively and surgently engaged with the world around them. Extraverted children and adolescents are described in big five studies as sociable, expressive, high-spirited, lively, socially potent, physically active and energetic (Caspi & Shiner, 2006). In contrast, introverted youths are quiet, inhibited and lethargic. Extraversion is often conceptualized as the predisposition to experience positive emotions (Watson & Clark, 1997). In adults, extraversion is robustly associated with positive emotions in emotionally neutral conditions and sometimes associated with stronger positive emotional responses to pleasant events (Lucas & Baird, 2004). Similarly, preschoolers’ tendencies toward “smiling, positive verbalizations, and joyful bodily movements” are one part of an overarching positive emotionality trait (Durbin, Klein, Hayden et al., 2005). In a related model, extraversion is conceptualized as representing individual differences in a behavioral activation, approach or appetitive system (Caspi & Shiner, 2006; Rothbart & Bates, 2006). The biological system posited to underlie variations in extraversion is argued to have enhanced tendencies toward exploration and mating opportunities and thus may have conferred evolutionary benefits in some circumstances but created greater risks to survival in others (Nettle, 2006).

**Neuroticism**

Just as children vary in their predisposition toward positive emotions, they vary in their susceptibility to negative emotions and general distress. In the big five studies, children and adolescents who are high on neuroticism are described as anxious, vulnerable, tense, easily frightened, “falling apart” under stress, guilt-prone, moody, low in frustration tolerance and insecure in relationships with others (Caspi & Shiner, 2006). Fewer descriptors define the lower end of this dimension; these include traits such as stability, being “laid back,” adaptability in novel situations and the ability to “bounce back” after a bad experience. As these descriptions of childhood neuroticism illustrate, the trait appears to include both the child’s experience of negative emotions and the child’s effectiveness at self-regulating such negative emotions. Although children and adults do appear to have a general tendency toward experiencing a wide range of negative emotions, it is often important to distinguish among a number of different likely subcomponents, because each is likely to index traits with different underpinnings and outcomes; such components are likely to include distinguishable tendencies toward fearfulness, anxiety, sadness and anger or irritation (which is also related to low agreeableness; Caspi & Shiner, 2006).

Recent research has demonstrated that higher neuroticism is associated with specific detrimental ways of appraising and coping with difficult situations. Children who are higher on negative emotionality are more likely to appraise negative life events as threatening and to use avoidant coping as a way of dealing with these life events, which in turn leads to poorer adjustment (Lengua & Long, 2002). Neuroticism in adults is likewise associated with more self-reported daily problems, stronger negative emotional reactions to everyday problems and to chronic problems, and greater negative “mood spillover” from one part of the day to the next (Suls & Martin, 2005). These findings regarding neuroticism are consistent with the claim that individual differences in neuroticism are associated with individual variation in a withdrawal, inhibition or avoidance system (Caspi & Shiner, 2006; Rothbart & Bates, 2006). The biological system underlying variations in withdrawal and avoidance is likely to have served the evolutionary purpose of protecting individuals from threats; although it is likely to be detrimental at high levels in contemporary society, it may also serve to protect individuals from risks and may confer benefits in some circumstances (Nettle, 2006). Although aspects of neuroticism have been studied in children (e.g., inhibition, anxiety), this trait as a whole warrants much more intensive developmental study, given its links with psychopathology, as discussed later in this chapter.

A temperament trait related to neuroticism that has received widespread attention is that of behavioral inhibition (sometimes termed “inhibition to the unfamiliar”; Fox, Henderson, Marshall et al., 2005). This trait indexes variations in the tendency to withdraw and express fear in the face of stressful novel situations. Inhibition has generally been measured by children’s observed behavior, including fearful responses to novel situations (e.g., a toy robot, an adult dressed as a clown) and reticent withdrawn behavior with unfamiliar adults or children. This trait has been studied extensively in terms of its biological substrates and has been hypothesized to be associated with increased amygdala function, but evidence on links with various indices of amygdala function has been mixed (Fox, Henderson, Marshall et al., 2005). Recent research suggests that behavioral observations of inhibition in young children may confound temperamental differences in low approach and high negative emotions (Putnam & Stifter, 2005); in other words, there is evidence...
that behavioral inhibition in high intensity situations may be evoked either by low approach tendencies (related to low extraversion) or high negative emotional tendencies such as fear (related to high neuroticism). Thus, future work on inhibition is likely to benefit from considering the dimensions of approach and fear separately.

Conscientiousness
An overarching conscientiousness trait taps children’s individual differences in self-control. In big five studies, highly conscientious children and adolescents are described as responsible, attentive, persistent, orderly and neat, planful, possessing high standards and thinking before acting (Caspi & Shiner, 2006). Children low on this trait are depicted as irresponsible, unreliable, distractible and quitting easily. Rothbart and Bates (2006) have identified in children a similar temperament trait termed effortful control, which includes children’s capacities to plan behavior, inhibit inappropriate responses, focus and shift attention, take pleasure in low intensity situations and perceive subtle external stimuli. In a series of studies, Kochanska and Knaack (2003) have developed a battery of tasks to measure children’s emerging effortful control; all of the tasks require a child to exert self-control by suppressing a dominant response in favor of carrying out a subdominant response. Temperament models of effortful control thus tend to emphasize early emerging differences in attention and impulse control, whereas personality models also include aspects of control that are not evident in children until they are older, such as orderliness, dependability and motivation to meet goals and complete work.

As described later in this chapter, conscientiousness in children and adults is associated with effective self-regulation in task-focused contexts (school and work), and with social competence with peers. Researchers studying the biological basis of self-regulation have pointed to the importance of the prefrontal cortex for a variety of self-regulatory skills, including working memory, emotional processing, planning, novelty detection, resolving conflicting information, initiating action and inhibiting inappropriate responses (Banfield, Wyland, Macrae et al., 2004). Rothbart and Bates (2006) consider many of these capacities to reflect individual differences in an overarching executive attention capacity.

Agreeableness
Agreeableness includes a variety of traits seen as very important by developmental psychologists; yet, historically, these traits have been left out of temperament models. The high end of agreeableness includes descriptors such as warm, considerate, empathic, generous, gentle, protective of others and kind (Caspi & Shiner, 2006). The low end of agreeableness includes tendencies toward being aggressive, rude, spiteful, stubborn, bossy, cynical and manipulative. In studies with both children and adults, agreeableness also includes being willing to accommodate others’ wishes rather than forcing one’s own desires and intentions on others; among children, this aspect of the trait also involves how manageable the child is for parents and teachers. Within the agreeableness trait, it is important to distinguish between prosocial tendencies and antagonistic aggressive tendencies. Although these tendencies are negatively correlated, they are not simply polar opposites and, in fact, appear to have distinct developmental origins (Krueger, Hicks, & McGue, 2001).

A number of researchers have argued that agreeableness reflects individual differences in the motivation to maintain harmonious relationships with others; from this point of view, agreeableness taps differences in the willingness to forgo individual interests out of concern for others (Graziano & Eisenberg, 1997). Agreeableness is positively associated in children and adolescents with stronger endorsement of constructive conflict tactics, such as negotiation and compromise (Jensen-Campbell, Gleason, Adams et al., 2003), and high-agreeable children negotiate conflict better. When children are observed in conflict situations in the laboratory, low agreeableness is associated with higher levels of conflict and tension, as well as more destructive conflict tactics (Jensen-Campbell et al., 2003). Interestingly, greater agreeableness does not predict more observed submissive behavior in children (Jensen-Campbell et al., 2003); apparently, agreeable people do not simply solve their interpersonal problems by giving in to other people. In short, more agreeable youths appear to generate fewer conflicts for themselves and have a greater capacity for handling the interpersonal conflicts that do arise. Differences in empathy, warmth and nurturance may arise from a biological system designed to promote parental investment in offspring and close family bonds. Some researchers (e.g., MacDonald, 1995) have argued that evolution yielded a human biological system that typically ensures that intimate relationships and the care of close others are inherently rewarding and pleasurable and that the loss of such relationships is painful and distressing. Such a system would clearly confer adaptive benefits, because it would promote successful care of offspring through the establishment of strong attachment relationships between infants and their caregivers. Further, there is some preliminary evidence in humans that affectional bonds may activate brain areas that support positive emotions and deactivate brain areas that are linked with aggression, fear and sadness (Diamond, 2004); this finding is consistent with the emotional profile associated with agreeableness.

Personality Trait Development

Genetic Influences on Personality
Personality traits are substantially influenced by genetic factors. Bouchard and Loehlin (2001) provide a comprehensive review of this research, pointing to heritability estimates (see chapter 23) across the big five factors in the range of 0.50 ± 0.10. There are some study-to-study fluctuations, but, in general: (i) all personality superfactors appear to be influenced by genetic factors to the same extent; and (ii) genetic factors influence males’ and females’ personalities to the same extent.
traits. Here we describe five processes through which an initial disposition is elaborated so that it increasingly organizes emotion, thought and action.

The first process refers to learning. Specifically, temperament differences influence several learning mechanisms, including positive and negative reinforcement, punishment, discrimination learning and extinction. For example, extraversion may involve an approach system that is sensitive to potential rewards, and neuroticism may involve an avoidance system that is sensitive to potential threats (Casspi & Shiner, 2006). The implication is that different individuals should learn different things from common experiences.

The second process is environmental elicitation. Temperament differences elicit different reactions from the environment and influence how other people react to children, beginning already in the first few months of life (Bell & Chapman, 1986). Research on evocative effects of children’s temperament on parents is especially well developed in relation to infants and young children with “difficult” temperaments (i.e., children who are irritable, hostile, prone to cry and hard to soothe; Crockenberg & Leerkes, 2003); more emotionally negative children evoke more negative parental responses than less emotionally negative children, even within the same family (Jenkins, Rashbash, & O’Connor, 2003). The evocative effects of children’s temperaments extend beyond the family environment to other caregivers, teachers and peers. For example, as described later in this chapter, children’s temperaments shape the quality of their relationships with peers. In turn, the responses that children evoke from others are likely to be internalized as part of children’s emerging self-concepts. Research has begun to uncover some of the microprocesses through which children’s temperament elicits responses from others. Specifically, individual differences in temperament and personality traits are reliably expressed in specific verbal and non-verbal behaviors, including vocal properties and facial expressions (Keltner, Moffitt, & Stouthamer-Loeber, 1995; Lin, Bugental, Turek et al., 2002). In turn, other persons in the immediate environment react to these behaviors and use this information to make inferences and attributions about the developing person (Borkenau & Liebler, 1995; Gifford, 1994).

The third process is environmental construal. With the emergence of belief systems and expectations, temperament differences also begin to influence how environmental experiences are construed, thus shaping each person’s “effective experience” of the environment (Hartup & van Liershout, 1995). Research about the construal process stems from the cognitive tradition in personality psychology that emphasizes each person’s subjective experience and unique perception of the world. This research focuses on what people “do” mentally (Cervone & Mischel, 2002), demonstrating that social information processing— including attention, encoding, retrieval and interpretation— is a selective process shaped by individual differences in temperament and personality (Derryberry & Reed, 2003). For example, individual differences in children’s positive and negative emotionality affect the cues they notice in the environment, the goals that are salient to them and the types of potential responses they generate.

Developmental Elaboration of Personality Traits

Personality traits develop through a process of elaboration. The process of developmental elaboration refers to the processes by which those temperament attributes that are part of each individual’s genetic heritage accumulate response strength through their repeated reinforcement and become elaborated into cognitive and affective representations that are quickly and frequently activated; that is, into personality traits. Here we describe five processes through which an
(Lemerise & Arsenio, 2000). Moreover, individual differences in children's self-regulation shape the responses they select and their ability to enact those responses.

The fourth process is environmental selection. As children's self-regulatory competencies increase with age, they begin to make choices and display preferences that may reinforce and sustain their characteristics. Processes of environmental selection become increasingly important across the years from childhood to adulthood (Scarr & McCartney, 1983). Even among very young children, temperament is likely to shape the spheres children occupy within the environments chosen for them by adults (e.g., inhibited toddlers may avoid interactions with other children in child care, or children high on intellect may choose more stimulating activities at home).

As children move into middle childhood and adolescence, they are given greater freedom to choose the environments in which they spend their time. Youths' personalities shape the activities in which they participate and the ways they choose to spend their free time (Shanahan & Flaherty, 2001) and predict the peer groups children join (Lacourse, Nagin, Vitaro et al., 2006), their experiences of peer rejection and acceptance (Hay, Payne, & Chadwick, 2004) and the quality of their friendships (Pike & Atzaba-Poria, 2003). Across adulthood, individual differences in personality increasingly predict experienced life events. For example, negative emotionality puts individuals at greater risk of being exposed to stressful life events, such as divorce and unemployment (Jockin, McGue, & Lykken, 1996; Kokko, Bergman, & Pulkinnen, 2003).

The fifth process is environmental manipulation. Once the self-concept is firmly established, and with the development of more sophisticated self-regulatory capacities, individuals begin to alter, modify and manipulate the environments in which they find themselves in ways that are consistent with their own personalities (Buss, 1987). These processes may become particularly important as children become more skilled in regulating their own behavior and more insightful into the causes of others' behaviors.

**Goodness-of-Fit: Personality-by-Context Interactions**

Many researchers, clinicians and parents intuitively believe that various temperaments can yield a range of later outcomes, depending on the fit between the child and his or her context. In their early theoretical work on temperament, Thomas and Chess put forth the idea of “goodness-of-fit” (i.e., that the environment moderates the outcomes of children's early individual differences; Thomas et al., 1963). Such a perspective would suggest that even young children with challenging temperaments have the potential to flourish if the context can adapt to their needs. Although the idea of personality-by-context interactions is compelling, it proved difficult to substantiate with data for many years, and in some cases a more direct link between temperament and outcomes seems to occur (Rothbart & Bates, 2006). More recent work, however, has demonstrated several replicable patterns of interactions between childhood temperament and contextual factors; in these instances, different combinations of temperament and context appear to predict whether temperament will remain stable or change and whether other outcomes (e.g., psychopathology) will be negative or positive.

Most of the research on temperament-by-context interactions has focused on parenting behavior as the context. Parenting behavior or socialization patterns can be described along at least three dimensions (Bugental & Grusec, 2006): parental support (which includes warmth, nurturance and affection), psychological control (which includes intrusive attempts to shape a child’s thoughts and feelings rather than accepting and validating the child’s point-of-view) and behavioral control (which includes making and enforcing rules and monitoring). Other aspects of the family environment have also been studied, such as family stress. Contextual factors outside the family are also likely to be important: children’s school experiences, peer relationships and neighborhoods could all affect the outcomes of children’s temperaments. Following are some of the patterns of temperament–parenting interactions, organized by the temperament traits studied. In all of these instances, certain temperamental tendencies appear to amplify the effects of parenting, or parenting appears to amplify the effects of temperament.

Children’s tendencies toward poor self-control have been examined, with such dysregulation measured in a number of ways (e.g., low effortful control, unmanageability, impulsivity). The traits identified have generally been aspects of low conscientiousness and low agreeableness. Across a number of studies, it has been found that children with poorer self-control are more vulnerable to the negative effects of adverse parenting (including low parental support, low behavioral control and high family stress), whereas children with better self-control are less affected by parenting (Rothbart & Bates, 2006). The negative outcomes studied thus far have ranged widely but have often focused on externalizing behaviors. Similarly, highly impulsive youths who live in better-off neighborhoods or who stay in school show lesser criminal behavior than impulsive youths who live in poor neighborhoods or who drop out of school prematurely (Henry, Caspi, Moffitt et al., 1999; Lynam, Caspi, Moffitt et al., 2000). Thus, youths with poor self-control appear to be particularly vulnerable to the dysregulating effects of negative parenting, poverty and dropping out of school.

Other research has examined traits associated with psychopathy in childhood. Psychopathy includes a number of behavioral and personality tendencies: grandiosity, manipulativeness, low fear, and lack of empathy and remorse (Lynam & Gudonis, 2005). The associated traits generally appear to combine low agreeableness with low fear. Across a number of studies, children who are low on psychopathy are more likely to develop conduct problems when facing poor parenting than those receiving more positive parenting (Blair, Peschardt, Budhani et al., 2006). In contrast, youths high on psychopathic traits appear to be less influenced by the rearing environment, which likely makes them very difficult to socialize.

Traits associated with tendencies toward negative emotionality have also received attention. First, children with high levels of negative emotions (including irritability, fearfulness...
and various combinations of negative emotions) appear to be vulnerable to developing behavioral and emotional problems in the face of unsupportive or intrusive parenting (Rothbart & Bates, 2006). Much of the research on negative emotionality has looked at general negative emotional tendencies, which makes the results difficult to interpret. Specific types of negative emotions are likely to have different patterns of effects; for example, in one study, high negative emotionality and high negative maternal control predicted increased externalizing behaviors when combined with low fear but predicted increased internalizing behaviors when combined with high fear (Gilliom & Shaw, 2004). Second, behaviorally inhibited children receiving intrusive, derisive or overprotective parenting remain more consistently inhibited across time than inhibited children receiving other parenting (Fox et al., 2005). Non-parental care may contribute to decreasing inhibition over time (Fox et al., 2005). In essence, behaviorally inhibited children appear to benefit from contextual experiences that provide opportunities to overcome their fears, whereas protection from novel situations results in more stable inhibition. Third, the combination of children’s fearfulness and parenting has been examined in relation to moral development. This line of research was inspired by Kochanska’s work on conscience development in children varying in fearfulness (summarized in Kochanska, 1997). Specifically, Kochanska found that fearful children show more positive conscience development when mothers use gentle discipline rather than power-assertive discipline; in contrast, relatively fearless children tend to develop stronger internalization when they are securely attached to their mothers and when their mothers are more responsive to them. These findings have not been replicated in all samples (Rothbart & Bates, 2006) and will require greater follow-up. Across numerous studies, the research on interactions of negative emotionality and context yields a complex set of patterns, depending on the particular combinations of negative emotional traits, contextual factors and outcomes examined.

All of the previously described patterns indicate that temperament can amplify the positive or negative effects of context, or that context can amplify the effects of temperament. A new line of work documents a different type of interaction, one in which children’s features may affect how sensitive they are to context. Specifically, Boyce and Ellis (2005) have argued, and provided some evidence for the possibility, that high stress reactivity may promote particularly positive functioning in especially protective conditions and particularly negative functioning in adverse conditions, whereas low stress reactivity may yield less responsiveness to contextual features. Stress reactivity is conceptualized and measured at the biological level as “heightened reactivity in one or more of the neurobiological stress response systems” (Boyce & Ellis, 2005, p. 284); the links between stress reactivity and temperamental traits are not yet clear. This new work on stress reactivity requires further replication but points to the intriguing possibility that the same temperamental differences may confer benefits or disadvantages, depending on the context (see chapter 25).

Taken together, there is now robust evidence for the developmental importance of “goodness-of-fit” between children’s temperaments and their contexts, at least for a subset of temperamental traits and contextual factors. Future work in this area will benefit from addressing three issues. First, it will be important to use standard, consensual ways of conceptualizing both temperament and context, in order to make results more interpretable across studies. Second, an important next step will be to focus on the processes through which such interactions exert their effects on development. Third, it is important to recognize that, for many years, goodness-of-fit effects were difficult to identify empirically. In some cases, the link between temperament and children’s outcomes is more direct and is not clearly moderated by the context (Rothbart & Bates, 2006). Thus, it will be important for future research to clarify the traits and outcomes where context has a moderating role and the cases where temperamental traits have a more direct effect on children’s outcomes.

**Personality Continuity and Change**

**Differential Continuity and Change**

Continuity and change are most often indexed by correlations between personality scores across two points in time (i.e., test–retest correlations). These differential, or rank-order stability correlations reflect the degree to which the relative ordering of individuals on a given trait is maintained over time. A meta-analysis of the rank-order stability of personality (organized according to the five-factor model) revealed three conclusions (Roberts & DelVecchio, 2000). First, stability correlations over time are moderate in magnitude, even from childhood to early adulthood. Second, there is a notable trend toward increasing stability of individual differences in personality with age (Fraley & Roberts, 2005); test–retest correlations increase with age, from 0.4 in childhood to 0.55 at age 30, and then reach a plateau around 0.7 between ages 50 and 70. Third, test–retest correlations do not vary markedly across the big five traits or by gender.

Two implications can be drawn from this meta-analysis. First, personality stability in childhood and adolescence is higher than proposed by many developmental theorists (Lewis, 2001), especially after age 3. Moreover, the level of stability increases in a relatively linear fashion through adolescence and young adulthood. Young adulthood has been described as demographically dense, in that it involves more life-changing roles and identity decisions than any other period in the life course (Arnett, 2000). Yet, despite these dramatic contextual changes, personality differences remain remarkably consistent during this time period. Second, personality stability in adulthood peaks later than expected. According to one prominent perspective, personality traits are essentially fixed and unchanging after age 30 (McCrae & Costa, 1994). However, the meta-analytic findings show that rank-order stability peaks some time after age 50, but at a level well below unity. Thus, individual differences in personality traits
continue to change throughout adulthood, but only modestly after age 50.

**Mean-Level Continuity and Change**

Mean-level change refers to changes in the average trait level of a population. This type of change is thought to result from maturational processes shared by a population, and is typically assessed by mean-level differences in specific traits over time which indicate whether the sample as a whole is increasing or decreasing on a trait. A meta-analysis of mean-level changes in personality (organized according to the five-factor model) revealed four conclusions (Roberts, Walton, & Viechtbauer, 2006). First, traits belonging to the domain of neuroticism decreased most prominently in young adulthood. Second, traits belonging to the domains of agreeableness and conscientiousness increased in young adulthood and middle age. Third, the pattern of change in extraversion was complex, until this superfactor was divided into constituent elements of social dominance (assertiveness, dominance) and social vitality (talkativeness, sociability). Traits associated with social dominance increased from adolescence through early middle age, whereas traits associated with social vitality increased in adolescence and then showed decreases in young adulthood and old age. Fourth, traits from the openness-to-experience domain showed increases in adolescence and young adulthood and a tendency to decrease in old age.

Three aspects of the results are of special interest. First, the majority of mean-level personality change occurs in young adulthood, not in adolescence as one might suspect given traditional theories of psychological development. This pattern of change is not simply a recent historical phenomenon, as it was observed in different birth cohorts across the 20th century. This finding suggests that the causes of normative personality change are likely to be identified by narrowing research attention to the study of young adulthood. Second, for selected trait categories, change occurs well past young adulthood, demonstrating the continued plasticity of personality well beyond typical age markers of maturity. Third, there are no discernible sex differences in patterns of mean-level continuity and change across the big five. Apparently, men and women change in the same ways over the life course, although mean-level differences between the sexes are maintained over time. This suggests that the causes of personality continuity and change across the life course are likely to be the same for the sexes.

**Personality Influences on Life Outcomes**

In this section we review evidence about personality effects on relationships, status attainment and health. We provide an overview of research conducted throughout the lifespan, and emphasize both prediction models and process analyses.

**How Personality Shapes Friendships and Intimate Relationships**

One of the most important tasks faced by children and adolescents is the establishment of friendships and acceptance among peers (Hartup & Stevens, 1999). Among children, all of the higher-order big five traits except openness are important predictors of social competence. Agreeable and extraverted children show better social competence and experience growth in perceived social support from early to late adolescence (Asendorpf & van Aken, 2003; Branje, van Lieshout, & van Aken, 2004; Graziano, Hair, & Finch, 1997; Shiner, 2000; Shiner, Masten, & Roberts, 2003). Children high on negative emotionality or low on aspects of conscientiousness (e.g., attention and self-control) have a variety of social difficulties (Eisenberg, Fabes, Guthrie et al., 2000). Perhaps so many aspects of personality predict social competence because social functioning requires a wide array of skills, including emotional expression, emotional understanding, and emotional and behavioral regulation (Rubin, Bukowski, & Parker, 2006).

Personality continues to be an important predictor of relationships in adulthood. Extraversion predicts positive relationships (Shiner, Masten, & Tellegen, 2002), whereas neuroticism and disagreeableness are the strongest and most consistent personality predictors of negative relationship outcomes – including relationship dissatisfaction, conflict, abuse and, ultimately, dissolution (Karney & Bradbury, 1995). These effects of neuroticism and low agreeableness have been uncovered in long-term studies following samples of children into adulthood, as well as in shorter term longitudinal studies of adults that collect data from dyads (Donnellan, Conger, & Bryant, 2004). One study that followed a large sample of adolescents across their multiple relationships in early adulthood discovered that the influence of neuroticism and low agreeableness on relationship quality showed cross-relationship generalization; that is, it predicted the same abusive relationship experiences across relationships with different partners (Robins, Caspi, & Moffitt, 2002).

An important goal for future research will be to uncover the proximal relationship-specific processes that mediate personality effects on relationship outcomes (Reiss, Capobianco, & Tsai, 2002). Three processes merit attention. First, personality traits influence people’s exposure to relationship events (see chapters 25 & 26). For example, people high in neuroticism may be more likely to be exposed to daily conflicts in their relationships (Bolger & Zuckerman, 1995). Second, personality traits shape people’s reactions to the behavior of their partners. For example, highly disagreeable individuals may escalate negative affect during conflict (e.g., Gottman, Coan, Carrere et al., 1998). Similarly, high agreeable people may be better able to regulate emotions during interpersonal conflicts (Jensen-Campbell & Graziano, 2001). Cognitive processes also come on line in creating trait-correlated experiences (Snyder, & Stukas, 1999). For example, highly neurotic individuals may overreact to minor criticism from their partner, believe they are no longer loved when their partner does not call or assume infidelity on the basis of mere flirtation. Third, personality traits evoke behaviors from partners that contribute to relationship quality. For example, people high
in neuroticism and low in agreeableness may be more likely to express behaviors identified as detrimental to relationships: criticism, contempt, defensiveness and stonewalling (Gottman, 1994).

Given the substantial research literature about personality effects on intimate relationships, it is curious that relatively little research has examined personality effects on parenting behaviors (Belsky & Barens, 2002). Although researchers interested in psychiatric disorders have documented that maternal psychopathology can compromise effective parenting (Goodman & Gotlib, 2002; see also chapter 27), developmental researchers have been slower to recognize that parental personality forms a critical part of children’s developmental context (Goldsmith, Losaya, Bradshaw et al., 1994). The handful of studies that have examined personality–parenting associations – using self-reports as well as observations of parenting – suggest that extraversion and agreeableness are related to sensitive and responsive parenting, whereas aspects of neuroticism, such as anxiety and irritability, are related to less competent parenting (e.g., Clark, Kochanska, & Ready, 2000; Prinzie, Onghena, Hellinckx et al., 2004). Research on personality effects on parenting is still in its early stages, and there are several important questions that have yet to be addressed.

First, most of the research to date has focused on parents of very young children to the virtual exclusion of adolescents. Second, most of the research has focused on the main effects of personality and has not addressed the conditions under which particular personality attributes are more or less important in explaining parenting behavior (e.g., are personality main effects moderated by qualities of the marital relationship or by the child’s temperament?). For example, there is some evidence that difficult children are particularly likely to be rejected by highly conscientious mothers during problem-solving tasks (Neitzel & Stright, 2004). Third, to our knowledge, no study has examined personality effects on parenting behavior in relation to multiple children in the same family, a design that has the power to test the cross-situational generalizability of personality effects (across offspring) and to estimate the influence of parental personality on family life independently of other family-wide environmental effects.

**How Personality Shapes Performance in School and Work Settings**

Personality traits from the domain of conscientiousness are the most important non-cognitive predictors of educational achievement and occupational attainment (Judge, Higgins, Thoresen et al., 1999), and they predict job performance across a wide variety of measures and across nearly all types of jobs (Barrick, Mount, & Judge, 2001). Conscientiousness encompasses many traits that are necessary for completing work effectively: the capacities to sustain attention, to strive toward high standards and to inhibit impulsive behavior. In contrast, neuroticism predicts lower academic attainment (Shiner, Masten, & Tellegen et al., 2002), lower adult occupational attainment (Judge et al., 1999) and has small, negative effects on job performance (Barrick, Mount, & Judge et al., 2001; Hurtz & Donovan, 2000). The predictive associations between temperament and personality traits and achievement are already apparent early in life, at the time that children first enroll in school (Miech, Essex, & Goldsmith, 2001). The finding that personality effects on achievement emerge early in life is important, because school adjustment and academic performance have cumulative effects over time (Entwistle & Alexander, 1993). Links between the other big five traits and academic and work achievement are less consistent and robust but are still found. Openness-to-experience/intellect predicts academic achievement in samples of school-age children, adolescents and college students (Graziano, Jensen-Campbell, & Finch, 1997; John, Caspi, Robins et al., 1994), and child and adult agreeableness sometimes do as well (Shiner, 2000; Shiner, Masten, & Tellegen, 2002). Meta-analyses reveal that extraversion, agreeableness and openness predict some more limited aspects of work performance in a subset of occupations (Barrick, Mount, & Judge et al., 2001).

Why are personality traits related to achievement in educational and occupational domains? The personality processes involved may vary across different stages of development, and at least four candidate processes deserve research scrutiny (cf. Schneider, Smith, Taylor et al., 1998). First, the personality–achievement associations may reflect “attraction” effects, or “active niche-picking,” whereby people actively choose educational and work experiences whose qualities are concordant with their own personalities. For example, people who are more conscientious prefer conventional jobs, such as accounting and farming (Gottfredson, Jones, & Holland, 1993). People who are more extraverted prefer jobs that are described as social or enterprising, such as teaching or business management (Ackerman & Heggestad, 1997). Moreover, extraverted individuals are more likely to assume leadership roles in multiple settings (Anderson, John, Keltner et al., 2001). In fact, all of the big five have substantial relations with better performance when the personality predictor is appropriately aligned with work criteria. This indicates that if people find jobs that fit with their dispositions they will experience greater levels of job performance, which should lead to greater success, tenure and satisfaction across the life course (Judge, Higgins, Thoresen et al., 1999).

Second, personality–achievement associations reflect “recruitment” effects, whereby people are selected into achievement situations and are given preferential treatment on the basis of their personality characteristics. These “recruitment” effects begin to appear early in development. For example, children’s personalities influence their emerging relationships with teachers already at a young age (Birch & Ladd, 1998). In adulthood, job applicants who are more extraverted, conscientious and less neurotic are liked better by interviewers and are more often recommended for the job (Cook, Vance, & Spector, 2000).

Third, some personality–achievement associations emerge as consequences of “attrition” or “deselection pressures,” whereby
people leave achievement settings (e.g., schools or jobs) that do not fit with their personality or are released from these settings because of their trait-correlated behaviors (Cairns & Cairns, 1994). For example, longitudinal evidence from different countries shows that children who exhibit a combination of high irritability/antagonism and poor self-control are at heightened risk of unemployment (e.g., Kokko & Pulkkinen, 2000).

Fourth, personality–achievement associations emerge as a result of direct proximal effects of personality on performance. Personality traits may promote certain kinds of task effectiveness; there is some evidence that this occurs in part via the processing of information. For example, higher positive emotions facilitate the efficient processing of complex information and are associated with creative problem-solving (Ashby, Isen, & Turken, 1999; Fredrickson, 2003). In addition to these effects on task effectiveness, personality may directly affect other aspects of work performance, such as interpersonal interactions (Hurz & Donovan, 2000). Personality traits may also directly influence performance motivation; for example, conscientiousness consistently predicts stronger goal setting and self-efficacy, whereas neuroticism predicts these positive motivations negatively (Erez & Judge, 2001; Judge & Ilies, 2002).

How Personality Shapes Health Trajectories

Personality traits contribute to the maintenance of physical integrity and health. Especially impressive are lifespan studies documenting associations between personality traits related to conscientiousness with longevity (Friedman, Tucker, Tomlinson-Keasey et al., 1993). Individuals high in traits related to disagreeableness (e.g., anger and hostility) appear to be at greatest risk of disease (e.g., cardiovascular illness; Miller, Smith, Turner et al., 1996). The evidence for the involvement of neuroticism in ill health is more mixed, with some research pointing to links with increased risk of actual disease and other studies documenting links with illness behavior only (Smith & Spiro, 2002).

Personality traits can affect health through at least three distinct processes (Conrada, Cather, & O'Leary, 1999; Rozanski, Blumenthal, & Kaplan, 1999). First, personality differences may be related to pathogenesis, mechanisms that promote disease. This has been evaluated most directly in studies relating various facets of disagreeableness/hostility to greater reactivity in response to stressful experiences (Smith & Gallo, 2001) and in studies relating low extraversion to neuroendocrine and immune functioning (Miller et al., 1996) and greater susceptibility to colds (Cohen, Doyle, Turner et al., 2003a,b). However, part of the complexity of testing hypotheses about the role of personality in the physiological processes of a disease involves the need for greater clarity about the relevant disease processes and about which processes may be affected by personality. Second, personality differences may be related to physical health outcomes because they are associated with health-promoting or health-damaging behaviors. For example, individuals high in extraversion may foster social relationships, social support and social integration, which are positively associated with health outcomes (Berkman, Glass, Brissette et al., 2000). In contrast, individuals low in conscientiousness engage in a variety of health-risk behaviors such as smoking, unhealthy eating habits, lack of exercise, unprotected sexual intercourse and dangerous driving habits (Bogg & Roberts, 2004). Third, personality differences may be related to reactions to illness. This includes a wide class of behaviors, including the possibility that personality differences affect the selection and execution of coping behaviors, modulate distress reduction and shape treatment adherence (see chapter 57).

The aforementioned processes linking personality traits to physical health are not mutually exclusive. Moreover, different personality traits may affect physical health via different processes. For example, facets of disagreeableness may be most directly linked to disease processes, facets of low conscientiousness may be implicated in health-damaging behaviors and facets of neuroticism may contribute to ill health by shaping reactions to illness. In addition, it is likely that the impact of personality differences on health varies across the life course. For example, the association between conscientiousness-related traits and health-risk behaviors is especially robust and appears to be stronger among adolescents than adults (Bogg & Roberts, 2004). It is apparent from the extant research that personality traits influence outcomes at all stages of the health process, but much more work remains to be done to identify the processes that account for these effects.

Temperament, Personality and the Development of Psychopathology

Much of the early interest in temperament traits was generated by Thomas and Chess’s suggestion that children’s early individual differences could help set off a chain of transactions between the child and the environment that could lead eventually to the development of clinical disorders (Thomas, Chess, & Birch, 1968). Recent years have seen a tremendous increase in research about the links between temperament and personality and the development of psychopathology, in both childhood and adulthood. In this section, we address two aspects of this burgeoning literature. First, we present an overview of how to conceptualize the associations between personality and psychopathology. Second, we summarize what is known about the correlations between temperament–personality differences and the emergence of psychopathology in childhood and adolescence.

A Conceptual Model for Personality–Psychopathology Associations

Personality and psychopathology may come to be linked through a range of processes (Widiger, Verheul, & van den Brink, 1999). In a vulnerability association, personality is a risk factor that causes individuals to be vulnerable to the development of particular forms of psychopathology, particularly in certain environmental conditions. In this case, the
CHAPTER 14

psychological disorder is distinct from the risk-inducing trait or traits. The traits may set in motion processes that cause the development of disorders over time (for a more thorough discussion of these processes see Caspi & Shiner, 2006). In contrast, in a spectrum association, psychopathology represents the extreme end of a continuously distributed personality trait or cluster of traits. In this case, the psychological disorder is not a categorically distinct condition, but rather it is an extreme expression of a dimensional trait. Although the vulnerability and spectrum associations are presented here as if they are distinct, the line between the two is blurred. Most of the associations that have been found between personality and psychopathology could be explained equally well by either the vulnerability or the spectrum model. Some disorders may be better described as discrete entities, whereas others may be better described as dimensional conditions. Further, some aspects of the same disorder may be discrete, whereas other aspects may be dimensional.

Although vulnerability and spectrum associations have received the most attention, other links between personality and psychopathology may occur as well. In a maintenance association, personality may influence the manifestation, course, and prognosis of a disorder once it has started. In a resilience association, personality may protect against the development of psychopathology in the face of stress and adversity. This is not simply the opposite of a vulnerability association. Indeed, to the extent that protective and risk factors operate dimensionally – at opposite ends of a continuum – there is little to be gained from focusing on the beneficial effects of, for example, low neuroticism than on the harmful effects of high neuroticism. But there is a great deal of value in testing two hypotheses:

1 Some personality factors provide protection in the presence of risk, even though they have no effect in the absence of such risk; and
2 Higher levels of a trait are necessary for protection under adverse conditions than are necessary for competent functioning in low-risk conditions.

A final personality–psychopathology link is that of a scarring association, in which the experience of significant psychopathology alters children’s personalities in lasting ways. For example, the early experience of depressive symptoms may influence children’s typical cognitive style, such that children who experience more depressive symptoms may begin to develop a more negative attributional style over time (Garber & Carter, 2006).

Associations Between Temperament and Personality Traits and Psychological Disorders in Childhood and Adolescence

Numerous studies have examined associations between temperament and personality differences and psychopathology, both concurrently and longitudinally. A number of recent reviews have described these associations, organized generally by findings for specific temperament or personality traits (Caspi & Shiner, 2006; Muris & Ollendick, 2005; Rothbart & Bates, 2006). In the following summary, we present an alternative view of these associations, organized instead by classes of disorders (Nigg, 2006; Tackett, 2006).

Emotional Disorders

Watson, Clark, Weber et al. (1995) developed a tripartite model to account for co-occurring emotional disorders in adults. According to this model, depression and anxiety tend to co-occur because both share high levels of negative affect or neuroticism, including distress and fearfulness. In addition, depression is specifically characterized by low positive affect (or extraversion) and anxiety is specifically characterized by physiological arousal. There is general support for these hypothesized associations in cross-sectional studies using a range of child populations, as well as some evidence that high negative affect predicts increases in anxiety, and low positive affect predicts increases in depression in youths (Lonigan, Vasey, Phillips et al., 2004). Further, a study of preschoolers’ positive emotionality (assessed through laboratory tasks and behavior observations) has provided intriguing evidence that low positive emotionality is specifically associated with maternal depression (Durbin et al., 2005); comparable links were not found for the preschoolers’ negative emotionality. Behavioral inhibition also poses risks for the development of anxiety disorders, particularly social anxiety, although most behaviorally inhibited children do not develop anxiety disorders (Tackett, 2006). As noted previously, because current measures of behavioral inhibition are likely to confound low approach and high fear, it is not clear which of these components (or both) is most predictive of anxiety disorders.

Although much of the research on emotional disorders has focused on positive affect (extraversion) and negative affect (neuroticism), aspects of conscientiousness and agreeableness may also be relevant. Lonigan, Vasey, Phillips et al. (2004) have argued for and provided some preliminary evidence that effortful control moderates the effect of high negative affect on the experience of anxiety symptoms. In other words, high negative affect predicts anxiety symptoms only when youths lack adequate levels of effortful control to be able to regulate their negative emotions and cognitive biases toward threatening information. Muris and Ollendick (2005) have presented some preliminary evidence, however, that it is the attention aspect of effortful control that is most relevant to internalizing disorders, perhaps because poor attentional control results in greater cognitive distortions. The role of attention in causing emotional difficulties is also supported by research demonstrating that greater attentional control is associated with more effective regulation of negative emotionality, beginning in infancy and continuing into later childhood (Eisenberg, Smith, Sadovsky et al., 2004). Finally, aspects of excessively high agreeableness, such as excessive empathy and compliance, may be related to the development of depression, particularly in girls (Keenan & Hipwell, 2005); the current evidence for this possibility is thin but worthy of further examination.

In summary, emotional disorders in childhood and adolescence are clearly associated with high negative affect.
ences, such as unsupportive or intrusive parenting, a lack of
are likely to be exacerbated by a range of contextual influ-
research on temperament by context interactions suggests
attention deficit/hyperactivity disorder (ADHD) and conduct
ity profile appears to characterize youths with co-occurring
emotional regulation (Frick & Morris, 2004). This personal-
tionality; in these cases, the problem is largely one of poor
angered but who have poor self-control may be particularly
characterized by high levels of anger, irritability and reactive

Disruptive Disorders
A number of disruptive disorders tend to co-occur. The most
likely temperamental contributor toward this disruptive spec-
trum is a general tendency toward disinhibition versus con-
straint, which includes both low conscientiousness and low
agreeableness (Clark, 2005). In childhood, tendencies toward
disinhibition are associated with disruptive behaviors as well.
Low effortful control and similar traits are robustly associated
with a variety of conduct problems (Rothbart & Bates, 2006).
Although the attentional component of effortful control is likely
to be most important for emotional disorders, effortful con-
trol more generally is likely to be important for disruptive
disorders; in other words, children who are low in planning,
cautiousness, deliberateness and self-control are at a higher risk
of developing oppositional behavior, aggression and conduct
problems (Caspí & Shiner, 2006; Muris & Ollendick, 2005).

Although disinhibition and poor effortful control are general risk factors for disruptive behaviors, there are likely
to be subtypes of youths with conduct problems that are characterized by additional personality patterns (Frick &
Morris, 2004; Nigg, 2006). First, there are disruptive youths characterized by high levels of anger, irritability and reactive
aggression (Frick & Morris, 2004). Children who are easily
angered but who have poor self-control may be particularly
vulnerable to developing conduct problems and opposi-
tionality; in these cases, the problem is largely one of poor
emotional regulation (Frick & Morris, 2004). This personal-
yty profile appears to characterize youths with co-occurring
attention deficit/hyperactivity disorder (ADHD) and conduct
disorder (Cukrowicz, Taylor, Schatschneider et al., 2006), as
well as those who go on to develop substance abuse problems
(Wills & Dishion, 2004) and problem gambling (Slutske,
Caspí, Moffitt et al., 2005). The previously described research on temperament by context interactions suggests
that the problems of children with this constellation of traits
are likely to be exacerbated by a range of contextual influ-
ences, such as unsupportive or intrusive parenting, a lack of
monitoring and structure, family stress or poverty. Second, there
appears to be a subset of previously described youths with
psychopathic tendencies, meaning that they display aspects
of low agreeableness (manipulativeness, low empathy and
remorse) and low fear (Frick & Morris, 2004; Nigg, 2006).
As described in the section on temperament-by-context inter-
actions, these youths are less susceptible to socialization, and
their disruptive behaviors may be less related to their context.
However, Kochanska’s (1997) work on conscience develop-
ment suggests the possibility that an early secure attachment
may help fearless children develop a stronger conscience.
Third, there is a group of youths who do not evidence sig-
ificant conduct problems as children but only develop
such problems as adolescents (Moffitt, Caspi, Dickson et al.,
1996); although this group of youths with “adolescent-onset”
conduct problems is difficult to identify in childhood, they
appear to have adolescent personalities characterized by a lack
of traditional values and a strong motivation to attract atten-
tion and wield influence over others.

Finally, Nigg (2006) has provided evidence that tempera-
ment may also be relevant to the development of ADHD. First,
the inattentive-disorganized symptoms of ADHD may represent
an extreme variant of low effortful control (thus, having a
spectrum association with this trait), accompanied by a range
of executive functioning deficits. Second, the hyperactive-
impulsive symptoms of ADHD may involve extreme approach
tendencies that are not restrained by good self-control or
adequate fearfulness.

In summary, disruptive behavior problems are robustly
associated with problems with self-control and a general
tendency toward disinhibition. There are likely to be several
subtypes of youths with disruptive problems: those with
strong irritability and aggression and general problems with
emotion regulation, likely exacerbated by negative environ-
mental influences; those with low empathy, guilt and fear,
with less consistent environmental contributors; and those with
non-traditional values and high social potency, who do not
develop significant behavioral problems until adolescence.
Aspects of ADHD are likely to be related to low self-control
as well, with attention problems associated with very low
effortful control and impulsive hyperactivity associated with
poorly restrained and modulated approach tendencies.

Temperament and Personality
Assessment and Treatment Relevance
Assessment
Four types of measures are available to assess childhood
temperament and personality, each with different strengths
and weaknesses. First, questionnaires are the most commonly
used measures. Although questionnaires are most often admin-
istered to parents, they can also be used to obtain reports from
peers, teachers and other informants. Self-report questionnaires
are available for older children. Questionnaires have a num-
ber of strengths: they aggregate information about children’s
behavior across a number of situations and over a period of time; they are inexpensive to administer; they efficiently gather a lot of information; and they can solicit information about relatively rare but important behaviors (see chapter 20). Questionnaires may be limited by reporter biases, including those that may be more emotionally motivated and those arising from an inability to report accurately (Funder, 2004). Parent-report temperament questionnaires have sometimes been criticized on this basis. However, research suggests that parent report still has a useful role in assessing temperament (Rothbart & Bates, 2006).

Second, peer and self-reports can be obtained through other means, specifically peer nomination measures and a puppet interview. In peer nomination measures, peers nominate other students who are “best” or “least well” described by particular items. With the Berkeley Puppet Interview, children aged 4–8 report on their traits and experiences by stating which of two puppets they are most like (Measelle, John, Ablow et al., 2004). This measure can be used to assess the big five traits, as well as a range other individual differences. These two types of measures generally possess the same strengths and weaknesses as questionnaires.

Third, naturalistic observation can be used to code children’s behavioral tendencies. For example, home observation systems have been developed to assess temperament or personality in preschoolers (Buckley, Klein, Durbin et al., 2002). Fourth, laboratory tasks create specific situations in which children’s behaviors can be observed. Tasks have been developed to assess specific individual differences, and a more comprehensive battery of laboratory tasks assessing temperament in children is available (Goldsmith, Reilly, Lemery et al., 1995). Naturalistic observations and laboratory assessments have the advantages of potentially possessing ecological validity and of providing an “outsider” view of the child’s behavior. Laboratory tasks also allow for fine-grained analysis of specific behaviors and for linking behaviors with brain functioning. These methods share the weaknesses of being time and labor intensive, being vulnerable to situational effects on behavior and limiting the possibility of observing rare behaviors. Further, any behavior may tap more than one underlying trait, which sometimes makes it difficult to interpret the meaning of any particular task.

Several recommendations are offered for choosing a measure for research. First, ideally more than one method should be used, to take advantage of the strengths of different methods and to counteract the weaknesses inherent in each. At the very least, it is important to include more than one informant when possible, as is true for assessing children’s functioning in general. Second, more than one trait should be measured, to provide evidence of divergent validity for the trait or traits of interest. Third, it is important to evaluate which method is best for measuring a particular trait, depending on the trait or research question being pursued. For further information on finding specific measures to use, readers are referred to citations in several recent reviews (Casp})
are especially low in frustration tolerance and high in inflexibility (Greene, Ablon, & Goring, 2003). Such youths may need an alternative approach to helping them learn to comply. The adaptation of treatment to children’s individual personalities has great potential for improving the effectiveness of treatment.

Youths’ personality strengths should be considered in treatment. Even the most troubled youths are likely to have areas of relative health in their personalities. These personality strengths are resources that can be drawn upon in treatment, and a better appreciation of youths’ individual strengths can sustain a sense of optimism for the youths themselves, their caregivers and their treatment providers. There is also evidence that some traits may promote resilient functioning in youths in the face of stress and adversity, and clinicians can work with children’s contexts to further promote these positive traits (Luthar, 2006).

Research on temperament and personality has demonstrated clearly the fundamental importance of these individual differences for youths’ development. An important next task for the fields of psychiatry and psychology will be to integrate more fully what is known about these individual differences into best practices in treatment and prevention.

TEMPERAMENT AND PERSONALITY
CHAPTER 14

Most modern industrialized nations have populations that are markedly heterogeneous with respect to ethnicity, first language, religion, socioeconomic status and cultural traditions. In this chapter, we seek to consider the implications of these concepts and these groupings for an understanding of psychopathological mechanisms and for the provision of services.

It will be appreciated that the terms themselves imply a rather diverse range of mediating processes. Thus, socioeconomic status and poverty both tend to put the emphasis on the constraints or opportunities provided by the broader external social and physical environment. In support, there is extensive evidence that social disadvantage and poverty are associated with increased risks for a multiplicity of health and psychological functioning outcomes (Bradley & Corwyn, 2002; Evans, 2004; Rutter & Madge, 1976). In the past, there was often an assumption that it was an absolute lack of resources that provided the risks, but there is now increasing evidence that inequalities, rather than absolute level, may provide the risk (Wilkinson, 2005; Wilkinson & Marmot, 2006).

A somewhat related set of issues applies to the observation that there are marked geographical variations in indices of physical health/illness, psychopathology and crime – differences that remain surprisingly persistent over time despite substantial turnovers in population (Rutter, 1981; Rutter, Giller, & Hagell, 1998; Rutter & Quinton, 1977; Townsend, Whitehead, & Davidson, 1992).

Finally, there is the rather different concept of culture – a term that is applied to social groups that are characterized by shared values, practices and traditions (Greenfield, Keller, Fuligni et al., 2003; Shweder, Goodnow, Hatano et al., 1997). Such groups may be defined on the basis of ethnicity, religion, nationality, geography or indeed any other feature that leads to group identification that provides a commonality among members of the group. The implication is not one of advantage or disadvantage, but rather one of meaningful differences in styles of life or styles of thinking. In this chapter, we seek to consider the varied meanings and implications associated with these concepts. The starting point needs to be evidence on social groups.

### Social Groups

Humans are social beings with a strong tendency to form social groups whenever they come together for some perceived social purpose. Such groups typically involve strong loyalties and negative feelings about other groups. The classic “Robbers’ Cave” experiment undertaken many years ago (Sherif, Harvey, White et al., 1961) showed how quickly such social groupings arose when young people were brought together in a summer camp and divided into two competing teams. Intense feelings and identifications developed rapidly. This occurred despite the fact that those in one group had no more in common with each other than they had with those in the other group. The brevity of their acquaintance did not prevent strong group identification and strong rivalries from developing. The process was shown in this case through a quasi-experimental approach, but it is evident naturalistically in numerous other contexts. Thus, we see the same phenomenon in the fighting between supporters of competing soccer teams, and in the national rivalries in the Olympic Games, despite the fact that it is supposed to be about the success of individuals rather than the success of nations.

The supposition is that people are much influenced in their attitudes and behavior by the mores, or ethos, of the social groups within which they function. A further classic study that illustrates this effect is that undertaken by Christensen (1960), who showed that the effects of a premarital pregnancy on the timing of subsequent marriage varied markedly according to the sexual mores of the community. An early example of an experimental approach to people’s susceptibility to social group influences is provided by Asch’s (1952, 1956) studies involving simple decisions about the length of lines. Research accomplices were instructed to give a unanimous judgment that was patently wrong from time to time. In just over one-third of cases individuals succumbed to the implicit group pressure to make a wrong judgment. On the other hand, when even one other accomplice agreed with the subject, the compliance dropped to just 5%. More recent research has taken much further the analysis of influences on the extent to which inter-group interactions differ from inter-individual interactions.
CHAPTER 15

(Wildschut, Pinter, Vevea et al., 2003) but the basic point that there are group effects has been well documented.

The possible relevance for psychopathology and for psychological functioning more generally is evident in the effects of school ethos on pupils’ scholastic progress and behavior, and the effects of peer group influences on the same. In both cases, the basic research challenge has been to determine the extent to which the social group truly has an environmentally mediated effect on individuals, compared with the extent to which the apparent effect is just a consequence of the characteristics of the individuals who happen to make up such groups. Longitudinal studies have been required to test these competing alternatives. Thus, Rutter, Maughan, Mortimore et al. (1979) examined the effects of school ethos by taking account of variations in the intake to schools. Substantial effects were found for both school ethos (as determined by school policy and practice) and school balance (meaning the extent to which the pupil body was made up of predominantly advantaged or disadvantaged children).

Peer group effects have somewhat similarly been examined by determining changes in people’s behavior over the time period extending from before to after joining a peer group (Kandel, 1978; Rowe, Wouldbroun, & Gulley, 1994). The findings show strong enduring effects of prior individual differences but also moderate effects of social group membership. A related strategy has been to check whether young people who join delinquent gangs commit more crimes when part of a gang than they do when outside such groups (Thornberry, 1998). The findings have shown that they do – indicating that the ethos and activities of the social group have effects on the behavior of individuals in them (Lacourse, Nagin, Tremblay et al., 2003). The body of research extends far beyond the few illustrative examples provided here, and it is fair to conclude that the reality of social group effects has been shown, even if debate continues on their relative importance in varying circumstances (Rutter, 1999).

Culture

Against that background, we need to turn to the concept of culture. It has, in common with social groups, the feature of shared experiences and meanings that result in values, beliefs and practices that are distinctively different from those found in other cultures (Greenfield et al., 2003). It differs with respect to the fact that cultures tend to be thought of in terms of groupings that we are born into, rather than ones that we choose to join. Thus, culture is often viewed as a function of ethnicity, race or nationality. This leads to an implicit expectation that each of us is part of just one culture that shapes our personal identity as well as our attitudes and behavior. Research findings indicate the highly misleading nature of these assumptions (Rutter & Tienda, 2005). Not only are each of the defining features complex and multifaceted, but also it is common for individuals to feel part of, and identify with, several different cultures. Moreover, it is also common for people to identify with some aspects of a culture but not others.

Thus, drawing on the large-scale British National Survey of ethnic minorities in Britain in the mid-1990s, Modood (2005) noted that many second-generation immigrants identified both with being British and with some aspect of their ethnic origin. However, the latter was not necessarily focused on the geographical origin from which their parents came. For many Caribbeans, one of their identifications was with being Black, and with many of the South Asians religion was the identifying feature. Also, over time, there was a reduced participation in distinctive cultural practices. For example, younger South Asians, when compared with their elders, were less likely to speak to family members in the South Asian language, to attend a place of worship regularly or to have an arranged marriage. Nevertheless, this did not necessarily mean any reduced identification with their cultural background. Modood drew a distinction between cultural practices and associational identity, in which the latter took the form of pride in one’s origins, identification with certain group labels and sometimes political assertiveness.

Rumbaut (2005), in his major Child of Immigrants longitudinal study in Southern California and South Florida, made somewhat similar points but also noted that ethnic self-identities differed substantially according to where the immigrant parents came from. A further complicating feature, to a greater extent in the UK than in the USA, is the high frequency of intermarriage across some ethnic groups. For example, among the British-born with a partner, half of the Caribbean men and one-third of the Caribbean women had a White partner. That was very much less common among Pakistani and Bangladeshi men, and very few South Asian women had a White partner. Furthermore, it was evident that Asians in Scotland, like other Scots, tended to consider themselves in terms of their Scottishness rather than their Britishness. It is very clear that to assume that anyone is a member of just one cultural group is a highly misleading oversimplification.

It is also clear that cultural identities and social group allegiances often change over time. For example, an early study by Lieberman (1956) showed that taking on a new role could change attitudes; thus, workers who initially held much the same attitudes towards management came to hold different ones when becoming foremen or shop stewards. Siegel and Siegel (1957) showed much the same phenomenon and Newcombe (1943, 1963) described both the persistence and change in the attitudes of girls from “conservative” families who attended a “liberal” college community. In the same way, it must be expected that as second-generation immigrants experience education and careers that differ from those of their parents, they may adopt different values and attitudes. Cultural identifications are influenced both by personal experiences of a positive kind and by discriminatory responses from host communities. In addition, it is obvious that the all too common experience of war and civil conflict may both increase identifications and disrupt cultures. To an even
greater extent, the pandemic of AIDS in Africa has hugely altered cultural context, family styles and caretaking patterns for many children in Africa.

Clearly, that does not imply that there are no meaningful cultural differences. Thus, it is obvious that cultures vary in the extent to which they use arranged marriages, emphasize the importance of the extended family or regard women as having a lower status and lesser rights than men, in the extent to which children are allowed autonomy, in dietary practices, in the use of fostering and other forms of child care, and in concepts of illness and agency – to mention but a few of a long list of features. Similarly, although systematic studies have found negligible correlations between perceived national stereotypes and measured personality characteristics (Terraciano, Abdel-Khalek, Ádám et al., 2005), there are national differences in styles of behavior – as is obvious in terms of times of eating, having a siesta, as well as in collectivistic versus individualistic orientations.

The use of the term “culture” implies that effects on individuals derive from the values, beliefs and practices of the cultural groups. As we have noted, such effects are real. Nevertheless, it is necessary to consider the alternative mediating mechanisms. Thus, apparent effects may stem from the broader societal context rather than from features within the cultural group. Some years ago the concept of a “culture of poverty” was put forward (Lewis, 1968) – the suggestion being that the poor behaved in ways that created a self-defeating culture that perpetuated their problems. The concept fell from favor both because of a lack of supporting evidence and a growing awareness of the societal constraints provided by discriminatory housing and benefits policies. Thus, Wilson (1987) argued that many of the supposed adverse consequences of being African-American in a predominantly White society stemmed from low socioeconomic status rather than from their ethnicity as such. He pointed out the substantial expansion over time of an African-American middle class, as well as the continuing disadvantage of the underprivileged living in ghettos (which applied to a far higher proportion of African-Americans than White people).

With respect to discrimination it is important to appreciate, too, the indirect as well as the direct effects. The latter were well demonstrated through experimental studies examining discrimination in housing and employment (Brown & Gay, 1986; Daniel, 1968). The former are more subtle but may have even greater effects because they impinge so unmistakably on individuals. For example, it could be argued that it was justifiable and rational for the police to stop and search young Black males in inner city areas rather than elderly White females in rural areas – because the crime rate in the former far exceeds the latter. Nevertheless, the consequence will be discriminatory because law-abiding individuals in the former group will suffer much more frequent police harassment than law-abiding individuals in the latter group. Equally, elderly White female criminals will escape detection more often than young Black male criminals. In brief, whenever group characteristics, rather than individual behavior, are used to justify official interventions, the effect will be unavoidably discriminatory.

Cultures and Community
Culture is sometimes extended to the related, but different, concept of community. In many countries, there is a quite marked tendency for new immigrants to choose to live in communities where there are already many people who come from the same country of origin. On the positive side, this has often provided a sense of both practical and social support that helps the newcomers to settle in their new country, and also helps them retain a sense of cultural identity (Bhugra & Becker, 2005). There has also been a negative side in so far as the areas in which such communities live have often been socially disadvantaged and have involved poor quality, overcrowded living conditions. The social support may have come at a price. A further consideration is that the key identifying characteristic of a community may be in terms of what it lacks rather than what it possesses. Thus, the study of neighborhoods in Chicago showed that the key risk factor for crime lay in the social disorganization and lack of community cohesion (Sampson, Raudenbush, & Earls, 1997). Other research has pointed to similar conclusions (Brooks-Gunn, Duncan, & Aber, 1997), and has also raised the possibility of the role of environmental hazards (Gee & Payne-Sturges, 2004). It is not inappropriate to conceptualize these lacks as representing any kind of culture.

Religion
In some communities a person’s religion is of little or no consequence, whereas in others it is the crucial defining characteristic. Thus, within academia in the UK only quite a small minority of people actively practice any religion and most of the time people are not even aware of what religious background others come from. That does not mean that their background is unimportant to them. For example, for many Jews, Quakers, Catholics or Muslims, although they have rejected the formal and structural aspects of religious beliefs and practices of their youth, nevertheless the values remain important and so does their cultural heritage. By contrast, there are other communities where religion is perceived as the defining characteristic. The perception may have been fueled by political and economic issues but nevertheless leads to bitter tensions – such as the rift between Catholics and Protestants in Northern Ireland, the riots and divisions that have occurred from time to time between Hindus and Muslims in Asia and between Jews and Muslims in the Middle East. However, these bitter rivalry groupings are by no means restricted to formal religions as ordinarily recognized. Thus, they have been devastating in their effects with respect to the clashes between Sunni and Shiite groups in Iraq and between tribes and sects of all kinds all over the world. Again, however, we need to emphasize the huge heterogeneity within each of these groupings. There is a tendency sometimes to identify particular religions with their fundamentalist extremes, despite the fact that the great majority of people of that religion
Ethnicity

The standard definition of ethnicity is that it refers to population groups “sharing a distinctive cultural and historical tradition, often associated with race, nationality, or religion, by which the group identifies itself and others recognize it” (Shorter Oxford English Dictionary, 2002). As is obvious from the definition, this leaves rather open which aspect should be given precedence in deciding ethnicity. It has become standard practice in both national statistics and research surveys in the UK or USA to assign ethnicity solely on the basis of the ethnic description that individuals attribute to themselves (Rutter & Tienda, 2005). The self-identification approach involves five main problems. First, at least as operated officially, people are forced to select from a predetermined set of categories that involve consequences. For example, in many countries, people of a mixed ethnic background are automatically treated as “non-White.” Logically, of course, they might just as well be classified as “non-Black,” or whatever terminology is being used for non-Caucasian groups. This may, or may not, coincide with the person’s own concepts.

Second, the categories used to deal with ethnicity differ strikingly across countries. Thus, “Hispanics” constitute a very large, highly diverse and rapidly growing segment of the US population but it is one so small in the UK that its existence is not even recognized. Conversely, there is a very large Asian community in the UK that is subdivided along religious lines or lines of national origin, there being no direct parallel within the USA. Within England, religious affiliation as Catholic or Protestant is seldom consequential, whereas in Northern Ireland it is the defining aspect of group membership for many people. Within those of Asian background in the UK, country of origin (e.g., India, Pakistan or Sri Lanka), community (e.g., Gujerati or Punjabi) or religion (e.g., Hindu, Muslim, Sikh, Buddhist) may be crucially important.

Language is sometimes a very important differentiator; thus in Canada it matters greatly whether someone is Francophone or Anglophone, and in Belgium it matters whether someone is Flemish or French-speaking. By contrast, within England for most people it matters little what a person’s first language is. In large cosmopolitan cities such as London, New York and Los Angeles the diversity of languages spoken at home is simply enormous. Census categories are often rejected by subnational populations. Within the UK, many Scottish and Welsh people clearly see themselves as meaningfully distinct ethnic groups on the grounds of both language and a different cultural heritage, but Welsh and Scottish is seldom included in different ethnic categories. In countries where there is not a large immigrant grouping, only national identity may be included in statistics but the reality is often that regional identities may be more important in terms of identity. For example, in India one is Punjabi, Gujerati or Tamil, and these identities include differences in language and culture but not always religion, although within these groupings religion may be the most important other influence for some.

Third, the use of a single category presupposes that ethnicity can be reduced to a single concept and also that designation should be categorical rather than dimensional.

Fourth, the categorical approach presupposes that each person has only a single ethnic identity, whereas research findings make it clear that many people have more than one, and indeed may have several, the relative importance of which varies by context. There is nothing contradictory in a person considering themselves simultaneously as “Black” (if that is the color of their skin), Glaswegian (if that is the part of the country in which they have grown up) and Hindu (if that is their religion).

The last problem is that a self-descriptive approach presupposes that it is each person’s self-concept that matters most, whereas, at least for some psychosocial features, it may be the response of others that is most decisive.

The social construction of ethnicity may differ quite markedly from self-identifications. For example, in the UK, society’s designation of “Black” includes dark-skinned Asians as well as Africans, despite the fact that neither see themselves as similar, and their historical and cultural backgrounds are as different as their genetic make-up (Rutter & Tienda, 2005). In parallel fashion, the insulting term “Paki” is applied to persons who originated from Bangladesh and India just as much as those who came from Pakistan, thus ignoring a host of differences among these groups, not the least of which is religion. Sometimes ethnicity is equated with social disadvantage or poverty. Of course, it is the case that some ethnic groups are disadvantaged in relation to the society in which they live, but that is by no means always the case. Thus, on the whole, people of Asian origin have been generally successful
in the countries to which they migrated. Moreover, although research has tended to equate ethnicity with minority status, ethnically privileged groups are no less affected by ethnicity issues, as is just beginning to be acknowledged (Quintana, Aboud, Chao et al., 2006).

**Race**

The equation of ethnicity with race has been viewed as controversial by many people. The reasons are not difficult to find, because racial concepts have so often been seen as fixed categories and to convey implications of inferiority or superiority. Nevertheless, the major racial/ethnic groups as identified in census statistics do differ, on average, in genetic make-up. Interestingly, and importantly, the genetic differences do not necessarily coincide with the cultural constructs of ethnicity (Rutter & Tienda, 2005). For example, some Asian groups cluster genetically with Europeans rather than with East Asians. Also, some ethnic groups, most especially Hispanics, are genetically admixed to a major degree. Most crucially, a high proportion of most populations have a heritage that includes a mixture of genetically different racial groups.

The positive side of a genetic focus on race differences is that there are some reasonably well-documented examples of race-related genetic differences that have psychopathological implications. For example, it is well known that some individuals of Asiatic origin have a genetic variant that means that they get a very unpleasant flushing reaction to the ingestion of alcohol – a reaction that has been found to be protective in relation to alcoholism (see chapter 36). The APOE-4 allele is known to carry a substantially increased risk of Alzheimer disease and not only does the frequency of this allele vary across race (being substantially lower among Japanese than African-Americans) but the strength of its association with Alzheimer disease varies hugely, from a factor of 33 in Japanese to 50 in Whites but only 6 in African-Americans (see chapter 23). The reasons for this variation remain unknown at present, but they are likely to have clinical implications.

There is some evidence of racial variations in the distribution of the allelic variations of the serotonin transporter gene that has been found to involve gene–environment interplay with respect to the risk of depression. Widom & Brzustowicz (2006) found that the moderating effect of the MAOA genotype on the effects of child abuse/neglect on violence/antisocial behavior in later life applied to Whites but not to non-Whites. It remains uncertain whether this reflects ethnic differences in the effects of polymorphism on MAOA expression, or other background genetic influences or the meaning of the childhood experiences. There is also limited evidence that there are racial differences in response to therapeutic medication (with regard to both efficacy and side-effects). This has led to a call for developing drugs specifically for certain racial groups. Although clearly there are important advantages in tailoring medication to individual variations in drug response, there are substantial problems in doing this solely on the basis of perceived ethnicity. That is because most individuals have a mixture of racial backgrounds and because the relevant variations in drug response are better assessed in terms of measured genes rather than perceived ethnicity.

With these broad themes as a background, six key issues need to be considered:

1. **Variations in rates of disorder across sociocultural/ethnic groups**
2. **The possible existence of culture-specific mental disorders**
3. **Varied manifestations of disorder across different groups**
4. **Similarities or differences in risk factors across groups**
5. **The universal meaning of measures; and**
6. **The unacceptability of culturally accepted behaviors that cause serious risks.**

**Variations in Rates of Disorder Across Sociocultural/Ethnic Groups**

Epidemiological studies, mainly based on questionnaires or structured interviews (Weisz, McCarty, Eastman et al., 1997), have generally shown that rates and patterns of disorder are broadly similar across groups, although there are differences in detail. Weisz et al.’s (1997) comparison of psychopathology in Thailand and the USA indicated that differences in perception and expectation had quite marked effects on rates of reported disturbance, which had service implications, but the overall prevalence of psychopathology differed little. The study by Luk, Leung, & Ho (2002) brought out a similar point in relation to hyperkinetic disorder, for which there were contradictory reports on whether the rate was higher or lower in Chinese children. The research team spanned Hong Kong and the UK and examined the question by using observational and psychometric measures as well as questionnaire and interview data. The findings were illuminating in showing that although teachers in Hong Kong tended to rate slightly more children as hyperactive than was the case in the UK, observational data suggested that, if anything, the true difference ran in the opposite direction.

Nevertheless, there are forms of psychopathology or psychological functioning that show substantial differences among ethnic groups. First, findings in both the USA (Morenoff, 2005) and the UK (Smith, 2005) noted that antisocial behavior is substantially higher in African-Caribbeans and African-Americans. Conversely, offending rates tend to be low among Pakistanis and Bangladeshis in the UK and among Hispanics in the USA. It is clear that social disadvantage as such cannot be the explanation for the high crime rate, and racial discrimination does not seem to be the main explanation either, because in the UK racial discrimination is high against both African-Caribbeans and Subcontinental Asians, and yet the crime rate of the former is high whereas that of the latter is low. There are substantial problems in measurement and it is likely that some of the differences are caused by the way that crimes are processed and dealt with, but that does not appear to be sufficient explanation. The challenge is to ensure that appropriate measurement is used to compare
rates of antisocial behavior but, equally, there is the challenge of determining what factors might be responsible.

Second, Taylor Gibbs (2005) has drawn attention to the curious paradox that, despite their greater exposure to psychosocial adversities, both Black and Hispanic youth in the USA have rates of suicide that are lower than that of their more advantaged White counterparts. Interestingly, however, the patterns in Black people and Hispanics differ. The findings for Black people indicate that their rate of depressive disorder and of suicidal ideation, as well as their rate of suicide, is low in comparison with White people. The main issue, therefore, is why all of those rates are relatively low. The situation with Hispanics is different in that their rates of depression and of suicidal ideation are not low, despite their low rate of suicide. Accordingly, for them the query is why their relatively high rate of suicidal ideation does not result in a correspondingly high rate of suicide. No good answers are as yet available and recent data suggest that the pattern may be changing, but the questions could be tackled by appropriate research.

Third, there are ethnic differences in educational attainments in both the UK (Maughan, 2005) and the USA (Hirschman & Lee, 2005). In the UK, scholastic attainments tend to be highest for African-Asians and Indians, intermediate for Pakistanis and White people, somewhat lower for Black Caribbeans and lowest of all for Bangladeshis. All ethnic groups have shown educational gains in relation to their immigrant parents, but these have been greatest for African-Asians and least for Bangladeshis. Black Caribbeans have experienced the highest rate of exclusion from school and also the highest rate of teacher–child conflict. Some have sought to explain the ethnic differences in scholastic attainment (as also in antisocial behavior) in terms of the high rate of single parent households in children of Caribbean immigrants, but the data in the UK do not support that conclusion.

Stevenson, Lee, Chen et al. (1990) undertook a comparative study of elementary school children in the USA, Taiwan and Japan. As found by others, attainments tended to be higher in the Chinese and Japanese groups but the groups also differed in terms of family involvement and expectations with respect to academic achievement and their explanations for success or failure. The Chinese and Japanese mothers tended to stress the importance of hard work whereas US mothers gave greater emphasis to innate ability. The study suggested the likely importance of family influences but other explanations are possible, and the study is mainly of value in indicating the utility of comparisons across groups.

Fourth, it has been found that the rate of schizophrenia is substantially higher among African-Caribbeans living in the UK than in either African-Caribbeans living in the Caribbean or White people living in the UK (Jones & Fung, 2005). The ethnic difference has been shown not to be an artifact of diagnostic practice or referral pattern and the difference is one that has been also found in the Netherlands. The elevated rate is not just confined to schizophrenia because, to a lesser degree, it also applies to mania, but there is no differential in minor psychiatric morbidity. Findings so far suggest that the higher rates of psychoses are not a result of differential migration or early brain injury and it appears that the causal influences are likely to lie in some aspect of psychosocial experiences associated with living in the UK for African-Caribbeans, but quite what those factors are has yet to be determined.

The strong message that derives from these findings is that the differences provide a means of testing competing hypotheses about possible mediating causal mechanisms. All too often, discussions about ethnicity are seen as politically unacceptable because they are so prone to degenerate into expressions of prejudice and stereotype. While that is clearly the case, it is important to recognize that such differences need to be investigated in a sensitive and discriminating way in order to understand how the differences, if confirmed, come about. The findings are likely to have implications that extend well beyond the particular ethnic groups that have been studied so far. What applies in such ethnic minorities is very likely to apply to Caucasian groups as well.

**Culture-Specific Syndromes**

An interest in the possibility of culture-specific syndromes first arose from the reporting of psychopathological patterns in adults in Asian and African communities that did not seem to fit the criteria for psychiatric disorders as conceptualized in standard classification systems largely developed from studies in industrialized western societies. The key question was whether these represented different manifestations of common disorders or, rather, unusual syndromes deriving from causal factors rarely encountered in western societies. A study by Guarnaccia, Martinez, Ramirez et al. (2005) illustrates well how the issue can be tackled. They focused on the syndrome of “ataque de nervios” – a pattern first recognized in Hispanic adults that involved screaming, crying and trembling, associated with aggressive behavior and a strong feeling of being out of control. The pattern often seemed to have been precipitated by some acute stressful experience. Guarnaccia et al. (2005) investigated the occurrence of these features in two samples of 4- to 17-year-old children in Puerto Rico – a general population sample and a clinical sample. The measures used included questions on the specific features of “ataque de nervios,” as well as the psychopathological features associated with western diagnostic concepts. In brief, 9% of children in the community sample and 26% in the clinical sample reported the specific features, these were associated with a family history of the same, and they were also associated with depressive, anxiety and disruptive behaviors, and with psychosocial impairment, as found in western populations. It was concluded that “ataque de nervios” represented a culturally influenced expression of emotional distress, associated with affective and anxiety disorders, especially panic. The findings suggested that it was unlikely that the syndrome was fundamentally different from disorders that are highly prevalent in western societies, but they also highlighted that, in contrast to the usual concept of panic disorder, the symptoms often
religious rituals can readily become the focus of compulsions that might be caused by mental disorder or might be normal. A key clinical issue concerns the interpretation of phenomena seemed to have a specific precipitant (Guarnaccia, Canino, Rubio-Stipec et al., 1993).

Early studies had suggested that anorexia nervosa and bulimia nervosa might constitute culture-bound syndromes because of their rarity in non-western societies (Cummins, Simmons, & Zane, 2005; Keel & Klump, 2003; Lester, 2004). Systematic evidence suggests that these eating disorders are actually more prevalent in non-western societies than the early claims suggested. Nevertheless, cultural influences do appear to be operative. For example, there is one study of the effect of the introduction of television in Fiji on binge-eating and purging at a normal weight (Becker, Burwell, Gilman et al., 2002). It has been pointed out that self-starvation can occur in any context, but binge-eating requires large stores of readily edible food and these would often not be available in developing countries where famine is all too common. The various studies indicate that there may also be differences in the particular patterning of eating disorders in different cultures, and it is important to pay attention to these when considering what should be regarded as the essential core of such eating disorders. Nevertheless, eating disorders do not appear to constitute culture-specific syndromes.

Dissociative identity disorder (previously termed multiple personality) seems a peculiarly North American phenomenon, although isolated cases have been reported elsewhere. Questionnaire studies have shown that features purported to index dissociative identity do occur in European samples, even though the diagnosis is made much less frequently (Gast, Rodewald, Nickel et al., 2001; Lipsanen, Korkeila, Peltola et al., 2004). To what extent the questionnaire responses truly reflect the postulated diagnostic category remains uncertain and, in any case, the validity of the diagnostic concept remains controversial (Merskey, 2000). Also, rates of so-called hysterical (conversion) disorders have varied greatly over time in keeping with cultural mores (Merskey, 2000). Very few data are available for any firm conclusions to be drawn, but the implication seems to be that these manifestations of psychopathology probably are influenced by culture, but whether or not they constitute culture-specific disorders of a meaningfully distinctive kind is much more questionable.

Cultural findings, like genetic findings (see chapter 23), serve to alert us to the fact that the current classification systems provide only a rough guide to the best conceptualization and grouping of disorders (see chapter 2). It would be a mistake to force all disorders into the currently prevailing rules of diagnosis, but, equally, there is no good evidence for culture-specific syndromes. Rather, we need to use the findings to ask questions about what should be the key criteria for particular disorders.

Cultural/Religious Beliefs and Psychopathology
A key clinical issue concerns the interpretation of phenomena that might be caused by mental disorder or might be normal in the individual’s own culture or religion. For example, religious rituals can readily become the focus of compulsions in obsessive-compulsive disorders (Greenberg & Wiesner, 2004). The Pentecostal “speaking in tongues” may appear as thought disorder. Thinking that you are possessed by evil spirits may appear delusional. There is both the danger of assuming psychopathology in ignorance of the relevant cultural beliefs and the danger of assuming normality when in reality the phenomena reflect mental disorder. In these circumstances, it may be helpful to seek the views of an experienced person in the relevant culture or religion. Often it will be found that there is a recognition that the phenomena in the referred patient are unusual and peculiar even within the culture or religion. There is also the clinical dilemma with respect to the situation in which someone has become increasingly religious to the extent that it is interfering with daily life or leading to clashes within the family. Is this “normal,” albeit unusually strong, religious devotion, or is it an indicator of psychopathology? There are no easy guidelines for making these differentiations and the main need is to be aware of the possibilities, to be sensitive to the specifics of the features in question and to consult with community or religious leaders when in doubt.

A further clinical dilemma, especially with the ultraorthodox in any religion, concerns the religious reservations about the propriety of discussing certain matters and a worry lest this could lead to a clinical questioning of religious dogma (Greenberg & Wiesner, 2004). The needs in this situation are similar to those regarding differential diagnosis.

Varied Manifestations of Disorder Across Different Groups
Some 30 years ago, Kleinman (1977) drew attention to the finding that, in some societies, emotional disturbance is often reported in terms of somatic symptoms rather than reports of altered mood. He went on to argue (Kleinman, 1987) that it could not be assumed that psychiatric categories and diagnoses have the same meaning when carried over to a new cultural context. The point is an important one but there is a danger of assuming an outmoded dichotomy between psyche and soma, with the expectation that the psychiatric category should truly be defined in mood terms. That ignores two key features. First, mood changes are accompanied by somatic changes (both in terms of complaints and physiological alterations). It is not that one causes the other, but rather that both are part of the same phenomenon. Second, the notion that children do not express mood in somatic terms in western cultures is obviously wrong. It is a commonplace for emotional disturbances to be reported by children in terms of headache, stomach ache and the like. It is clinically most important to recognize the range of ways in which emotional disturbances may be experienced, reported and given particular attributions. The prevailing psychiatric classifications accord a priority to the mood features, and that makes good sense, but we need to appreciate the various ways in which these may be expressed.

Similarities or Differences in Risk Factors Across Groups
In so far as evidence is available, it appears that almost all
the risk and protective factors that operate in one group operate somewhat similarly in other groups. It appears that child abuse and neglect are serious risk factors in all populations. Similarly, committed personal relationships that are continuous over time, matter in all cultures. Social groups pressures are universally operative as are the benefits of interactive play and conversation. Equally, separation from a close caring relationship is stressful for all children. On the other hand, there are some differences that alert one to the dangers of drawing wrong conclusions about the nature of the mediating mechanisms. For example, it might be assumed that the high rate of single parent families in African-Caribbean communities in the UK or in African-American families in the USA would be a major risk factor for adverse psychopathological outcomes. However, the evidence suggests that actually this is not the case (Maughan, 2005; Morenoff, 2005). This probably does not mean that family influences are radically different across cultures, but rather that the structure of the family is not the major mediating variable; rather it is the quality of relationships and care that has implications for psychopathology. The complicating feature is that the associations between quality and structure may well vary across cultures. It may also mean that the social selection factors that lead to single parenthood are not the same in all groups.

The commonality in major risk factors across groups does not necessarily mean that there are no variations in the way the mechanisms operate. For example, Pachter, Auinger, Palmer et al. (2006) compared White, Black and Latino families with children aged 6–9 years in the US National Longitudinal Study of Youth. Much the same risk factors operated in all three groups, but whereas the risk effects of maternal depression were partially mediated through parenting in the White and Latino samples, they were direct and unmediated through parenting practices in the Black sample. Similarly, neighborhood effects were present in the White and Black samples but not significant in the Latino sample. The meaning of these differences remains uncertain at the moment because of parallel uncertainties as to whether variables have precisely the same meaning in the different groups. Nevertheless, it may well be that the social context influences the ways in which more proximal risk processes operate (Rutter, 1999).

Rubin, Hemphill, Chen et al. (2006), using a standard paradigm developed by Kagan and colleagues, found that there were cross-cultural differences in behavioral inhibition. It is possible that these reflect biological differences, as Kagan and Snidman (2004) have suggested. However, it could also be that they reflect either cultural differences in the experience of separations or with respect to emotional expression (Camras & Fatani, 2006; Wang, 2006). Greenfield et al. (2003) have also pointed out that parental goals may vary across cultures with respect, for example, to individuality and to social or familial interdependence.

The studies by Deater-Deckard, Dodge, & Sorbring (2005) and Lansford, Deater-Deckard, Dodge et al. (2004) brought public attention through its finding that whereas corporal punishment tended to be associated with more disruptive behavior in White Americans, it tended to have the reverse effect in African-Americans. However, in all groups physical abuse was a substantial risk factor. Research findings based on a twin sample have been important in showing that the risks of physical maltreatment for later psychopathology do indeed reflect an environmentally mediated process (Jaffee, Caspi, Moffitt et al., 2004, 2005). The same study, however, suggested that much of the risk effect apparently associated with corporal punishment reflected genetically influenced mediation rather than an environmental effect. The evidence on the reality of the risks associated with corporal punishment remains uncertain if viewed in the context of efficacy or inefficacy (Larzelere, Kuhn, & Johnson, 2004; Larzelere & Kuhn, 2005). The public concerns over the risks associated with the regular use of corporal punishment derive from both the evidence of the risk that regular use of corporal punishment tends to predispose to a slide into physical abuse (Jaffee et al., 2004), and the human rights consideration that it is not acceptable for it to be legal to beat your child whereas it is not legal to beat your spouse or neighbor (Commission on Families and the Wellbeing of Children, 2005). At the moment, there are no data on whether this risk that the regular use of physical punishment predisposes to a slide into physical abuse applies within African-American or African groups within the UK, both of whom tend to make more use of physical punishment and find it more acceptable.

A further issue is that there seem to be cultural variations in the prime goals of childrearing. Thus, Halgunseth, Ispa, & Rudy (2006) argued that in Latino families in the USA, the fostering of strong family ties and of respect for elders may be viewed as more important than the fostering of independence. As with other cultural groups, parents use control, guidance and modeling and these will impact on children’s psychological development. The psychopathological effects may differ because the goals are not the same.

Universal Meaning of Measures

A somewhat related issue concerns the question of whether measures can, and do, have the same meaning in all contexts. The topic is most readily illustrated by considering context specificity for cognitive functioning (Ceci & Roazzi, 1994). Many psychologists have made the assumption that it is possible to have culture-fair tests – meaning ones that are not dependent on specific experiences or schooling. However, it is not as straightforward as that, in that problem-solving is very dependent upon the way in which questions are put. For example, Schliemann and Carrera (1994) found that proportional reasoning problems were solved better by Brazilian street vendors who had little or no schooling than by schooled individuals when the problems involved selling–purchasing operations. By contrast, the reverse was true when the same problems were couched in the language of the mathematics text used in Brazilian schools. Schliemann and Nunes (1990) found a similar sort of answer with respect to tasks in which fishermen were asked to calculate prices and
quantities having to do with catching, processing and selling fish. In this case, even schooled fishermen tended to work things out in ways that did not use the proportion algorithms that they had been taught as part of their formal education.

It is important to emphasize that this situation specificity in terms of reasoning extends way beyond culture. For example, Johnson-Laird and Wason (1972; Johnson-Laird, 1983) showed that university students were very poor at a number-letter decision task when it was put in an abstract form but much better when put in a familiar practical form. This is not to argue that cognitive skills show cultural specificity, but that it makes quite a sizeable difference to cognitive performance how questions are posed and how this relates to their everyday experience. Exactly the same is likely to apply to almost any psychological feature when comparing across social groups, societies or cultures, so steps have to be taken to ensure that the meaning of measures is similar across the groups and that this has been tested for and not assumed. For obvious reasons, it would make little sense to use one social group as the standard against which all others have to be compared – although that was an assumption that was built into many early studies.

### Unacceptability of Culturally Accepted Behaviors that Carry Serious Risks

There are two parallel dangers in relation to this issue. First, it is important to be aware that we are all at risk for assuming that the mores in our own culture are necessarily the right ones and, therefore, differing mores in other cultures are unacceptable. The other danger is the assumption that because something is acceptable in some cultures, it necessarily means that it is not harmful. Clearly, that is a logical non sequitur. Until relatively recently, lynching of Black people in the USA was seen as culturally acceptable in some parts of the South (that was so in 1961–1962 when one of us [M.R.] was working in New York) and, even today, beating of children is seen as culturally acceptable to many people in the UK. That definitely does not mean that either are desirable or acceptable practices. The same applies to the practice of female circumcision, or what are misleadingly termed “honor killings,” and the subordination of women in some cultures around the world.

Several considerations arise from these findings and concepts. First, whether or not something is helpful or damaging needs to be based on robust empirical evidence rather than on the prevailing values in any particular society, our own or others. Second, there needs to be a recognition that the reasons why individuals engage in practices that are manifestly harmful may derive from cultural values rather than from individual psychopathology. That does not mean that they are any more acceptable, but it does mean that they need to be dealt with in a rather different way. Third, it is necessary to appreciate that with virtually all examples, there is substantial variation within cultures. There is also substantial variation across generations. This means that there needs to be a sensitivity to, for example, the way in which women are dealt with in different societies but, equally, there needs to be an appreciation that what applies to some people in particular cultures does not necessarily apply to all. The planning of therapeutic interventions needs to be done with a sensitivity to cultural mores but it should be done in a way that responds to the specifics of individual children and individual families, rather than on the basis of any assumption that everyone from any particular cultural or ethnic group is the same. Equally, sensitivity to cultural mores cannot alter situations where the risk nature of the experience has been well established.

### How Can Services be Culturally Sensitive and Appropriate?

It is important not to confuse what may be appropriate with respect to service development in developing countries (Hackett & Hackett, 1999; Nikapota, 2002) with how services should become culturally appropriate within industrialized nations with reasonably good resources. So far as the former is concerned, it is necessary to make use of existing personnel rather than assume that a multidisciplinary western style of practice is needed. However, it is important to encourage the development of methods of intervention for which there is good evidence of efficacy. Of course, it cannot be assumed that what worked best in one social context will work equally well in all others; by the same token it cannot be assumed that there will necessarily be differences. The matter needs to be put to the test in a systematic fashion.

Cultural sensitivity and appropriateness are important for all service contexts. With respect to these issues within western industrialized societies, it is clear from what has already been discussed that the need is not for clinicians to learn about supposedly specific patterns and needs for each cultural or ethnic group. Also, it should not necessarily be assumed that services are always best provided by someone from the same background. What is necessary is to recognize that the use of services, and the response to service provision, are likely to be influenced by people’s concepts of causation and of psychopathology. That does require service providers to be aware of such variations and the acceptability of services may well be aided by ensuring that the responsible professionals include people of varied ethnic and cultural background.

There is also a research need to learn more about variations in people’s expectations of services and what sort of help they wish to receive. The ways in which families are dealt with by services also need to be responsive to cultural variations in how families are expected to function.

This may be illustrated by reference to religious variations. For example, ultra-Orthodox Jews may be unwilling to sit alone in a room with a person of the opposite sex or may insist that a rabbi or other figure of authority be present throughout to ensure that the patient is protected from exposure to non-religious values (Greenberg & Wiesner, 2004). Somewhat similarly, some Muslim girls and women consider it essential to wear a full veil that conceals the whole of the face other
CHAPTER 15

The most important issue with respect to clinical practice concerns the need to appreciate the rich diversity (e.g., with respect to culture, ethnicity, religion, language) in most societies. Clinicians need to be sensitive to this diversity in the ways in which they approach diagnostic issues and plan therapeutic interventions. Human distress and disruptive behavior are universal but the ways in which they are expressed are immensely varied. Because the diversity within all groups is as great as that between groups, the solution does not lie in learning a set of “rules” as to how each and every group expresses their feelings. Rather, clinicians need to be alert to possible differences in emotional expression and to variations in the kinds of explanation that people have for the causes of mental disorder. Equally, clinicians need to be aware that children may not always view things in the same way as their parents, although some do. This may be a particular issue for children of first-generation immigrants.

The top research priority is the use of variations among groups in rates or types of psychopathology to tackle questions on causal mechanisms. Why is the rate of schizophrenia higher in people from the Caribbean now living in the UK or the Netherlands than it is in Whites living in the same region or in people of the same ethnic origin living in the West Indies? Similar questions can, and should, be posed with respect to group differences in antisocial behavior, scholastic attainment and suicide. If causal mechanisms are to be identified, it will be necessary to examine risk and protective processes both within and between groups, and the testing of causal inferences will be greatly facilitated by using migration as a kind of “natural experiment” that brings about change (Rutter & Tienda, 2005).

In the same vein, there needs to be a focus on the few instances in which risk factors seem to operate in different ways in different groups. It is not that it is likely that there are major differences among sociocultural or ethnic groups in the nature of risk and protective processes. Rather, it is that the differences raise questions about the meaning of associations in all groups, and similarly they raise questions about how the impact of proximal risk and protective factors may be influenced by the broader social context. The aim needs to be to use variations as a way of providing a broader understanding of the development of psychopathology in all populations. The implication is that we need to bring cultural studies into the mainstream of research, but to do so in a way that downplays their special features and emphasizes their broader value.

Although for some the question of so-called culture-specific syndromes has not been fully answered, it does not seem to provide a fruitful area of study. The “dhat” loss of semen syndrome seems likely to have about as much validity as the western concept of “masturbatory insanity” had a century or so ago. Of course, cultural beliefs can constitute sources of distress as well as providing sources of foci for people’s explanatory concepts regarding the disorders they experience. Thus, this would seem to apply to anorexic and bulimic eating disorders. However, in our view, the way ahead needs to lie in the study of the possibly etiological role of attitudes to body shape and size rather than the study of group differences as an end in itself. In other words, cultural variations can be very informative but they are most likely to be so when they are part of a broader scientific enterprise.

The issue of the extent to which there are variations in symptom expression raises questions about the comparability of patterns across groups, and is another area worth further study. In essence, it needs tackling in much the same way that apparent sex or age differences in patterns of psychopathology have been investigated (Moffit, Caspi, Rutter et al., 2001). The need is to compare causes, correlates, course and consequences in order to determine whether there are important valid differences that need to be recognized (Rutter, 2007). Up to now, there have been rather few studies that have done this in a systematic fashion. Assumptions about age and sex differences in psychopathology need testing just as much as do cultural variations.

Some 30 years ago, Liederman, Tulkin, & Rosenfeld (1977) noted that the comparative study of societies provided a
fertile ground for hypothesis testing. They emphasized the need to understand the cultures and societies being investigated and to use measures that were sensitive to key features. They added that it was also important to appreciate that the comparisons across societies can be strengthened significantly through the study of individual differences within groups. It is necessary to discover whether or not the relationship of processes within each of the groups is relevant to any of the differences found between groups. It is evident from more recent conceptual and methodological critiques (Swanson, Spencer, Harpalani et al., 2003) that all too few studies have really taken on board how those cultural and ethnic variations need to be dealt with in research.

Some might argue that there is a need to define what is meant by culture. Along with others (Canino & Guarnaccia, 1997), we disagree. That is because the concepts and differences that we have discussed in this chapter are so multifaceted and so various. There is a need to understand better how cultures develop and how they change over time and in response to altered circumstances. Surprisingly, although opinions abound, there is little systematic knowledge on these matters. It may not have great importance for psychopathology, but it is an important topic in its own right.

CHAPTER 15

in Europe. In M. Rutter, & M. Tienda (Eds.), *Ethnicity and causal mechanisms* (pp. 227–261). New York: Cambridge University Press.

The use of psychotropic medications in children has increased dramatically over the past decade (Zito & Safer, 2005). An increase in clinical research followed, partly resulting from governmental regulations and legislation that encouraged studies on the safety and efficacy of drugs that are approved for use in adults but not for children, yet are widely used off-label to treat children (DeVeauh-Gees, March, Shapiro et al., 2006). Most studies have been conducted to evaluate established clinical practices, and some have generated significant controversy – if they did not support these practices (Vitiello, 2006) or questioned their safety (US Food and Drug Administration, 2003b, 2004a, 2005).

This pattern, of research following practice, has led to a rather slow development of new pharmacological treatments with improved efficacy and safety. Basic principles and findings from the neurosciences could be better integrated into innovative, theory-driven treatment development (Vitiello, 2006). In this chapter, we summarize some basic properties of psychoactive medications used in the treatment of psychiatric disorders of childhood. The areas of neurochemistry and psychopharmacology provide extensive information that can be used to specify rational dosing regimens and to identify mechanisms of action of the commonly prescribed drugs. We describe methods from clinical pharmacology that have been successfully applied to evaluate amount (dose) and timing (dosing rate) of drug administration, and we describe methods from brain imaging that have elucidated cellular targets of some commonly prescribed medications and their effects on brain function. We focus on basic principles in neurochemistry and psychopharmacology that could help us understand how currently available psychotropic medications exert their clinical effects on the core symptoms of some childhood disorders for which cellular targets have been proposed (e.g., attention deficit/hyperactivity disorder [ADHD], major depressive disorder [MDD], anxiety disorder [ANX] and schizophrenia [SCZ]). Better basic understanding should guide us in the development of new and improved pharmacological treatments for these disorders and for others, such as autistic spectrum disorder (ASD), for which currently there is neither a proposed cellular target nor a pharmacological treatment that is effective for the reduction of the core symptoms of the disorder. We have organized the chapter into three sections.

First, we review some basic pharmacokinetic (PK) methods that describe how psychotropic drugs are delivered to the brain after administration of clinical doses, some basic pharmacodynamic (PD) analyses that model responses at sites of action in the brain, and some basic PK/PD analyses that describe the relationships between drug concentration and effect (Fig. 16.1).

Second, we discuss neurotransmitters that are the primary targets of medications used to treat ADHD, MDD (and ANX) and SCZ (and ASD), namely dopamine (DA), norepinephrine (NE) and serotonin (5-HT), and their synaptic components that participate in neurotransmission and are targets for psychotropic drugs (transporters, enzymes and receptors).

Third, we describe how positron emission tomography (PET) imaging has been used to measure directly in the human brain the concentrations of psychotropic medications, their effects on cellular targets and their functional effects on brain circuits which are involved in multiple processes associated with cognition and emotion.

To link psychopharmacology with neurochemistry, we discuss how PET imaging methods can be used to investigate the cellular mechanisms involved in response to psychotropic medications. In Plate 16.1(a), we show a schematic DA synapse, and surrounding it we present images from different PET methods that have been used to characterize the components related to the neurotransmitter DA: transporters, which recycle the neurotransmitter back into the neuron after its release; enzymes, which are involved in neurotransmitter metabolism; and receptors, which mediate the functional effects of the neurotransmitter. We include a summary of some basic pharmacokinetic and pharmacodynamic principles as well as a description of some of the important PET methods that have been used to characterize the components related to the neurotransmitter DA (Fig. 16.1).

synthesis and metabolism; and **receptors** at postsynaptic sites, which transmit the signal when activated as well as at presynaptic sites, which regulate neurotransmitter synthesis and release. Also, we present an example of a functional PET image of **glucose metabolism**, which represents an integrated consequence of these factors operating in combination.

Figure 16.1 presents a framework for the three sections of this chapter that present information about the fate of a drug after it is administered by a given route (e.g., oral, transdermal, intranasal, intravenous). To start the processes outlined in Fig. 16.1, a clinician must make a series of choices. After the initial choice of the particular medication (which is typically related to diagnosis), further decisions are necessary about the dose (which varies between individuals and is based on titration) and the frequency of dosing (which may be controlled by the formulation). After entering the body, processes occur that define the PK and PD properties of the drug. Based on a common description from clinical pharmacology (Gupta, Hwang, Benet et al., 1993), the PK processes on the left side of Fig. 16.1 reflect “what the body does to the drug,” and the PD processes on the right side reflect “what the drug does to the body.” Here we present some simple methods from clinical pharmacology to describe the PK processes on the left (absorption, distribution and elimination of the drug) which describe the maximum plasma concentration ($C_{\text{max}}$), when it occurs after dosing ($T_{\text{max}}$) and the plasma half-life ($t_{1/2}$). We also present some PET imaging methods that have been used to describe the PD processes shown on the right (e.g., drug effects of transporter blockade and receptor occupancy). We illustrate these methods for stimulant, selective serotonin reuptake inhibitor (SSRI) and neuroleptic medications. These examples are intended to demonstrate how the basic principles of clinical pharmacology and neurochemistry can be used to provide a fundamental understanding of how these drugs exert their clinical effects.

### Psychiatric Disorders and Psychotropic Medications

A relatively small number of drugs are approved by regulatory agencies for the treatment of psychiatric disorders of childhood and adolescence, but many others not approved are used off-label (Emslie, Hughes, Crismon et al., 2004; Pliszka, 2005; Wilens, 2004). Table 16.1 was adapted from the Children’s Medication Chart prepared by the National Institute of Mental Health (2002), which lists the commonly prescribed medications and the approved age for their use for the treatment of classes of disorder (i.e., “Medications for ADHD,” “Anti-depressant and Antianxiety Medications,” “Antipsychotic Medications” and “Mood Stabilizing Medications”).

We use our framework of clinical pharmacology and PET imaging to discuss some important current issues in child psychopharmacology:

1. The use of controlled delivery formulation of the stimulant medications;
2. The difficulties of demonstrating efficacy of antidepressant medications; and
3. The side-effects of antipsychotic medications.

Chapter 67 describes the use of psychotropic drugs in clinical practice.

### Stimulant Medications for ADHD

The place of drug treatment in ADHD is discussed in chapter 34. Animal studies have suggested that the stimulants amphetamine (AMP) and methylphenidate (MPH) have their primary effects on two neurotransmitters: DA and NE (Solanto, 1998). The enhancement of catecholaminergic activity in the basal ganglia and prefrontal cortex increases the readiness to respond to external stimuli and the saliency of external stimuli, and these in turn increase the clinical targets of attention and executive function. In addition, adverse effects in limbic areas (including hypothalamus) decrease appetite and sleep.

The immediate-release (IR) formulations of AMP and MPH were used before the modern Food and Drug Administration (FDA) approval process was even established, and since then thousands of studies have been published about their efficacy and safety (Pliszka, 2005; Swanson, McBurnett, Wigal et al., 1993). The PK properties of IR formulations of these stimulants document rapid absorption, with a $t_{\text{max}}$ of about 1–2 hours and rapid metabolism with a $t_{1/2}$ of around 3–4 hours, with slightly greater values for AMP than MPH. The PD properties parallel the PK profiles. So, for effective treatment across the day, multiple doses of IR formulations are required, and these treatment regimes (i.e., IR MPH t.i.d. and IR AMP b.i.d.) emerged from almost a half century of clinical use (Swanson, McBurnett, Wigal et al., 1993). The basic findings for school-aged children are the following: the two stimulants have large short-term effects that reduce the core symptoms of ADHD (reduction of inattention, hyperactivity and impulsivity) and some associated features if they are present (aggression and defiance); efficacy is about the same for these two stimulants (effect size about 1.0; about 80% response rate); across individuals the range of clinical doses for optimal response is large (five- to sixfold) so a titration process is used to select the best dose for each individual (see chapter 34).

Despite decades of concentrated research, there are still many critical unanswered questions about the effects of the stimulant medications, including questions about effects in age groups typically not treated with stimulants, long-term effects on efficacy and side-effects, and emergence of side-effects over time.

The use of stimulants is primarily with school-aged children (Centers for Disease Control and Prevention, 2005; Jick, Kaye, & Black, 2004), but their use to treat ADHD in adults (Spencer, Biederman, Wilens et al., 1996) and preschool children (Greenhill, Beyer, Finkelson et al., 2002) has been increasing over the past decade (Zito, Tobi, de Jong-van den Berg et al., 2006). These reports suggest that treatment of adults and preschool children results in similar effects as in school-aged children, but with somewhat reduced effectiveness and/or greater side-effects, which may be partially due to more diagnostic uncertainty in these extreme age groups than in the...
school-aged group for which the diagnostic criteria were developed. For example, the Preschool ADHD Treatment Study (PATS) ($n = 145$) documented safety and efficacy of IR MPH in children with ADHD below the age of 6 years (Greehill, Biederman, Boellner et al., 2006; Wigal, Greenhill, Chuang et al., 2006), but lower rates of response, smaller benefits and greater side-effects were seen in this age group than typically observed in school-aged children with ADHD.

Long-term trials have suggested improvement over time, but whether this is related to past or continued treatment is not clear. For example, a single site study ($n = 62$) of AMP (Gillberg, Melander, von Knorring et al., 1997) suggested that improvement in the first year was maintained after withdrawal of treatment, but a dual site study ($n = 103$) of MPH (Abikoff, McGough, Vitiello et al., 2005) suggested that continued treatment is necessary to maintain improvement into the second year of treatment. The Multimodal Treatment Study of ADHD (MTA), a large multisite study ($n = 579$), added to the literature by documenting long-term efficacy of MPH. The benefits of IR MPH t.i.d. treatment compared with non-pharmacological (behavioral) treatment over the first year were clear and large (MTA Cooperative Group, 1999a,b). A secondary analysis of the MTA revealed that some of the beneficial effects of medication were larger for the subset

ADHD, attention deficit/hyperactivity disorder; DA, dopamine; GABA, &-amino butyric acid; NE, norepinephrine; OCD, obsessive-compulsive disorder.
of cases with pervasiveness of symptoms across home and school settings that qualified them for ICD-10 diagnoses of hyperkinetic disorder (Santosh, Taylor, Swanson et al., 2005).

The evaluation of the MTA groups in a naturalistic follow-up has provided information on the persistence of effects over longer periods of time than 1 year. The relative superiority of medication was reduced by 50% at the 24-month follow-up (MTA Cooperative Group, 2004a,b) and dissipated completely at the 36-month follow-up (Jensen, Arnold, Swanson et al., 2007), when no effect of prior assigned treatment or current actual treatment with stimulant medication could be documented for reduction of ADHD symptoms (Swanson, Hinshaw, Arnold et al., 2007b) or emergent problems of delinquency or substance use (Molina, Flory, Hinshaw et al., 2007). A statistical procedure (growth mixture modeling) was used which identified three subgroups with different trajectories of outcome (symptom severity) over time, which appeared to be independent of history of assigned or actual treatment with stimulant medication. This naturalistic follow-up of the MTA randomized clinical trial offers new and potentially important information about prognosis of the ADHD condition. First, there appears to be a general trend of improvement regardless of treatment modality (medication or behavioral). Second, there are clear short-term but not long-term relative benefits of medication of ADHD symptoms, suggesting that the beneficial effects of stimulants on symptom reduction may dissipate over a period of 2–3 years of treatment or as the treated patients become older (which were confounded in the MTA protocol).

Side-effects of the stimulant medications are typically mild and manageable, with suppression of appetite and sleep, which dissipates over time, or can be managed by adjustment of doses, timing of doses or type of stimulant (Greenhill, Pliszka, Dulcan et al., 2001). Recently, the MTA follow-up (MTA Cooperative Group, 2004a; Swanson, Elliot, Greenhill et al., 2007a) revived concern about stimulant-related growth suppression, which had previously been thoroughly discounted (Spencer, et al., 1996) and thus had not been considered worthy of an a priori hypothesis in the MTA design and analysis plan. A post hoc analysis of the randomized clinical trial phase of the MTA (MTA Cooperative Group, 2004b) revealed stimulant-related reduction in growth rate (by about 1 cm per year in height and 2.0 kg per year in weight) over the initial 14-month phase of supervised and randomly assigned to treatment with medication compared to behavioral modification without MPH. This reduction in growth rate appeared to persist in the naturalistic follow-up (MTA Cooperative Group, 2004b), with a cumulative stimulant-related growth suppression effect of about 2.0 cm in height and 2.7 kg in weight after 3 years of continuous treatment (Swanson, Elliot, Greenhill et al., 2007a). The evaluation of growth in another controlled trial, the Preschool ADHD Treatment Study (PATS), also revealed a significant stimulant-related growth suppression of height and weight in preschool children with ADHD during the initial year of a continuous and monitored treatment with IR MPH (Swanson, Greenhill, Wigal et al., 2006c), which was slightly larger than in the school-aged children of the MTA (Wigal, Greenhill, Chuang et al., 2006). These reports from controlled trials (i.e., MTA and PATS) stand in contrast to the reports of some recent chart review studies of modern clinical practices that do not show stimulant-related growth suppression (Pliszka, Matthews, Braslow et al., 2006; Spencer, Faraone, Biederman et al., 2006b).

In addition, side-effects related to rare cardiac effects of the stimulant medications have been evaluated by regulatory agencies in Canada (Health Canada, 2005), the USA (US Food and Drug Administration, 2005) and in the European Union (NICE, 2005). These reviews have generated considerable controversy about whether these serious adverse events are greater than expected in the population (Anders & Sharfstein, 2006; Nissen, 2006; Rappley, Moore, & Dokken, 2006; Shader & Oesterheld, 2006).

In the mid-1990s, pharmaceutical companies initiated research programs to evaluate and improve the formulations of stimulant medications. One new development that produced a dramatic shift in clinical practice is reviewed here: the development and use of controlled-release (CR) formulations of both MPH (Concerta®, Metadate CD®, Ritalin LA®, and Focalin LA®) and AMP (Adderall XR®). The CR formulations were developed to replace specific dosing regimens of the IR formulations, including IR MPH t.i.d. for Concerta® (Swanson et al., 2003), IR MPH b.i.d. for Metadate CD (Wigal, Sanchez, DeCory et al., 2003) and Ritalin LA (Biederman, Quinn, Weiss et al., 2003) and IR AMP b.i.d. for Adderall XR (Greenhill, Swanson, Steinhoff et al., 2003). The development programs, funded by pharmaceutical companies, all used PK and PD methods to select the drug delivery profile to be established by controlled delivery systems. These PK and PD methods are described and addressed in a subsequent section of this chapter.

Two basic systems have been used that deliver an initial bolus of IR drug (mg), followed by delayed release from a reservoir of drug at a specified dosing rate (mg/hour). The first application was an osmotic release oral system (OROS) for the delivery of MPH (Concerta®). This system uses an “overcoat” of IR MPH as an initial bolus, with controlled release from a three-part reservoir consisting of a semipermeable membrane to control the entry of water, a polymer that expands to create an osmotic pump, and methylphenidate layered to be delivered over an 8-hour period of time as the system traverses the gastrointestinal tract (Swanson et al., 2003). The subsequent applications for CR formulations were based on dual-beaded systems, which provide an IR bolus by uncoated beads of the drug followed by delayed release from beads with polymer coats that dissolve in the gastrointestinal tract to allow the drug to escape. This dual-beaded technology was used for MPH (Metadate CD®, Ritalin LA® and Focalin LA®) and AMP (Adderall XR®).

After the introduction of Concerta®, within a year most prescriptions in the USA for MPH were for the CR formulation instead of the multiple daily doses of IR MPH that had been accepted and used in clinical practice for decades. After the
CHAPTER 16

introduction of Adderall XR®, within a year most prescriptions in the USA for AMP were for the CR formulation instead of multiple daily doses of the IR formulation. This rapid acceptance of second-generation CR formulations of the stimulants stands in stark contrast to the lack of clinical acceptance of the first-generation of CR formulations (Ritalin SR® and Dexedrine Spansules®), which were considered to have reduced efficacy compared to multiple daily doses of IR formulations. The achievement of sustained efficacy by the second-generation CR formulations has been attributed to the rational dosing regimen that was chosen based on PK/PD studies and analyses, which are described in a subsequent section.

Non-stimulant Medications for ADHD

In 2000, pharmaceutical companies initiated drug development programs for non-stimulant alternatives. This was prompted in part by concerns about the stimulants, such as abuse potential, lack of efficacy in a percentage of children with ADHD and side-effect profile. The first development program was for atomoxetine (ATX), which Lilly Pharmaceuticals successfully developed as a treatment for ADHD (Allen & Michelson, 2002) and received FDA approval for this indication in late 2002. Buitelaar, Danckaerts, Gillberg et al. (2004) described the use in non-North American clinical populations of children. Animal studies suggested that ATX did not affect the neurotransmitter DA in the basal ganglia and its effects were primarily on the neurotransmitter NE and perhaps on DA in the frontal cortex (Bymaster, Katner, Nelson et al., 2002; Swanson, Perry, Koch-Krueger et al., 2006a).

The PK properties of ATX and the stimulants are similar in children (see below), but the dosing regimen is different than for IR stimulants. Some clinical trials of ATX (Buitelaar et al., 2004; Michelson, Faries, Wernicke et al., 2001; Michelson, Adler, Spencer et al., 2003) used twice daily dosing (0.5–1.8 mg/kg/day up to 120 mg) administered in the early morning and late afternoon, but others used once daily dosing in the morning (Kelsey, Sumner, Casat et al., 2004; Michelson et al., 2003). These trials documented effectiveness compared to placebo based on ratings of ADHD symptoms by parents, but they did not report information from teacher ratings. Clinical impressions suggested that the magnitude of effect in typical cases with ADHD was less than for stimulants (Steinhoff, 2004). Recently, the effectiveness of ATX has been demonstrated for the treatment of children with ADHD and comorbid conditions, including anxiety (Kratochvil, Newcorn, Arnold et al., 2005), tics (Allen, Kurlan, Gilbert et al., 2003) and pervasive developmental disorder (PDD) (Troost, Steenhuis, Tuynman-Qua et al., 2006). A review of the side-effect profile suggested that insomnia was similar to the stimulants, anorexia less than the stimulants and vomiting more common (Gibson, Bettinger, Patel et al., 2006). Because ATX was classified as an antidepressant, it received the same black box warning about possible suicidalty as did the antidepressant drugs (US Food & Drug Administration, 2005). The UK Committee on Safety of Medicines recommends warning families of suicide risk so that they can be vigilant.

The PK properties of ATX have been well described in children (Witcher, Long, Smith et al., 2003) and adults (Sauer, Ring, & Witcher, 2005). A standard dose of 1 mg/kg produces a maximum plasma concentration of about 300 μg/L about 2 hours after dosing with a t1/2 of about 3 hours. Polymorphism in a gene for a cytochrome enzyme (CYP-2D6) affects metabolism of the drug. One variant produces fast metabolism and a short t1/2 (3–4 hours), and the other produces slow metabolism and a long t1/2 (24 hours) (Witcher, Long, Smith et al., 2003). Surprisingly, this PK difference did not translate into differences in titrated daily dose, efficacy or side-effect profiles (Allen & Michelson, 2002; Michelson et al., 2001) so prescription based on genotype was not considered necessary. In spite of the short t1/2, Sauer, Ring, & Witcher (2005) suggested a rationale for once daily dosing: studies on rats showed that some PD effects (inhibition of the NE transporter) may persist much longer than the short PK t1/2 of 2 hours.

However, some recent PD studies suggest waxing and waning of effect across the day. For example, a recent PD study of children with ADHD revealed a correlation of PK and PD effects, with rapid onset and offset on surrogate measures of efficacy in a laboratory school setting (Wigal et al., 2005). This study investigated the PD effects of a single daily dose of ATX (titrated up to a maximum of 1.2 mg/kg) in children with ADHD. This study showed clear acute effects of ATX that lagged but paralleled the PK profile of rising and falling blood levels, with a significant and near-maximum effect 2 hours after dosing which dissipated by 7 hours after dosing. Furthermore, slow metabolizers develop plasma concentrations about five times higher than fast metabolizers and manifest both greater efficacy and greater side-effects (increases in heart rate, blood pressure, tremor and decrease in appetite). These clinical differences can be attributed to differences in plasma ATX exposure (see Michelson, Read, Ruff et al., 2007).

In 2000, another pharmaceutical company (Cephalon) initiated a program to develop modafinil (MFL) for the treatment of ADHD. MFL is a novel medication which was developed for the treatment of narcolepsy (which was once treated with stimulant medications). A maximum plasma concentration is achieved about 3 hours after dosing and the t1/2 is about 4 hours, with a PD profile that suggests rapid onset and offset. However, in a study of once daily (300 mg) versus twice daily (100/200 or 200/100 mg) dosing to evaluate acute tolerance, administration of the full dose in the morning produced a larger overall effect than either divided dose (Biederman, Swanson, Wigal et al., 2006). This offered no evidence of acute tolerance as with the stimulants, and also suggested once daily dosing.

These early studies suggested a higher dose of MFL would be required for the treatment of ADHD in children (200–400 mg) than for the treatment of narcolepsy in adults (100–200 mg), and that once daily dosing was superior to dividing the dose. Based on this, MFL was reformulated in a concentrated form (Sparlon®) to make smaller tablets for the higher doses estimated to be required for clinical treatment of children. Three clinical trials provided evidence of efficacy (Biederman,
Swanson, Wigal et al., 2005; Greenhill, Biederman, Boellner et al., 2006; Swanson, Greenhill, Lopez et al., 2006b). The FDA review process accepted efficacy, but expressed concern about possible rare, serious dermatological side-effects, including suspected cases of Stevens–Johnson syndrome and a variety of skin rashes. The FDA requested further studies of this possibility, but the company elected instead to withdraw the application and to cancel the development of MFL for the treatment of ADHD (Cephalon, 2006).

Antidepressant and Antianxiety Medications

The use of antidepressants to treat children with psychiatric disorders is increasing (see chapter 37 for their clinical use in depression). Zito and Safer (2005) estimated that the recent treatment rate was three times higher in the USA (1.63%) than in Europe (less than 0.55%), and documented significant cross-national differences in the clinical practices, which resulted in different preferences for one class of antidepressant over the other (e.g., SSRIs are favored in the USA while tricyclics are favored in Germany).

The increase in use of SSRIs preceded studies of the efficacy of these drugs in children. Lack of efficacy of tricyclic antidepressants (Hazzell, O’Connell, Heathcote et al., 1995) and concern about rare but serious cardiac side-effects (Riddle, Geller, & Ryan, 1993) led to widespread clinical use of SSRIs (e.g., fluoxetine, paroxetine, sertraline) in the treatment of depression in children.

The use of SSRIs to treat depression in children was based on documented efficacy in adults, and became a common clinical practice even though these drugs were not fully evaluated and approved for use in children (Hughes, Emslie, Crismon et al., 1999). Research followed clinical practice, and some trials did not find effectiveness. Reviews of the published studies of SSRIs for the treatment of childhood depression are provided by Cheung, Emslie, & Mayes (2006) and Wagner (2005), and reviews of unpublished \( n = 10 \) as well as published \( n = 6 \) studies are provided by the US Food and Drug Administration (2003a) and the UK Medicines and Healthcare Products Regulatory Agency (2003). Only one drug, fluoxetine (Prozac®), was shown to be superior to placebo in more than one randomized clinical trial (RCT) (Cheung, Emslie, & Mayes, 2006). Emslie, Rush, Weinberg et al. (1997) conducted a single-site RCT that showed a significant difference in response in the drug than the placebo condition (56% vs. 33%), and this response rate was replicated (52% vs. 37%) in a multisite study (Emslie, Heiligenstein, Wagner et al., 2002). The US FDA considered these two trials and approved this SSRI (fluoxetine) for the treatment of childhood depression in 2003 (US Food and Drug Administration, 2003a). A multimodal RCT against placebo (March, Silva, Petrycki et al., 2004) found a similar response rate (61% vs. 35%). Clinical recommendations are provided in chapter 37.

The review of other SSRIs is complicated by high rates of response to placebo (30–60% in various trials), different outcome measures across trials, small number of trials and a variety of other factors, including choice of dose and dosing regimen (Findling, Nucci, Pergies et al., 2006). No other SSRI has reached the criterion of two positive RCTs that the FDA requires for approval, although one combined analysis of two studies provided evidence of efficacy for sertraline (Wagner, Ambrosini, Rynn et al., 2003) as did one study of citalopram (Wagner, Robb, Findling et al., 2004). RCTs of the other SSRIs were negative (Wagner, 2005). RCTs in adults, however, suggest that the SSRIs are equally efficacious. Cheung, Emslie, & Mayes (2006) suggested that it is unlikely that the various SSRIs differ in efficacy in children; rather, methodological differences across the studies may be responsible for the lack of significant effects in some studies.

Concern about side-effects of SSRIs related to suicidal ideation has generated considerable controversy, with multiple committees and reports from the US Food and Drug Administration (2004a,b) and the UK Medicines and Health Products Regulatory Agency (2003). Analyses of combined cases from multiple studies suggested that the relative risk is significantly greater than 1.0 in RCTs; this rare adverse event was more commonly reported in the drug (4%) than the placebo (2%) condition. Analysis of suicide rates during times of increasing use of the SSRI (Gibbons, Hur, Blaumik et al., 2005), the absence of SSRI in the serum of many suicide victims (Leon, Marzuk, Tardiff et al., 2004) and the absence of any suicides in the RCTs (Klein, 2006) have led some to discount the significance of this finding. However, a “black box” warning has been recommended for the package labeling of all SSRIs in the USA, and the UK Committee on Safety of Medicines recommends that SSRIs other than fluoxetine are not routinely indicated (Medicines and Health Products Regulatory Agency, 2003).

The SSRIs are the first-line pharmacological treatments for anxiety disorders in adults (Baldwin, Anderson, Nutt et al., 2005), but there are few studies in children and approval by regulatory agencies has not been obtained. Nevertheless, evidence of efficacy of the SSRIs for treatment of anxiety disorders in children has been addressed by the National Institute of Mental Health (NIMH) supported Research Unit for Pediatric Psychopharmacology (RUPP) network. The first RUPP study (Walkup, Labellarte, Riddle et al., 2002) of 128 children with diagnoses of anxiety documented efficacy of 8 weeks’ treatment with the SSRI fluvoxamine, with 76% of the group randomly assigned to medication \( n = 63 \) showing benefit versus 29% of the group randomly assigned to placebo \( n = 65 \). Another RUPP study addressed the treatment of anxiety when it occurs in com-bination with ADHD: it found that adding fluvoxamine for the treatment of anxiety symptoms, after stabilization of treatment of ADHD with MPH, was no different than adding placebo (Abikoff et al., 2005). A trial of another SSRI, sertraline, is now being conducted by the Child and Adolescent Anxiety Multimodal Study of the RUPP network.

Antipsychotic Medications

Antipsychotic medications are used to treat childhood onset schizophrenia, a rare but severe condition (Spencer &
CHAPTER 16

Campbell, 1994; see chapter 45). The effect size (ES), the
difference in standard deviation units, from drug-placebo
comparisons indicates that the effects of typical or first-generation
antipsychotic medications (e.g., haloperidol) are large (ES > 1.0),
the difference in standard deviation units. The effects are
on both positive and negative symptoms, because of potent
blockade of DA D2 receptors (Seeman & Tallerico, 1999).

However, side-effects are present (weight gain and tardive
dyskinesia) that limit their long-term use and may be of par-
ticular concern in children and adolescents during periods of
rapid physical growth (see chapter 45).

The development of second-generation or atypical anti-
psychotic medications (e.g., clozapine) with different relative
effects on classes of dopamine receptors (e.g., D1 vs. D2)
improved efficacy and reduced the incidence and severity of
some side-effects (e.g., tardive dyskinesia). In adults, the
primary atypical antipsychotic medication, clozapine, is con-
sidered to have greater efficacy and reduced risk for tardive
dyskinesia than the primary typical antipsychotic medica-
tion, haloperidol. Atypicals, however, show metabolic side-
effects related to obesity and diabetes, and rare hematological
hazards are present. These adverse effects are particularly strong
for clozapine, so treatment guidelines (Lewis, Davies, Jones
et al., 2006) suggest clozapine is used only after other atypical
antipsychotic medications have been tried and failed. In chil-
dren, there are few data for any of the atypicals (Findling
et al., 2006; Glick, Murray, Vasudevan et al., 2001).

Recently, a small RCT of clozapine and olanzapine was con-
ducted on children with schizophrenia who had failed trials
on typical antipsychotic medication (Shaw, Sporn, Gogtay et al.,
2006). Over a 7-year period, 25 subjects were identified
and entered into a rigorous protocol designed to compare the
differential efficacy and side-effects of these two atypical
antipsychotic medications when titrated to a clinically effect-
dive dose (maximum = 900 mg for clozapine and 20 mg for
olanzapine). This study demonstrated greater efficacy (ES dif-
ference approximately 0.5) for clozapine (average dose = 327
mg) than olanzapine (average dose = 18.1 mg), not only on neg-
ative symptoms (as expected) but also on positive symptoms
of the disorder. Some adverse events were greater on clozap-
ine than olanzapine in these doses (enuresis, tachycardia and
hypertension), but the increase in prolactin was less.

Antipsychotic medications are also used for adolescents
to treat prodromal symptoms of schizophrenia, and trials
suggest that they may delay the conversion to frank schizoph-
renia (see chapter 45).

Antipsychotics are also used for other purposes. A summary
of the recent studies on the use of antipsychotics in children
and adolescents with bipolar, mood and behavioral disorders
is provided by Scahill, Koenig, Carroll et al. (2007).

The use of antipsychotic medications to treat aggressive
behavior in childhood is common but evidence of efficacy and
safety in children is sparse (Schur, Sikich, Findling et al., 2003).
However, treatment guidelines have been developed (Pappado-
pulos, Macintyre, Crismon et al., 2003) to guide use based on
clinical experience as well as evidence from controlled trials.

The antipsychotic medication risperidone (RIS) has been used
to treat autism. The first RCT was from the RUPP network
(McDougle, Scahill, McCracken et al., 2000), which evaluated
101 children, with 52 assigned to placebo and 49 assigned
to RIS using ratings on the Aberrant Behavior Checklist.
Treatment with RIS improved scores on some subscales (irri-
tability, hyperactivity and stereotypy) but not on others
related to the core features of autism (social withdrawal and
inappropriate speech). A subsequent publication (McDougle,
Scahill, Aman et al., 2005) used a secondary measure designed
to evaluate symptoms of autism (social relatedness and lan-
guage); it revealed no difference between treatment with RIS
and placebo on these subscales, despite differences on other
scales (sensory motor, affectual reaction and sensory response).

A separate industry-sponsored study by Shea, Turgay, Carroll
et al. (2004) evaluated 79 children, with 39 assigned to placebo
and 40 to RIS: it showed a similar degree of improvement on
ratings of irritability and hyperactivity. Recently, an open
study of ATX for the treatment of children with PDD and
autistic features (Troost, Steenhuis, Tuynman-Qua et al.,
2006) was conducted with a small group of patients (n = 12).
This suggested a pattern of effectiveness of a standard dose
of ATX (about 1 mg/kg) as with antipsychotic medications
(i.e., a reduction of ADHD-like symptoms but not core com-
ponents of autism). These studies suggest that autism does
not yet have a simple biochemical target to define the ration-
ale for pharmacological intervention as for other childhood
disorders.

In the studies of atypical antipsychotic medications (i.e., RIS)
for the treatment of autism, the most worrisome side-effect
was weight gain. In the RUPP study, the weight gain over 8
weeks was 2.7 kg in the RIS condition and 0.8 kg in the placebo
condition. In the study by Shaw et al. (2006), over 8 weeks
of treatment the weight gain in the RIS condition was 2.7 kg
and 1.0 kg in the placebo condition. Correll, Penzner, Parikh
et al. (2006) provided a summary of the adverse effects of
various atypical antipsychotics, and concluded that (because
of little information from head-to-head trials) no differences
across medications had been established. Also, in the study of
ATX for the treatment of PDD with autistic features, adverse
effects were present in a high proportion (42%) of this small
group (e.g., gastrointestinal symptoms, irritability, sleep prob-
lems and fatigue) which limited treatment.

Basic Principles of Clinical
Pharmacology

Blood levels are not typically measured in clinical practice
to determine if the dose of medication places an individual
within a “therapeutic range” defined by plasma levels. Titration
effect is used to establish the dose of a drug, and usually
the concentration of the drug is merely proportional to the
doze and therefore does not add much to the titration pro-
cess. Therefore, the use of blood levels in clinical practice is
not recommended or needed to select the optimal doses for
individual patients. However, the population estimates of PK and PD properties of common medications could be used for rational recommendations about dosing level and dosing frequency, and to guide the development of new formulations, as demonstrated by Swanson, Gupta, Guinta et al. (1999a) and Swanson et al. (2003) for the stimulants. Such evidence-based dosing strategies are apparently not used often, even in otherwise sophisticated randomized, placebo-controlled efficacy trials (for examples for childhood depression see Findling et al., 2006).

Here we emphasize how PK analysis is important in drug development (Fleishaker & Ferry, 1995). PK parameters differ across some subgroups based on age, gender and other factors (Davis, Chen, & Glick, 2003). This provides the rationale for the requirements and guidelines from some regulatory agencies (e.g., US Food and Drug Administration) to obtain PK information in the age group for intended treatment. However, in the reactive research related to current incentives to perform studies in children, PK information has been obtained late in the stages of drug development and has not been used in the design of the clinical trials (DeVeaugh-Geiss et al., 2006). Also, PK analysis has been valuable in characterizing genetic differences in the P450 enzymes that have an important role in the metabolism of many drugs and in characterizing drug interactions (Greenblatt, von Moltke, Harmatz et al., 1998).

Some influential clinical pharmacologists have recommended a concentration-controlled paradigm (Peck, 1993) for clinical trials, in which dose is titrated so that all individuals have the same plasma concentration and the variation in effect is evaluated. Others have recommended the effect-controlled paradigm (Levy, Ebling, & Forrest, 1994), in which dose is titrated so that all individuals have the same effect and variation in plasma concentration is evaluated. Levy (1994) points out that individual differences in effect (the PD properties of a drug, shown on the right of Fig. 16.1) are greater than individual differences in concentrations of the drug in plasma (the PK properties of the drug, shown on the left of Fig. 16.1). In the effect-controlled trial, doses of medication are gradually increased to achieve predetermined intensities of effects, which is similar to the way clinicians titrate dose in clinical practice. For effect-controlled studies, blood samples are obtained from individuals taking different doses of medication, either using sparse sampling of a single blood sample across many individuals to characterize the PK properties in the population (Shader, Harmatz, Oesterheld et al., 1999), or using dense sampling to characterize the PK properties at the effective dose (Swanson et al., 2003; Wigal et al., 2006).

**Basic Pharmacokinetics**

In clinical practice, empirical dosing regimens have been established by experience. When taken orally (the usual route of administration) in an IR formulation, the recommendation for clinical treatment for most of the drugs listed in Table 16.1 is for administration of the total daily dose in divided portions given two or three times daily (Wilens, 2004). However, long-standing clinical practices may be non-ideal (Findling et al., 2006; Swanson, Agler, Fineberg et al., 1999b). For example, in the development of the MTA protocol, an empirical dosing regimen was established in which IR MPH was administered at 7:30 AM, 11:30 AM and 3:30 PM, but the third dose in the three times daily regimen was reduced relative to the first dose, was established (Greenhill, Abikoff, Arnold et al., 1996; Greenhill et al., 2001). This was based on the assumption that once established for an individual, the optimal dose (or plasma concentration) would remain constant, and with multiple doses (i.e., three times daily, with a 4-hour interdose interval), the carry over from early doses would require lower doses to maintain the constant optimal level of the drug across the day.

Later, when acute tolerance to MPH was discovered, the opposite appeared to be true – the later doses should be the same or larger than the initial dose of the day to achieve an ascending drug (D) and plasma concentration (C). This pattern was incorporated into the controlled-release formulations of MPH (Concerta®; Swanson et al., 2003) and AMP (Adderall XR®; Greenhill et al., 2003). Similar evaluations with basic PK/PD methods have not been applied to optimize the delivery of antidepressant medications. Even in controlled clinical trials based on IR formulations, empirical rather than rational dosing regimens have been used, and these may not be optimal (Findling et al., 2006).

The basic PK and PD principles outlined in Fig. 16.1 can be used to understand and evaluate the twice daily (b.i.d.) or three times daily (t.i.d.) dosing regimes. The starting place for PK analyses is the concentration–time graph (Fig. 16.1), which shows four important PK parameters: C max, T max, t 1/2, and area under the curve (AUC). The maximum concentration achieved by an oral dose (C max, in ng/mL) and the time when it occurs (T max, in hours) depend on absorption from the gastrointestinal tract into the blood stream. The time required for the drug concentration to fall by 50% is the elimination t 1/2 of the drug and can be estimated by taking the difference between T max and the time when the concentration is 50% of C max.

The calculation of the AUC is somewhat more complicated, but can be based on a simple principle, the trapezoid rule. Trapezoids are formed based on the points available, the area under each trapezoid is calculated and the AUC is the sum of these areas. AUC is expressed in units derived from the product of concentration (ng/L) and time (hours) or ((ng × hours)/L).

Volume (V) of distribution and clearance (CL) are two of the most important PK concepts for establishing the frequency of dosing (the dosing rate). V can be estimated (Hardman, Limbird, Molinoff et al., 1996) by estimating the zero intercept of the concentration–time curve (C 0), and dividing it into the dose of medication (D:C 0), which yields units of volume [mg/(ng/mL) = liters]. CL is derived using the formula CL = D/AUC, so it is stated in units of volume and time (e.g., L/hour).
CHAPTER 16

Dosing rate (DR) is another PK parameter with considerable potential for understanding drug delivery systems that are used in the new formulations to maintain a target concentration. For a given target concentration (\(C_t\)), the dosing rate is merely CL times the target concentration, \(DR = CL \times C_t\). Because the units for CL are volume and time (ng/min or L/hour) and for \(C_t\) are amount and volume (ng/mL or mg/L), the DR is stated in units of amount and time (mg/hour). DR is crucial for optimizing drug delivery in CR formulations of medications, as well as for determining the size and frequency of doses in regimens with multiple administrations per day. For example, when the volume of distribution of the drug in the body varies across subgroups (e.g., children, adolescents and adults), but the \(C_{\text{max}}\) for titrated clinical effect is assumed to be the same, then DR should vary across age directly in proportion to CL. This concept may help the practitioner understand some actions and statements of regulatory agencies.

The age-related values of volume of distribution and clearance of MPH provide an instructive example. In the review of the application to approve Concerta® for use in adolescents, there was evidence for higher clearance in adolescents (384 L/hour) than in school-aged children (243 L/hour), but less than expected for adults (497 L/hour), which may be related to differences in body weight and volume in these groups. This led to a change in the prescribing information (see www.Concerta.net), which now contains a note that these PK factors suggest why older (and larger) adolescents may have lower exposure to MPH than younger (and smaller) school-aged children taking the same doses of the drug.

At the other end of the age spectrum, Wigal, Greenhill, Chuang et al. (2006) showed that CL was lower in preschool children (99 L/hour) than in school-aged children (232 L/hour), suggesting that less frequent dosing may be appropriate in preschool children than in school-aged children. Taken together, these studies suggest that on the average CL is directly proportional to age, ranging from about 500 L/hour in adults to about 100 L/hour in preschool children. Consideration of these population values of this basic PK property may help clinicians make rational choices about dosing frequency of MPH as a function of age, as suggested by the FDA review and by Wigal, McGough, McCracken et al. (2005).

Using these basic terms and formulas from clinical pharmacology, population PK information for a medication may be used to suggest a rational dosing regimen without the need to obtain blood samples or drug levels for each individual. Consider IR MPH. In clinical practice, the optimum regimen is established empirically by titration. Because PK and PD effects are closely linked, the first dose in the morning will be expected to produce its maximum effect soon after \(T_{\text{max}}\), or about when \(C_{\text{max}}\) is achieved, so the concentration of the dose that produces the best effect about 2 hours after the initial dose would be considered optimal (\(C_{\text{opt}}\), with some practical range (i.e., an upper and a lower limit). The effect would be expected to dissipate as the concentration of the drug falls and thus be proportional to \(t_{\text{1/2}}\). For short-acting medications that do not reach steady-state levels, basic PK principles suggest that a rational choice for multiple doses would be to administer the first dose to achieve the upper limit of \(C_{\text{opt}}\) and that the next dose be administered at a time after the first dose such that the declining concentration does not fall below the lower limit of \(C_{\text{opt}}\). If neural adaptations occur, then the values for \(C_{\text{opt}}\) and its upper and lower limits may change over time (e.g., the limits may increase across the day in the face of acute tolerance; Swanson et al., 2003).

The basic PK principles suggest that, when the optimal initial dose has been established by titration, the subsequent DR should be set to maintain plasma concentration within the upper and lower limits of \(C_{\text{opt}}\), and that this would depend on CL. DR, given by the formula \(DR = CL \times C_{\text{opt}}\), specifies the amount of medication per unit of time (e.g., mg/hour). For example, ADHD children who are responders to stimulants vary in terms of the titrated dose of MPH for optimal response, and the literature suggests that \(C_{\text{opt}}\) values would vary too. For a typical 10-year-old child, the expected values for the initial morning dose would be about 10 ng/mL for a low (e.g., 10-mg) dose, 15 ng/mL for a medium (e.g., 15-mg) dose and 20 ng/mL for a high (e.g., 20-mg) dose. Because CL varies with age, different DRs as a function of age would be required to maintain this level over the day (i.e., from DR \(-100 \text{ L/hour} \times 10 \text{ ng/mL} = -1 \text{ mg/hour for preschool children up to DR \(-500 \text{ L/hour} \times 10 \text{ ng/mL} = -5 \text{ mg/hour for adults}}\).

An understanding of these basic PK principles may help the practitioner conceptualize and explain how a flat (zero-order) or ascending (first-order) concentration profile over time is achieved, as described by Swanson et al. (2003). It is instructive to note that blood sampling and measurement of plasma concentrations in each patient are not necessary to apply these basic principles. For example, Swanson, Gupta, Guinta et al. (1999) did not obtain blood samples or use plasma concentrations in the study that proposed acute tolerance to clinical doses of methylphenidate, but instead used published PK values for use along with PD measures from a laboratory classroom setting.

From the concentration–time graph, \(C_{\text{opt}}\) and AUC can be estimated. AUC can be used to define CL for the dose administered (D/AUC). The product of \(C_{\text{opt}}\) and CL specifies DR. The desired length of duration (e.g., 10 hours) times DR gives the total daily dose (DD). Under the constraints of DR, duration and DD, a rational choice of frequency and size of multiple doses can be made on the basis of convenience and efficacy: larger doses can be given less often or smaller doses given more often for a given value of DD. The choice of size and frequency will set the upper and lower peaks and valleys in plasma concentrations between doses in the regimen.

However, it should be noted that plasma concentrations of a drug have a logical limitation, because it is the concentra-
tion at the site of action (i.e., in the brain) not in the blood that is the target of a rational dosing regimen. Basic PK principles also include methods for estimating brain levels of a drug by mathematical modeling. Compartmental PK models are used to estimate the effect site concentration (C<sub>e</sub>). The methods for this are provided in standard books on clinical pharmacology (Gabrielsson & Weiner, 1997), and have been applied to characterize medications used in child psychiatry (Modi, Wang, Hu et al., 2000; Swanson, Gupta, Guinta et al., 1999a).

The example provided by Swanson et al. (1999a) shows how PK modeling can be used to estimate the succession of processes of the body that operate after a drug is taken – in other words, what “the body does to the drug.” Based on published PK properties of MPH (Chan, Swanson, Soldin et al., 1983), factors related to the drug’s absorption from the gastrointestinal tract into the blood stream, distribution from the blood to the brain, and elimination were incorporated into a complex equation (in which D = dose, V = volume of distribution, t<sub>i</sub> = time since i<sup>th</sup> dose and t<sub>0</sub> = time since first dose) to estimate a value at a point in time:

\[
C_{e(i)} = \sum_{i=1}^{n} \left( \frac{D_k k_{e(i)} e^{-k_{e(i)} t}}{V_k (k_e - k_i) (k_{in} - k_i)} \right)
\]

Of course, these calculations would not be made in clinical practice, but they were important for the development of new CR formulations of MPH.

For MPH (as with most drugs), a time delay exists between the plasma concentration and the effect site concentration. When a lag occurs between the concentration in the blood and in the brain, and perhaps also between the concentration in the brain and the effect (as shown in Figure 16.1), then the time courses of the concentration–time curve and the effect–time curve are offset. This complicates the definition of the relationship between effect (as shown in Figure 16.1), and concentration. For example, if the effect continues to increase after the peak concentration is achieved, then a model to account for this lag between PK (plasma) and PD (brain) concentrations is necessary.

The estimated effect site concentration may not be sufficient for optimizing drug delivery, because neural adaptations are likely to occur which also must be considered. In PK/PD analyses, a “link” model provided estimates of the concentrations at the site of action (rather than in the plasma or blood) to relate to effect (E). This is described in detail by Swanson et al. (2003) for the example of MPH, in which additional modeling was required to adjust for acute tolerance.

### Basic Pharmacodynamics

The data from measurement of the effect (E) over time can be used to graph the relationship (see right panel of Figure 16.1). This effect–time curve may be similar to the concentration–time curve (see left panel of Figure 16.1). After oral administration of a drug, there is a delay between the plasma concentration and the effect. When effect is plotted versus concentration, the effect–concentration relationship may be distorted by a counterclockwise hysteresis loop. The use of C<sub>e</sub>, with an adjustment for the time lag, may be necessary to reveal the true effect versus concentration relationship.

The basic assumption of PD analysis is that the concentration of a drug at the site of action (C<sub>e</sub>) produces a biochemical effect that starts a cascade of effects (E) (see top of Figure 16.1) that eventually result in the clinical response (i.e., symptom reduction).

The information from the concentration–time and effect–time (see left and right sides at the bottom of Figure 16.1) relationships can be used to describe the concentration–effect relationship. Logically, if the two curves were identical, the concentration–effect curve would be represented by a 45° line on a graph. However, even though they may be similar in shape, a lag in the effect–time (see middle of the bottom of Figure 16.1) curve is often present because of the time taken for the psychotropic drug in the blood to reach the site of action in the brain. In addition to the expected time lag, neural adaptations (sensitization or tolerance) may occur. When these processes are present, characteristic patterns in the concentration–effect curves are manifested as deviations from the 45° line, or hysteresis loops. The hysteresis loops are clockwise if sensitization is present and counterclockwise if tolerance is present. When time lag and neural adaptation effects are present, interpretation is difficult, and consideration of both is likely to be required to understand the relationship between C<sub>e</sub> and E. This was necessary for PK/PD analyses of MPH (Swanson et al., 2003). An example of a counterclockwise hysteresis in the concentration–effect curve that is caused by the lag between C and C<sub>e</sub> is shown in the middle panel at the bottom of Figure 16.1. Expected distortions of the concentration–effect relationships because of a time lag or neural adaptations can be removed by modeling the relationship between C<sub>e</sub> and E.<br />

Instead of using the complicated mathematical modeling methods to estimate the drug concentrations at the effect size (C<sub>e</sub>), it is also possible to measure C<sub>e</sub> directly (Plate 16.1b–d), using radiolabeled drug (e.g., [11C] MPH) and serial PET scans (Volkow, Wang, Fowler et al., 1998). Examples from PET studies of brain PK are shown in three sections of Plate 16.1 for methylphenidate (b), haloperidol (c) and mirtazapine (d). PET methods can also be used to obtain direct measures of PD effects on intermediate response in the brain. Examples from PET studies of brain PD are shown in the four sections of Plate 16.2 for transporters (a), receptors (b), neurotransmitters (c) and circuits (d). In subsequent sections of this chapter, we focus on the modern direct
CHAPTER 16

measurements from PET imaging methods that inform us about how some intermediate responses occur in the brain.

PK/PD models are used to describe the relationship between the drug concentration (C) and effect (E). A simple linear function, E = E0 + b(C), where E0 is the starting measure of effect when the concentration is zero and b is the increase in E usually does not describe the relationship. The more complex and realistic models for describing concentration–effect relationships are non-linear, because increases in dose (D) or concentration (C) rarely produce proportional increases in effect (E) across the entire range. Based on the Law of Mass Action, PD analyses are based on the assumption that at the site of action, a drug will occupy its targets proportional to C, and the effects will be proportional to the percentage of targets occupied.

In evaluations of medications in children (or in adults), it is impractical or unethical to make observations across a wide range of concentrations, because the maximum effects of a drug are often associated with side-effects that should or must be avoided. Over a typical acceptable range of concentrations, the concentration–effect relationship may appear linear, with only minor departures from a straight line at the higher doses. Fortunately, methods to estimate the true underlying non-linear relationship are available, such as the Emax model, which uses the equation

E = E0 + (Emax × C)/(EC50 + C)

to describe the parabolic relationship between effect and concentration. The first part of the parabola, from 0 up toward the maximum, is often approximately linear and describes the relationship over the clinical range of doses and concentrations of a drug and effect. The Emax model has been applied to address important questions such as whether sensitivity to a new drug is greater than to an established standard and how sensitivity changes with increases in dose (for an example for benzodiazepines see Schoemaker, van Gerven, & Cohen, 1998).

Homeostatic mechanisms operate at the cellular (e.g., internalization of transporters and receptors) and neurocircuitry levels (modulation of neuronal firing by more than one process or neurotransmitter). These adaptive mechanisms may operate in the short term during the exposure to a single dose of short-acting medication, as well as in the long term to repeated or chronic exposure to medication. Some of these adaptations may occur rapidly, and the theory of acute tolerance offered by Swanson, Gupta, Guinta et al. (1999a) is an example. This neural adaptation was proposed as the underlying reason why increasingly higher concentration of stimulant medications would be required to achieve similar effects throughout the day. In other instances, adaptations occur over time. This is the mechanism thought to underlie the therapeutic effects of antipsychotics and antidepressants and does not occur until after 2–3 weeks of administration. Recently, by using serial PET imaging methods, a direct alternative for estimating brain concentrations of drugs has been applied for stimulants (Volkow, Ding, Fowler et al., 1995), neuroleptics (Schlyer, Volkow, Fowler et al., 1992) and antidepressants (Marthi, Jakobsen, Bender et al., 2004). In the next section, these methods and these examples are discussed.

Imaging Studies on the Distribution of Drugs in the Human Brain

PET is used to measure the regional concentrations of positron-labeled radiotracers with short half-lives in the human brain. For example, using a positron emitter for carbon or fluorine, chemists can label psychoactive medications (11C-methylphenidate or 18F-haloperidol) without affecting their pharmacological properties. Measurement of the regional concentration of the positron-labeled drug (i.e., brain PK properties) can then be obtained non-invasively in the human brain (Plate 16.1b–d). This permits evaluation of the drug’s absolute uptake and rate of entry into the brain. Relationships based on these direct measures can be compared with relationships based on values estimated by complex mathematical equations. These estimated values represent the concentration at the site of action in the brain (C; see Plate 16.1b–d) and the effect at the brain site of action (E; see Plate 16.2a–d).

The strategy of labeling psychotropic drugs and using PET for brain PK to measure the equivalent of C has been applied for some therapeutic drugs as well as for some drugs of abuse (e.g., cocaine, methamphetamine). Here we exemplify this PET method for brain PK analysis (Plate 16.1b–d) for each of the main classes of psychoactive medications used for the treatment of childhood psychiatric disorders (e.g., stimulants, neuroleptics and antidepressants).

Stimulant Medications

The value of the brain PK approach is illustrated for MPH (see Plate 16.1b). The pharmacokinetics and bioavailability of MPH in the human brain were investigated using PET and 11C-labeled methylphenidate ([11C] MPH) by Volkow, Ding, Fowler et al. (1995). When administered intravenously, the uptake of [11C] MPH in the human brain is high (7.5% ± 1.5% of the injected dose) and fast; peak concentration in the brain (C) is reached within 10 minutes of its administration. The PK properties of orally administered MPH in brain are significantly slower than after intravenous administration, and peak concentration in brain is not reached until 60–90 minutes after its administration. The elimination of MPH, estimated after oral intravenous administration, showed a time to half-peak concentration that ranged from 50 to 90 minutes. The elimination of orally administered MPH could not be measured because of the short (t1/2 of 11C) (20 minutes).

The striatum is the brain area with the highest accumulation of MPH, where it binds to dopamine transporters (DAT). Plate 16.1b (top panel) shows the distribution of [11C] MPH in the brain at different times of its administration along with the concentration–time (C–time) curves for its absorption, distribution and elimination. These studies were particularly
useful for comparing MPH with cocaine, which has a similar potency in blocking DAT. Cocaine is believed to exert its reinforcing effects through DAT blockade (Volkow, Wang, Fowler et al., 1998), and because MPH shares this effect at the site of action in the brain, there were important questions: why MPH was not as reinforcing as cocaine and why it was so infrequently associated with abuse and addiction. Specifically, these PET studies revealed that while their potencies in blocking DAT (Cmax) and their rates of uptake into the brain (Tmax) were similar, their rates of elimination (t1/2) were not. By comparing the temporal course of the reinforcing effects of intravenous cocaine and of intravenous MPH with their rate of uptake and elimination from brain, this PET method revealed that it was the fast uptake of the stimulant drugs in the striatum that was associated with their reinforcing effects rather than the absolute concentration (Ce).

The much slower brain elimination of MPH than of cocaine is therefore likely to interfere with its frequent and repeated administration because it would rapidly lead to DAT saturation (Plate 16.1b, bottom panel). In contrast, the fast elimination of cocaine from brain allows repeated administration without saturation of DAT and this property is likely to contribute to its higher rate of abuse than MPH. MPH when used therapeutically is given orally, which leads to very slow uptake in brain, so this too dampens its reinforcing effects. The contrast between MPH when used for use versus abuse, including a discussion of acute tolerance that occurs in both use and abuse, has been addressed elsewhere in detail (Spencer, Biederman, Ciccone et al., 2006a; Volkow & Swanson, 2003).

**Neuroleptics**

The value of the brain PK approach is illustrated for haloperidol (Plate 16.1c). The PK and bioavailability of this “typical” neuroleptic medication in the human brain were investigated using PET and 18F-labeled haloperidol (Schlyer et al., 1992). Because the haloperidol molecule contains a fluorine atom, one can use the positron emitter 18F to label it. The advantage of such an approach in this case is that 18F has a longer t1/2 than 11C (120 versus 20 minutes), which is particularly useful for drugs that clear from the brain slowly (t1/2 > 90 minutes). The study showed a high brain uptake of [18F] haloperidol (6.6% of the injected dose), which peaked at 2 hours with minimal elimination at 10 hours, which was the time at which the last PET measurement was made.

The distribution and site of action concentration (Ce) of the drug in brain were much more extensive than would be expected by the distribution of DA D2 receptors as revealed for example by the D2 receptor radioligand [18F] N-methylspiroperidol (Plate 16.1c). The cerebellum, striatum and thalamus showed a greater concentration than the cortex. This is likely to reflect not only the fact that haloperidol distributes into specific as well as non-specific binding sites, but also that it binds not only to DA D2 receptors but also to other receptor types (e.g., acetylcholine receptors, sigma receptors, 5-HT2 receptors). The diversity among neurolep-tics in affecting receptors other than the DA D2 (i.e., Dα, 5-HT, D1, D3) is likely to underlie why some patients respond to some neuroleptics better than to others and why atypical but not typical neuroleptics appear to be beneficial for the treatment of negative symptoms (Reynolds, 2004).

**Antidepressants**

The value of the brain PK approach is illustrated for mirtazapine (Plate 16.1d), a noradrenergic and specific serotonergic antidepressant that does not block monoamine transporter and instead is believed to act at the receptor level by inhibiting α2-adrenergic auto- and heteroreceptors.

The regional brain concentrations (Ce) were assessed with PET and [11C] N-methylmirtazapine (Marthi et al., 2004). Peak levels of activity in the brain were observed at 10 minutes post-injection and half-peak elimination varied among the brain regions with a range of 30 to 50 minutes. The distribution was highest in hippocampus and amygdala followed by thalamus and with lower levels in cerebellum (Plate 16.1d).

The brain PK of this antidepressant exemplifies the dissociation that exists between the short PK of some medications and their longer lasting clinical effects. These adaptations can be further analyzed with effect-concentration analyses designed to quantify hysteresis (Gupta et al., 1993; Sheiner, Stanski, Vozech et al., 1979).

**Imaging Studies of the Effects of Drugs at their Cellular Targets**

As outlined in Fig. 16.1, the concentration of the drug at the site of action in the brain (C) is assumed to be proportional to its effect at that site of action (E). One effect of the drug on the brain can be measured by the neurotransmitter level. The mechanics of how drugs affect neurotransmitter levels are complex. As a starting place, we present in Plate 16.1(a) a simplified view of three distinct steps:

1. Cell firing releases the neurotransmitter that has specific receptor(s) as targets;
2. A transporter recycles some of the released neurotransmitter, which regulates its temporal and spatial distribution in the extracellular space; and
3. Enzymes operate to either metabolize or synthesize the neurotransmitter, which inactivates or increases its concentration, respectively.

PET (and single photon emission computed tomography; SPECT) have been used to evaluate the potency of psychoactive drugs at their molecular target. This strategy utilizes radioligands that bind to the cellular targets of the medications (i.e., DAT for stimulant medications, D2 receptors for neuroleptics and SERT for SSRI). When a ligand is available, PET studies can be used to measure the effects at these brain sites (Plate 16.1a).

Table 16.2 summarizes the ranges of occupancies at the relevant molecular targets. One class of target is the transporter,
Table 16.2 Ranges of target occupancies for therapeutic doses of stimulant medications, neuroleptics and antidepressants that have been measured with positron emission tomography (PET) in the human brain.

</table>
which is the target for stimulant medications and SSRIs. Another class of target is the receptor, which is the target for neuroleptic medications. In Table 16.2, we summarize the effects at the brain sites of action, shown as the percentage of occupancy measured with PET in the human brain for transporter and receptors.

Two different strategies have been used to determine the effect of the drug at its molecular target. One strategy involves pre-administration of various doses of the drug at pre-fixed times (usually at times when peak plasma concentrations are reached) prior to injection of the radioligand to determine the degree to which the various doses block the radioligand binding. The rate of radioligand blockade by the drug can be calculated after appropriate modeling (to account for metabolism of the radiotracer in blood, its delivery into the brain, its transfer into the tissue and its non-specific binding). The rate of blockage will be a function of the receptor or transporter occupancy by the drug. In the other strategy, the drug is administered after the radioligand has reached equilibrium in the brain and the rate of its displacement is a function of the potency of the drug for its target. This method can provide information on the rate at which the drug binds to its target, which is obtained by measuring the time from injection of the drug to that of radioligand displacement.

**Blockade of Transporters**

**Stimulant Medications**

The value of this approach for PD analysis is illustrated for MPH (see Plate 16.2a). Occupancy of DAT (represented as E in Fig. 16.1) by therapeutic doses of MPH was measured by PET and the DAT radioligand \[^{11}C\] cocaine, which has a high affinity for DAT. Subjects were pretreated with various doses of MPH given 120 minutes prior to the radioligand and compared with the administration of a placebo. The study revealed that at the site of action in the brain, therapeutic doses of oral MPH induced an effect (represented as E in Fig. 16.1) characterized as a dose-dependent blockade of DAT (Volkow, Wang, Fowler et al., 1998). Efficient DAT blockade was observed with 20 mg MPH (50 ± 5%), and was nearly complete with 40 and 60 mg doses (72 ± 3% and 74 ± 2%, respectively). Thus, the ED\[^{50}\] of oral MPH was estimated to be 0.25 mg/kg, and the standard dose of 0.5 mg/kg was shown to block more than 60% of DAT (Volkow, Wang, Fowler et al., 1998). The framework provided by Fig. 16.1 can be used to describe these effects of MPH at the site of action. DAT occupancies (C in Fig. 16.1) were significantly correlated with the plasma concentration of d-threo-MPH (C in Fig. 16.1) at 120 minutes after dosing when DAT measurements were made.

PET imaging was used to estimate the plasma concentration of d-threo-MPH (C in Fig. 16.1) required to block 50% of the DAT (E in Fig. 16.1). The estimate, about 6 ng/mL (Plate 2a), was surprisingly low and was achieved in these adult subjects at doses in the range used clinically to treat ADHD (0.3–0.6 mg/kg). Until this study, MPH had been traditionally considered a weak psychostimulant, and the lower abuse potential (compared to cocaine) was assumed to be related to rapid metabolism of the drug to ritalinic acid, which has a weak affinity for the DAT, and therefore would have minimal pharmacological effects. The surprising results from this study indicated that after therapeutic oral doses of MPH, the drug itself does reach the brain and has about the same affinity for DAT as cocaine (Volkow, Wang, Fowler et al., 1998). The difference in abuse liability has been attributed to differences in the time course of occupancy of DAT, not the level of occupancy.

A recent PET study that used a different DAT radioligand \[^{11}C\] alatropane corroborated that therapeutic doses of MPH block more than 60% of the DAT (Spencer et al., 2006a). In addition, this study compared the brain PK (represented by C in Fig. 16.1) and the reinforcing effects of orally administered IR MPH with the effects of CR MPH (OROS). Spencer et al. (2006a) accomplished this by measuring the levels of DAT blockade for a given dose of IR MPH and of OROS MPH across multiple time points after administration. They showed that doses of IR MPH (40 mg) and of OROS MPH (90 mg) lead to equivalent maximum effects in the brain (which could be represented by E in Fig. 16.1), reflected by the peak levels of DAT blockade (72% for IR MPH and 68% for OROS MPH) but at different time points. The peak DAT blockade was achieved significantly faster for the 40 mg IR MPH (at 1.7 hours) than for 90 mg OROS MPH (at

CHAPTER 16

5 hours). Also, the levels of DAT blockade during the first 2 hours were significantly higher and therefore were achieved faster for IR MPH than for OROS MPH. The peak level of DAT blockade achieved by 40 mg of IR MPH was associated with mild reinforcing effects (assessed with self-reports of drug liking), but the same peak effect for 90 mg OROS MP was not.

These findings corroborate that the reinforcing effects of stimulant drugs are driven by the rate at which DA increases (change in DA concentration per time unit) rather than DA level per se (for a discussion of adaptation and tolerance see Volkow & Swanson, 2003). Based on this, Spencer et al. (2006) speculate that delivery systems that lead to very slow rates of DAT blockade and slow rates of DA increase are likely to have less abuse liability than delivery systems that lead to faster DA changes. This study also compared differences in the duration of DAT blockade between IR and OROS and showed that it was longer for the OROS MPH than for IR MPH, so that at a constant time after dosing (e.g., 7 hours) the level of DAT blockade for OROS MPH (65%) was considerably higher than for IR MPH (40%).

Because the rate of DA change (rate of DAT blockade) is positively associated with the reinforcing effects of MPH, the slower elimination from brain and the longer occupancy of DAT when MPH is delivered by the OROS formulation than by the IR formulation are likely to limit further the rate at which MPH will be self-administered. Also, the rate at which rodents self-administer stimulant drugs has been shown to be associated with the downward slope of DA after its peak in the nucleus accumbens (Ranaldi, Pocock, Zereik et al., 1999). This predicts that stimulant drugs delivered by a system (formulation) that maintains steady state or increasing plasma levels (C) and brain levels (Ce) for longer time periods are less likely to be abused than when delivered by a formulation that leads to more abrupt changes. In fact, the slow onset of CR MPH can even block the effects of other DA agonist drugs, as has recently been shown by Tihonen, Kuoppasalmi, Foer et al. (2007), who documented that 54 mg CR MPH was an effective treatment for the prevention of relapse of intravenous AMP abuse.

**Neuroleptics**

The value of this brain PD approach is illustrated by haloperidol (Plate 16.2b). The study used fluorine-18-N-methylspiroperidol (FNMSP), a dopamine D2 receptor ligand, to assess the effects of pretreatment with different doses of haloperidol. This study showed that, as expected, haloperidol blocked binding of the D2 receptor ligand. The percent inhibition of binding (represented by E in Fig. 16.1) correlated with the plasma concentration (represented by C in Fig. 16.1) of the neuroleptic.

This study demonstrated that relatively low plasma concentrations of the neuroleptic were able to produce more than 80% inhibition of DA D2 receptors, and that much larger plasma concentrations were required to further increase inhibition. It also showed that the quantification of plasma neuroleptic dose correlated with percent inhibition of D2 receptors by the drug, and that the length of interaction of the neuroleptic with DA D2 receptors (i.e., E, the effect at the site of action in Fig. 16.1) was shorter than previously described – significant recovery of D2 receptors was seen as soon as 24 hours after discontinuation of the neuroleptic and returned to almost normal levels 7 days later. This apparent discrepancy between the faster rate for the recovery to baseline levels of D2 receptor availability upon drug discontinuation than the time required for psychotic symptoms to return, suggests that while D2 receptors are the targets for haloperidol, adaptations or downstream effects triggered by the receptor blockade underlie its clinical effectiveness. This would explain why discontinuation of neuroleptic treatment does not result in an immediate relapse, and why clinical effectiveness does not occur until several days after neuroleptic administration even though effective D2 receptor blockade is achieved within days of neuroleptic initiation.

The levels of D2 receptor blockade (represented as E in Fig. 16.1) have been measured with PET for a wide variety of neuroleptics (Table 16.2). Based on this literature the consensus is that in the striatum typical neuroleptics require approximately 80% receptor blockade for clinical effectiveness whereas atypical neuroleptics require approximately 40–60% blockade (Bressan, Erlandsson, Jones et al., 2003). In cortical regions the level of DA D2 receptor blockade achieved with therapeutically effective doses of atypical neuroleptics is significantly higher than in striatum (Bressan et al., 2003; Grunder, Landovg, Vernaleken et al., 2006).

**Antidepressants**

Because radioligands for the norepinephrine transporter (NERT) have only recently been developed, there are no published PET studies yet on the potencies of tricyclic antidepressants at the NERT. However, radioligands have been available for the serotonin transporter (SERT), and thus there is a literature on the effects of SSRIs on SERT (i.e., at the site of action, represented by E in Fig. 16.1). For example, the relative potencies of various SSRIs (citalopram, fluoxetine, sertraline, paroxetine or extended-release venlafaxine) at the SERT were evaluated using PET and the SERT radioligand [11C] DASB (Meyer, Wilson, Sagrati et al., 2004). This study showed a non-linear dose–SERT occupancy relationship that peaked at high doses, which would define the effect–concentration relationship (represented by E versus C in Fig. 16.1). It also showed that all of the SSRIs tested at therapeutic doses occupied greater than 80% of the SERT. The relevance of this study lies in the demonstration that: (i) greater than 80% SERT occupancy is required for therapeutic efficacy of SSRIs; and (ii) that differences in the clinical efficacy between the SSRIs cannot be explained on the basis of their differences in the levels of SERT blockade but are likely to reflect differences in PK and bio-availability as well as their effects on targets other than SERT.
Neurotransmitter Concentration

Receptor radioligands have relatively low affinity, so they compete for binding to the receptor with the endogenous neurotransmitter. Thus, they can be used to measure changes in neurotransmitters induced by drugs. The most widely utilized radioligand for this purpose has been $[^{11}C]$raclopride, which has been used to assess the effects of stimulant drugs (MPH and AMPH) on extracellular concentrations of DA (represented by $E$ in Fig. 16.1). Because $[^{11}C]$raclopride competes for binding to the $D_2$ receptor with endogenous DA, the comparison of its binding after placebo from that after the drug can be used to estimate the relative changes in DA it induces (Volkow, Fowler, Wang et al., 1993; Plate 16.2c). This strategy was used to compare the potency of AMPH with that of MPH in increasing DA in the non-human primate brain (Schiffer, Volkow, Fowler et al., 2006). It revealed potency for these two drugs that parallel their relative therapeutic potencies; that is, double the dose of MPH was required to achieve the DA increases induced by AMPH.

A study in healthy adult controls to assess the relationship between the levels of DAT blockade achieved after 60 mg oral MPH and the concomitant increases in striatal DA induced by this dose (Volkow, Wang, Fowler et al., 2002). The study showed that in some subjects the same level of DAT blockade induced much greater increases in DA than in others (see Plate 16.2c). This highlights that differences in the response to a drug between subjects are not necessarily explained by differences in plasma concentration (represented by $C$ in Fig. 16.1), or even delivery into the brain and its relevant molecular targets, but to the differences in the reactivity of the neurotransmitter system (in this case activity of the DA cells). That is, for a given level of DAT blockade, subjects with low DA neuronal firing will show smaller DA increases than subjects with high neuronal firing. The variability in effects of DAT blockade also provides an explanation of why some ADHD subjects do not respond to MPH despite having adequate plasma concentrations. This may account for the large (fivefold) individual difference in dose of medication required to produce a titrated clinical response when used to treat the psychiatric disorders of childhood considered here.

DA cell firing in a given subject fluctuates in part as a function of context: DA cells fire when exposed to stress and to reinforcing, novel or unexpected stimuli. This would suggest that the effects of stimulant medications should be sensitive to the context in which they are administered. Indeed, an imaging study compared the increases in DA induced by MPH as a function of the context of its administration (Volkow, Wang, Fowler et al., 2004). It showed that the DA increases were greater when MPH was given concomitant to a reinforcer (money) than when no reinforcer was available. This provides a mechanism to understand the context dependency for stimulant effects, which was first noted by Conners (1966) 40 years ago.

Effects of Drugs on Brain Function and Neural Networks

The effects of medications on neural networks reflect their downstream effects: the initial molecular targets transmit these signals predominantly through glutamatergic (stimulatory) and GABAergic (inhibitory) pathways. Most of the neurotransmitters that are the main targets for the effects of medication used in child psychiatry have been linked to neural networks (Table 16.3). For example, Alexander, Crutcher, & DeLong (1990) described neural networks as parallel segregated circuits linking cortical, striatal and thalamic brain regions. Le Moal and Simon (1991) used these circuits to propose how a specific neurotransmitter (DA) affected behavior by modulation of activity in these parallel segregated circuits and affected behavior related to psychiatric disorders such as schizophrenia, which is associated with disrupted executive function.

Functional brain imaging techniques have been used to identify the downstream effects of the pharmacological effects of drugs. In the current literature, measures of function are often derived from functional magnetic resonance imaging (fMRI) techniques and the blood oxygen level dependent (BOLD) measure. It is generally believed that the activation signal, which is generated from fMRI, is due to differences in magnetic properties of oxygenated versus deoxygenated hemoglobin (BOLD contrast). During activation of a brain region there is an excess of arterial blood delivered into the area with concomitant changes in the ratio of deoxyhemoglobin to oxyhemoglobin, which generates the signal detected by fMRI. However, functional measures can also be obtained from some PET imaging techniques. For example, as shown in Plate 16.1(a), regional changes in brain glucose utilization can be used to document the consequences of drug effects on neural circuits that are distant from the pharmacological or neurochemical site of action.

Glucose metabolism is measured using PET and the radioligand fluoro-deoxyglucose labeled with $^{18}$F (FDG) (shown in Plate 16.1a) and CBF is measured with oxygen-15 labeled water (not shown). Measures of brain glucose metabolism and of CBF serve as surrogate markers of brain activity because glucose is a source of energy for the brain and its transport into the tissue is dependent on CBF. By comparing PET images obtained after placebo and the drug, the selective effects on function can be estimated.

Although initial studies targeted measures of the effects of drugs on specific brain regions, increasingly, studies are targeting the effects of drugs on regional circuits. Inasmuch as drugs target specific neurotransmitter systems, these investigations are providing knowledge on the role of neurotransmitters in the function of brain circuits. Moreover, these imaging studies are also enabling us to understand how regions interact with one another to form circuits responsible for behavior and how their disruption may occur in psychiatric diseases. For example, Seminowicz, Mayberg, McIntosh
CHAPTER 16

et al. (2004) used PET imaging studies to develop a model for major depression based on a limbic–cortical circuit with three “compartments” (sensory–cognitive, emotional–cognitive and autonomic).

While initial studies evaluated the effects of the drug under no intervention conditions (resting state), there is an increasing number of studies that have evaluated the effects of the drug on brain activation patterns as the individuals are involved in emotional or cognitive tasks. This approach sheds light on the role of neurotransmitters in the function of a given circuit and on its consequent output. We have manipulated expectation in studies of metabolic response to MPH i.v. (Plate 16.2d) in subjects with a history of stimulant (cocaine) abuse (Volkow & Swanson, 2003) and in normal control subjects (Volkow, Wang, Ma et al., 2006). As shown in Plate 16.2(d), in subjects with a history of stimulant abuse (and therefore experienced in the euphoric effects of i.v. stimulants), the effects of MPH on brain metabolism were not in the basal ganglia (the site of biochemical effects presented and discussed earlier), but were primarily in the cerebellum (vermis), thalamus and occipital cortex. In addition, when MPH was unexpected, the metabolic response in the left lateral orbital-frontal cortex was enhanced. In control subjects without prior experience with i.v. stimulants, the effects of expectation on MPH response were largest in the anterior cingulate gyrus and the nucleus accumbens, which are areas related to emotional reactivity and reward. These metabolic responses were interpreted as consequences of biochemical effects concentrated in the caudate nucleus, and apparently reflect the MPH-induced activation of a cortical–striatal–thalamic circuit described by Alexander, Crutcher, & DeLong (1990) and Posner and Raichle (1994).

As more knowledge is gained from these imaging studies on how the brain functions, and in particular how various neurotransmitters overlap in their regulation of brain regions and circuits, it is becoming evident that in most instances the abnormality in a disorder does not reside solely in the one neurotransmitter modified by the medication, but in the brain regions that it regulates or the regions or other neurotransmitters that modulate its function.

Conclusions

The application of basic principles from neuropsychopharmacology has contributed considerably to our understanding of the dose–response and time–response characteristics of medications used to treat childhood psychiatric disorders. PK and PD analyses of medications listed in Table 16.1 are rare but do exist for some drugs. For example, the PK analysis of the stimulant medications, described above, altered clinical practice in terms of frequency of dosing (which moved from once daily to twice or three times daily regimens, in order to cover a longer duration with these short-acting drugs) and conditions of dosing (which moved from before meals to with or after meals, which allowed flexibility in managing the common side-effect of appetite suppression). Also, PK studies of antidepressant drugs in children have been performed (Wilens, Biederman, Baldessarini et al., 1992), but the information obtained has not typically been used to set the dosing regimens used in most clinical trials. Findling et al. (2006) suggested that even though the clinical trials of antidepressant drugs have sometimes been unsuccessful in documenting efficacy under double-blind conditions, the efficacy of the drugs themselves should not be dismissed without consideration of their PK properties. Clinical trials should be developed that use rational or optimal drug regimens to evaluate efficacy and safety.

PD analyses have been used to evaluate dosing regimens for stimulants and for non-stimulants that are used for the treatment of ADHD, and this has influenced recent changes in clinical practice. For example, PK/PD inspired CR formulations of MPH (Swanson et al., 2003) and AMP (Greenhill et al., 2003; McCracken, Biederman, Greenhill et al., 2003) are now the most prescribed stimulant formulations for the treatment of ADHD in the USA. PK/PD analyses have also been applied (see Wigal, McGough, McCracken et al., 2005) to evaluate possible age-related differences in dose or dosing rate in the treatment of adolescents and preschool children.

Other examples of how PK/PD analyses have affected clinical practice are provided by the drug development programs for the FDA-approved use of ATX and the unapproved experimental use of MFL. In these examples, PK/PD analysis was used to evaluate the titration schedules (i.e., how rapidly increases in dose are made) and the daily dosing schedule (i.e., once daily and twice daily dosing regimens). For ATX, PK/PD analysis of ATX (Michelson et al., 2007) was used to justify the recommendation for once daily dosing. For MFL, PK/PD analysis were used to evaluate the difference between slow (weekly) and fast (daily) increases in dose for titration, and resulted in the recommendation of the fast schedule that produces the same results as the slow schedule (Greenhill et al., 2006; Swanson, Greenhill, Lopez et al., 2006b).

In this chapter we focus on the effects of drugs on their direct targets and on downstream circuits, but we do not address parallel molecular biology studies that are shedding light on how the effects of drugs affect the transduction signals that regulate cell function, and we do not discuss the intracellular events that follow the interaction of the drug with its target (Popoli, Brunello, Perez et al., 2000). Instead, we describe modern direct measurements from PET imaging methods that inform us about how some intermediate responses occur in the brain, including biochemical effects on neurotransmitter systems (transporters, enzymes, receptors, neurotransmitter release) and on functional effects on brain circuits (glucose utilization and blood flow).

We consider the use of PET for brain PK and PD analysis to be a major methodological advance in this area. Until recently, most of the knowledge on the pharmacological properties of psychoactive drugs relied on the use of preclinical models,
in vitro measurements and on behavioral studies linking drug plasma concentrations and behavioral effects. The advent of imaging technologies has revolutionized the way we characterize medications, for these methods have enabled us not only to assess the PK properties and bioavailability of drugs directly in the human brain, but also to assess the potency of drugs at their relevant targets and their effects on neuronal circuits implicated in the neurobiology of the psychiatric disorders.

CHAPTER 16

Clinical Neurophysiology
Torsten Baldeweg and Stewart Boyd

General Principles of Electroencephalography

The electroencephalogram (EEG) is a technique that measures the electrical activity of the brain non-invasively, from electrodes placed on the scalp. It is widely used in clinical practice and is also an important tool in basic and clinical neuroscience research. There are dramatic neurophysiological changes with age, so EEG and related methods, such as event-related potentials (ERP), are paramount for our understanding of the relation between brain maturation and normal as well as abnormal cognitive and behavioral development. This chapter reviews some principles of their application in clinical pediatric practice as well as in research in the developmental neurosciences.

Introduction and Historical Note

We identify three major phases in the history of neurophysiology and EEG, in particular as applied to the search for neural correlates of mental processes and their application to psychiatry:

1. The pioneering discovery of the EEG by Berger;
2. Its application to neurology, including the invention of evoked potential techniques; and
3. The present day cognitive neuroscience approach attempting to capture and understand the dynamic properties of cognitive processes and neural computations by means of EEG-based methods.

We have structured this chapter along this meandering road of discovery.

The EEG was discovered by Berger (1873–1941), a psychiatrist working in Jena, Germany, who early in his career attempted to study human mental function through physiological measurement. He began by observing changes in cerebral blood flow in patients with pulsating skull defects and by measuring temperature in neurosurgical patients during mental tasks. He was forced to give up because these techniques were too crude for the task he set out to achieve (Gloor, 1994). He then turned to electrophysiology following the pioneering work in animals by Caton (1842–1926) and in 1924 Berger succeeded in measuring the electrical activity of the human brain. Using what he called the Electroencephalogram, Berger described the different brain rhythms, such as alpha waves, today also known as Berger’s rhythm. By 1939 he had described all the major features of the normal and abnormal EEG, including EEG alterations in sleep and states of diminished consciousness (Berger, 1969). Although he did not fulfill his ultimate ambition to capture neural signatures of mental processes, EEG proved the most lasting of his psychophysiological methods, finding a permanent place in clinical investigations of neurological patients, particularly those with epilepsy. In the 1930s, EEG entered routine clinical diagnostics and EEG patterns associated with different seizure disorders were described by Gibbs, Davis, and Lennox in 1935.

The desire to investigate perceptual and cognitive processes resulted in the invention of the evoked potential technique by Davis, Davis, Loomis et al. (1939) and Dawson (1947, 1954). The discovery of this method of recording small electrical potential changes on the scalp to simple sensory stimuli had a long-term impact — again, mainly for neurological diagnosis.

The era of cognitive neurophysiological research was initiated by Walter and colleagues in 1964, who recorded slow frontal EEG potential shifts (“contingent negative variation”) during stimulus–response tasks. The discovery of these “cognitive” evoked potentials, today known as ERP, has brought Berger’s original idea to fruition, by identifying physiological changes associated with specific cognitive operations. Today, we witness the merging of the concepts of EEG (as a measure of brain dynamics) and ERP (as markers of cognitive processing stages) by incorporating both measures into a more unified theoretical treatment of brain function (see p. 242). We expect that this novel approach will ultimately shed more light on the subtle neurophysiological processes underlying synaptic plasticity and connectivity in the developing and mature brain and their disruption in psychopathology.

Neurophysiological Origins of EEG

The electrical activity that can be recorded using surface electrodes is a summation of the synchronous activity of thousands or millions of neurons, which communicate with each other using two major forms of electrical signals: action potentials propagated along axons to generate postsynaptic potentials in the dendrite of the receiving neuron. Action potentials are too short in duration (a few milliseconds) to produce sufficient summation of electrical potentials to be detected by surface electrodes. In contrast, the slower postsynaptic potentials (typically tens of milliseconds to over 100 ms in duration)
can produce externally detectable potentials, especially when generated in pyramidal cells. The elongated shape of these neurons leads to a separation of the electrically active part (mostly causing extracellular negativity) and passive parts (positivity) of the pyramidal cell. This is called an electrical dipole and the external electrical field is most likely to be detected at a distance if these dipoles are arranged in parallel with each other. In contrast, in cells with a spherical shape of the dendritic tree (e.g., interneurons) the external electrical field will cancel out because of random orientation of dipoles.

Therefore, the slow postsynaptic electrical activity of pyramidal cells in the cortex is the largest contributor to surface EEG. This activity is volume conducted through the overlying tissues (cerebrospinal fluid, skull and skin) with different and non-homogenous conductance, thus contributing to a substantial spread and distortion of intracerebrally generated electrical fields at the scalp. This property and the limits imposed by the physics of electromagnetism prevent an accurate reconstruction of the cortical generators of EEG and ERP. Nevertheless, techniques of topographical (spatial) EEG analysis as well as magneto-encephalography (MEG) can be used to find approximate generator estimations (see p. 243).

**Classification of EEG Rhythms**

EEG rhythms span a broad frequency range, from slow oscillations (0.5–1 Hz) and delta waves (1–4 Hz) dominating during sleep to the faster rhythms of wakefulness: theta (4–8 Hz), alpha (8–12 Hz), beta (12–30 Hz) and gamma frequencies (from >30 Hz to over 100 Hz). These rhythms show a characteristic scalp distribution (e.g., the alpha rhythm has a posterior maximum), while a characteristic mu rhythm (8–10 Hz) is found over the sensorimotor regions. There are marked developmental changes in their scalp distribution too (see p. 242).

Brain arousal states are characterized by changes in the EEG spectrum. The waking EEG is dominated by fast rhythms (alpha, beta and gamma). Eye closure augments alpha activity while eye opening suppresses this prominent posterior wave pattern (alpha-block). The onset of sleep is characterized by sleep spindles (7–14 Hz), while EEG in deep sleep is dominated by delta and theta waves (hence called slow wave sleep), in contrast to paradoxical or rapid eye movement (REM) sleep, where these slow oscillations are suppressed (misleadingly termed EEG “desynchronization”) and replaced by fast waves (waking EEG pattern).

**Maturation of EEG Activities**

After birth, the normal EEG continues to mature until adolescence, although the most striking changes are seen in the first few years of life. Rhythmic precursors of prominent normal features such as mu and alpha rhythms appear in the first few months of life, and reach alpha frequencies by 1 and 3 years, respectively. The alpha rhythm continues to mature until adolescence with a gradual increase in frequencies.

Prominent features of sleep mature over the first 18 months (K-complexes) to 2 years (sleep spindles). Rhythms of drowsiness remain prominent until near puberty, while posterior temporal slowing only appears with adolescence, as does midfrontal theta activity. Still other features, such as the slow occipital transients seen in relation to eye movements, remain throughout childhood, although they peak at around 2 years. All these normal features continue to be misinterpreted as abnormalities on occasion. This point is considered further below (see p. 240).

Maturation of normal activities continues from the first appearance of EEG activities around 23–24 weeks post-conceptional age, with the most marked changes occurring throughout infancy. The activities are initially discontinuous (trace discontinuus) but become continuous in all states except for a transient phase of quiet sleep (trace alternant). The adult sleep onset pattern where non-REM stages are seen before the first period of REM appears from around 44–47 weeks, associated with a maturational change in the responsiveness of pedunculopontine neurons.

**Neurophysiological Origin of EEG Rhythms**

The mechanisms underlying the generation of rhythmic background EEG activity during waking and sleep are now well understood (for reviews see McCormick, 2002; Steriade, 2006; Steriade, McCormick, & Sejnowski, 1993). The cerebral cortex and thalamus can both generate cyclical oscillations of neuronal activity, which are determined by the physiological properties of neurons and the highly interconnected nature of the brain. The major components of the oscillatory network are as follows:

1. **Cortical neurons**, receiving input from and transmitting information to
2. **Thalamocortical relay cells**, which in turn also send collaterals to
3. **Thalamic reticular cells**.

Activation of the latter inhibitory cells determines the periodicity of firing of thalamocortical cells and hence shapes oscillation frequency and pattern of the whole thalamocortical network. Several forms of epileptic activity appear as aberrations of the normal activity within cortical and thalamocortical circuits.

The cellular and network mechanisms of rhythm generation are known in much detail for spindle oscillations (7–14 Hz), which characterize light sleep as well as for the slow oscillations (0.5–1 Hz) in deep sleep. Both types of rhythm are characterized by inhibitory processes in thalamic and cortical neurons, thus gating sensory information and preventing the processing of such external information in the cortex. Similarly, the mechanisms behind fast rhythms (beta and gamma: 20–60 Hz) are increasingly understood, suggesting an essential role for inhibitory interneurons in shaping frequency and type of network behavior (Whittington & Traub, 2003).

Mechanisms of theta wave generation (4–7 Hz) are still not well understood. Theta waves represent an “on-line” state of the hippocampus, generated by rhythmic inputs from other limbic structures (Steriade & Llinas, 1988). Human frontal theta activity does not arise from the hippocampus directly, but is probably generated in limbic projection regions in the cingulate cortex and other frontal regions.
CHAPTER 17

Similarly, the precise neural mechanism of alpha wave (8–12 Hz) generation is not known. However, it is suggested that alpha waves, which share the frequency range of sleep spindles, also emerge from the interplay of thalamocortical connections, especially of the visual cortex and visual thalamus (Lopes da Silva, 1991). Several sources of focal alpha activity have been detected in the parieto-occipital and calcarine cortex using MEG (Hari, Salmelin, Makela et al., 1997). During alpha activity there is widespread cortical deactivation in frontal, parietal and occipital regions and increased thalamic activation as measured in combined EEG and functional imaging studies (Goldman, Stern, Engel et al., 2002).

The mu rhythm is a sensorimotor rhythm in the alpha range (8–10 Hz) seen over the central regions in a relaxed awake subject. This activity is blocked by making or receiving an instruction to make a movement. MEG studies suggest that this rhythm arises mainly from the somatosensory area with contributions from the motor cortex (Hari et al., 1997).

In more general terms, the period of oscillation is constrained by the size of the neuronal pool engaged in a given cycle. Higher frequency oscillations are confined (due to axon conduction and synaptic delays) to a small neuronal space, whereas very large networks are recruited during slow oscillations (Buzsaki & Draguhn, 2004).

Neuromodulatory influences on thalamocortical rhythms arising from ascending monoaminergic and cholinergic midbrain projections are especially important in regulating sleep stages and associated EEG rhythms (Hobson & Pace-Schott, 2002; Steriade, 2006). Cholinergic activity arising from the tegmentum inhibits the cells of the reticular nucleus of thalamus, thus releasing thalamocortical relay cells from their inhibitory influence, which results in EEG activation (“desynchronization”) and arousal (sleep–waking transition).

Functional Roles of Cortical EEG Rhythms

There is continuing debate about the functional significance of spontaneous EEG oscillations, with some regarding them as epiphenomena, while recent evidence suggests that such brain rhythms during different behavioral states have distinct functional roles (for review see Buzsaki & Draguhn, 2004). These roles can be grouped as follows:

- **Input selection and plasticity** Oscillatory activity facilitates responsiveness and plastic changes in the strength of connections among neurons, supporting the process of information representation and memory storage (Steriade, 2006). The evidence for cognitive roles is best established for the hippocampal theta and cortical fast gamma and beta rhythms (Kahana, 2006).
- **Binding cell assemblies** Information in the brain has been hypothesized to be processed and stored in flexible cell assemblies, defined as distributed neuron networks that are transiently synchronized by dynamic connections. This hypothesis has been specifically formulated for gamma oscillations enabling phase-locked discharges of distributed neurons to “bind” different stimulus features into a coherent perceptual concept (Gray, Konig, Engel et al., 1989). This “gamma binding hypothesis” is challenged by the observation of identical waves during slow wave sleep. A number of hypotheses about the role of gamma oscillations in psychopathology are reviewed by Herrmann and Demiralp (2005).

  • **Consolidation and combination of learned information** Synaptic modifications in neural networks, which were brought about by experience and learning during wakefulness, are being “frozen” into the oscillatory dynamics during sleep to be turned into long-term memory.
  • **Representation by phase information** Evidence for such function largely comes from recordings of hippocampal place cell firing during theta oscillations (O’Keefe, 1979). At a network level this means that neurons with stronger dendritic inputs will discharge earlier in the oscillatory cycle than neurons with weaker inputs.

**Transition of Normal Rhythms into Electrical Seizures**

Aberrations in the thalamo-cortical interplay that underlies EEG rhythms can lead to the emergence of seizure activity (Steriade, 2006). The occurrence of spike-and-wave seizures (absence or petit mal) is especially facilitated during transitional states from waking to slow wave sleep or during drowsiness. Abnormally strong activation of the inhibitory thalamic reticular neurons can result in the transformation of a normal sleep rhythm (spindles) into one that resembles those underlying absence seizures (3-Hz rhythms).

Seizures characterized by 3-Hz spike–wave complexes are strongly associated with generalized, notably childhood absence, epilepsies. Originally ascribed to a “centrencephalic” system 3-Hz spike–wave complexes have recently been shown to be initiated by a cortical focus, rapidly transmitted to other (contralateral) cortical regions (within 20 to 100 ms) and the thalamus (within a few seconds). This corticofugal input has two effects on thalamic neurons:

1. Interneurons in the reticular nucleus are excited and then actively participate during seizure activity; and
2. Thalamocortical relay cells are inhibited, resulting in loss of external sensory input to the cortex, and hence explaining the loss of consciousness during absence seizures (Steriade, 2006).

The neurophysiological mechanisms behind spike and wave generation involve both excitation and inhibition in close succession: the surface negative spike is the result of excitatory postsynaptic potential (EPSP) generation primarily in apical dendrites of pyramidal neurons; while the longer lasting surface negative wave is generated by inhibitory postsynaptic potentials (IPSPs) predominantly on or near the soma of pyramidal cells. The subsequent slow component has predominantly inhibitory effects on cerebral function and is responsible for alterations in cognitive function (Shewmon & Erwin, 1988).

Spike–wave discharges can also arise in the cerebral cortex alone from disruption of a synchronized slow oscillation (<1 Hz) that occurs in sleep. These slow oscillations are the result of a cyclical interaction between recurrent cortical excitation (depolarization) and its control by inhibitory mech-
anisms (hyperpolarization). Again, loss of cortical inhibitory control allows this normal activity to become epileptiform. Together, the cerebral cortex and thalamus can form loops of activity that contribute to some forms of epileptic seizures (McCormick, 2002).

**EEG Recording Techniques**

**Standard EEG Recording**

This continues to form the backbone of clinical neurophysiological investigation in children with possible central nervous system (CNS) problems. Although there are many limitations in sampling the EEG activity randomly and for a limited period, this has served well for over 50 years. In younger children, a recording lasting 30–40 minutes may well include a period of spontaneous sleep, and this can be encouraged by manipulating aspects of the environment, such as lighting and laying the child on a bed wrapped in a blanket. In older children and adolescents sleep may be induced by the use of some form of sedation or by sleep deprivation (see p. 239).

In pediatrics, digital EEG recordings should be time-locked to video recording (subject to consent; see p. 239) particularly if the nature of episodic behavior changes or possible seizures (here defined as “events”) is part of the question. Simultaneous recording of other physiological variables (polygraphy) such as surface electromyography (EMG), electrocardiography (ECG) and oxygen saturation may be particularly helpful. Although such recordings document attacks in children relatively often compared with adults, most recordings will be interictal, and this must be borne in mind when interpreting the result. Caution is also needed in interpreting localization on the basis of a single recording, as the apparent site of spike activity may vary between records (Kaufman, Harris, & Shaffer, 1980).

**Video-EEG Telemetry**

Extended EEG recordings over periods of days to around a fortnight are indicated when shorter recordings have not answered an important clinical question about the nature or frequency of events. Such video-EEG recordings, which require a ward setting, are usually carried out in specialized telemetry units. Events must be sufficiently frequent to be likely to be captured during the time available (usually 2–3 times per week to be confident of documenting an event in 4–5 days of recording). Shorter periods of telemetry can be used to ensure that a whole night-time’s sleep is obtained; this may be important when clinical events are confined to particular times of day.

**Ambulatory EEG Recording**

Ambulatory EEG recording is carried out when the events are both frequent and markedly related to environmental factors. Recording periods are usually extended for 2–3 days at a time, indicating that events should be occurring 3–4 times per week to have a realistic hope of capturing one. The lack of simultaneous time-locked video in these circumstances means that interpretation of changes in behavior or perception, signaled by pressing the “event-button,” rely upon the event diary being kept accurately.

**Evoked Potentials**

Evoked potentials (EPs) constitute part of the ongoing EEG that is specifically elicited by sensory stimuli (auditory, visual or somatosensory). Sensory EPs, with peaks within 50 ms post-stimulus, can be contrasted with stimulus-induced EEG changes of longer latency in response to specific psychological
CHAPTER 17

task instructions. These latter are ERP (see p. 243). EPs are very often much smaller in amplitude than the on-going EEG activity, and this adverse signal : noise ratio can be improved by repeating the stimulus and averaging the EEG response across many repetitions.

Despite some caveats, replicable series of averaged waveforms can be obtained in a wide range of clinical settings, and clinical EP studies have been widely used to elucidate function in particular sensory pathways. Normal values for standard clinical EPs have been established taking account of maturational changes in waveforms and latencies. EP techniques have established roles in intraoperative monitoring, particularly of the spinal cord during neurosurgical and orthopedic operations, and in specialist audiological and ophthalmological applications.

EP peaks are labeled by their polarity at the scalp (P for positive, N for negative) and the typical peak latency (i.e., time [in ms] poststimulus, at which they are elicited in the adult: N20 or P25) or by the number in a sequence of peaks (i.e., P1/N1/P2). EPs are quantified using peak latency and amplitude.

Short-latency EPs often used in clinical studies include the following.

Brainstem Auditory Evoked Potentials (BAEPs) These are a series of vertex-positive waves in the nanovolt range revealed by averaging a repeated set of simple auditory stimuli such as clicks or pure tones. These waveforms originate in auditory pathways through the brainstem and when recorded and interpreted carefully can give information about the conduction through the brainstem which is not accessible using standard EEG recordings. Apart from their obvious audiological applications, they can be useful in the intensive care unit (ICU) and in determining brainstem involvement in neurological conditions affecting white matter.

Visual Evoked Potentials (VEPs) These can be recorded from two types of visual stimuli: pattern and flash. Although both may evoke a negative–positive–negative waveform, with the positivity around 100 ms, they are essentially testing different aspects of the visual system. Pattern EPs to a reversing checkerboard are sensitive to changes in white matter and are often used in suspected demyelinating conditions in adults. However, they require the patient’s active cooperation in fixating on a central target and are particularly vulnerable to fatigue. For these reasons, they are more reliable when used in older children. Flash VEPs may, by contrast, be used in children of all ages, and require no active cooperation, but the waveforms are degraded by a wide range of cortical and subcortical disorders. The flash VEP waveform does not show the consistent increase in latency of the main components with demyelination seen in the pattern VEP and interpretation is more subjective.

Somatosensory Evoked Potentials (SSEP or SEPs) These are recorded maximally from the centro-parietal area over the primary somatosensory cortex. They also show a complex waveform but most attention is usually given to the short-latency components (N20, P25 and N30) following stimulation of the median nerve. The N20 persists after the EEG is completely suppressed by sedatives, and measurement of this component is often used to monitor patient progress in the ICU.

Activation Procedures

Overbreathing

Overbreathing is carried out for 3 minutes primarily as a method of activating epileptiform features associated with both generalized (absence) and focal (e.g., temporal lobe) epilepsy. The amplitude and to some extent frequency of the normal EEG response to overbreathing are functions mainly of age, being more marked in younger children, but neither feature of itself is a marker of abnormality. They become much less marked in adolescents, and should not be asymmetrical or focal. An initial slowing followed by recrudescence of marked slow activity (generalized, lateralized or focal) after the end of overbreathing can be evidence of vascular disease, notably moyamoya syndrome. If the latter is suspected, then overbreathing should be avoided because of the risk of precipitating long-term neurological deficits.

Photic Stimulation

Photic stimulation is a long-established method of provoking epileptiform changes, but the results must be interpreted with caution. Spikes confined to the occipital region have a very low risk of associated clinical seizures. Only widespread spiking (usually mixed with slow waves) carries a substantial risk of seizures, particularly if the spikes persist after the train of photic stimuli is ended (self-sustaining). However, this is a common finding around puberty and may be confined to the test situation. Furthermore, around 2–3% of the population show this risk of clinical seizures in the presence of flickering light, mostly between the rates of 16 and 25 Hz.

Sleep Recording

Sleep recording is indicated when the “events” are confined to sleep and/or when the waking EEG has been uninformative or inconclusive; this will usually be in the context of a suspected epileptic process or syndrome or other sleep disorder. Different states within sleep associated with different patterns of activity or with distinctive waveforms have been recognized for many years, the criteria of Rechtschaffen and Kales (1968) being the most widely used to score these stages. It is often difficult to differentiate drowsiness and stage 1 sleep, particularly in children. The presence of distinctive runs of spindles around the central regions associated with larger generalized biphasic slow waves (K-complexes) indicates that the child is finally definitely asleep (stage 2 or spindle sleep). Both focal and generalized epileptic disorders may demonstrate most epileptiform activity at this stage. This is followed by the appearance of increasing amounts of slow activity, with reduction in spindles as the child enters the deeper stages of non-REM sleep (rarely reached in routine EEG recordings), followed by an abrupt transition to a period of awake-like irregular activities associated with rapid eye
movements and virtual absence of muscle activity (REM sleep). The particular focus of interest may be on drowsiness and light sleep, stage 2 sleep (benign epilepsy with centrotemporal spikes) or following arousal (juvenile myoclonic epilepsy).

Currently, several methods are used to obtain sleep, depending to some extent on the age of the child and, increasingly, on parental preferences. Induction of sleep by melatonin avoids the problems of conventional sedatives (EEG changes and prolonged sedation effects after the test) and is now widely used. Sleep deprivation remains an alternative when melatonin is unacceptable or has previously failed.

One particular variant of sleep recording, the multiple sleep latency test (MSLT), is carried out when the clinical question is that of narcolepsy. The child is instructed to fall asleep then awakened after 20 minutes on five or six occasions over the course of a day. The number of periods of REM sleep and the latency to sleep onset are measured. The MSLT interpretation is limited if the previous night’s sleep pattern has not been monitored.

Consent and Ethical Issues
Other aspects of the recording require consent from carers, particularly video recording, activation procedures (overbreathing, photic stimulation) and sleep deprivation or sedation for sleep. Sleep is often achieved by giving an age-dependent dose of melatonin at the beginning of the procedure. The carers consent to this either before or on arrival, with full information about melatonin-induced sleep given when the appointment is made. Sleep deprivation is potentially more difficult, because the patient is already sleep-deprived on arrival for the test. This often requires the clinician requesting the test to explain the procedure.

Normal and Abnormal EEG
Normal EEG Features

The continuous mixture of “ongoing” activities (loosely referred to as “background activity”), normally contains rhythmical elements (e.g., alpha rhythm) against which identifiable components such as normal lambda waves or abnormal epileptiform spikes are seen.

The development and functional correlates of alpha rhythm (associated with visual function) and the sensorimotor mu rhythm have been described above, and the presence of these rhythms is checked during recording by appropriate maneuvers. If the child falls asleep, the sequence of changes during drowsiness and onset of sleep are recorded. Rhythms associated with drowsiness are often difficult to assess because this involves a subjective evaluation of the amount and type of rhythmic slow activity (see p. 240). This physiological slow activity can appear in generalized bursts, and may in some cases contain sharp components. Such sharp appearances and semirhythmic groups of 2–3 occurrences are also a feature of normal K-complexes in younger children, reflecting the state of a network which may at this point be readily suborned by epileptic activity.

EEG Variants in Children and Adolescents

A group of unusual but relatively stereotyped EEG appearances remain officially designated as “variants”: alpha variants, midline rhythms, rhythmic temporal theta bursts of drowsiness, breach rhythms and others. For practical purposes these may be regarded as part of the normal EEG, or at the least as not having specific pathological connotations.

Pathological EEG Features

Clear-cut and characteristic EEG abnormalities are seen consistently in a very few conditions, but in the majority of clinical situations abnormalities are non-specific and variable. Furthermore, the point is often made that “normal” is itself a statistical concept and an interpretative term when applied to EEGs. In spite of this, the EEG can be seen as a measure of global cerebral dynamics, and a general indicator of pathological processes.

Discrete lesions in a single area are most likely to produce localized or focal disturbances of function. If the lesion is small and located in an area of cortex that is not eloquent, there may be no clear EEG change. However, if located in an area that transmits to a wide area of cortex, this may result in marked and widespread alterations in function, reflected in the EEG changes, much of which will appear remote from the site of the lesion itself. This is also the case with a lesion sited subcortically. Diffuse cerebral pathology and lesions affecting deep structures such as the brainstem will produce “generalized” EEG abnormalities. These EEG abnormalities will appear as either loss of activity, EEG slowing or as epileptiform activity.

Loss of Activity

Loss of activity is the most severe manifestation of cerebral pathology and, apart from deep anesthesia, is associated with severe neurological or metabolic changes when generalized, and with corresponding neurological deficits when localized.

EEG Slowing

The most common manifestation of altered cerebral function is EEG slowing, which once again may be localized or generalized. The extent to which this is seen will depend on the rate of change in the lesion as well as in the pathology itself. Therefore, a long-standing lesion may show little or no disturbance, while a rapidly expanding lesion in the same area will show marked disturbances, usually with much slowing of activities, and possibly epileptiform spiking if it involves cortex. Abnormal slow waves in the delta range are a marker of acute disturbances, and often the assessment of the degree of abnormality of the EEG will depend on the presence and amount of this type of activity as well as its response to changes in state (e.g., sudden alerting).

Differentiating different types of posterior slow activity remains one of the most difficult areas of pediatric EEG. Occipital transients following eye blinks or eye movements are normal and common between 2 and 4 years, diminishing rapidly thereafter, before disappearing in the teens.
CHAPTER 17

temporal slow activity is a normal finding in the young, particularly after puberty, disappearing in the early twenties. Differentiating posterior temporal slow waves that exceed the norm for the child's age remains difficult, and extreme caution is advised, unless the suspect activity is completely unilateral, mixed with unequivocal spikes or it persists through sleep and wakefulness. It most often appears as a non-specific abnormality. Rhythmic 3-second activity, sometimes associated with small spikes, may appear following eye closure in some children with absence seizures. Of itself, it does not imply a focal origin for the seizures or an adverse prognosis.

Epileptiform Activity

Epileptiform abnormalities are often the most enigmatic changes found in the EEG, especially when they occur interictally. The term “epileptiform” simply refers to waveforms that might be associated with an epileptic seizure. Epileptiform spikes are defined as abrupt changes in activity that stand out from the ongoing activities and last less than 70 ms, while sharp waves last up to 300 ms but otherwise have the same characteristics. Such distinctions are often not useful, because both may reflect a propensity for seizures to develop and the less specific term “epileptiform activity” is preferred here. It should be remembered, however, that some normal physiological features appear as sharp waves in particular states, such as vertex waves in early sleep. A more clear-cut epileptiform abnormality is a spike/sharp wave followed by a slower negative wave forming a spike–wave complex (see p. 236).

The boundaries between interictal and ictal events are sometimes difficult to define, because even brief runs of spike–waves may be associated with alterations in cognitive function (transitory cognitive impairment; TCI). The type of impairment is related to the site of the discharges, but lasts only a few seconds (Binnie, 2003). There is evidence that when epileptiform activities are seen interictally, they represent a successful containment of the abnormal activity. A perennial difficulty in ascribing significance to these interictal changes is that they may be seen in around 2–3% of children who never develop clinical seizures. The ictal EEG changes associated with different clinical seizure types range from sudden decrements in activity associated with infantile spasms and tonic seizures to runs of well-formed 3-s spike–wave complexes associated with typical absence seizures (see chapter 22).

Periodic phenomena are waveforms that appear at more or less regular intervals of more than 1 second and may appear focal or generalized, associated with different pathologies. Periodic lateralized epileptiform discharges (PLEDs) are a distinctive variant seen as a focal or localized change. PLEDs can be a sign of cerebral infarcts or vasculitis, but perhaps most often reflect the incomplete resolution of a seizure. They are seen in the classic form of herpes simplex encephalitis, occurring as focal periodic changes over the affected temporal lobe.

Generalized periodic complexes are seen in subacute sclerosing panencephalitis as complexes of varied (bi- or polyspastic) morphology lasting 0.5–2 seconds, recurring between 4 and 15 seconds (although occasionally longer). In adults with Creutzfeldt–Jakob disease (CJD) they appear as sharp waves with a period of around 1 second, but are not found in cases of new-variant CJD.

Interpretation and Reporting

EEG reporting is still most often carried out by visual inspection of waveforms in time series, describing features in terms of their frequency, amplitude, behavioral associations and topography. Artifacts (non-cerebral scalp potentials) are more readily recognized using these techniques. The use of digital recording allows display of the relative differences in potentials between different electrodes on the head in any combination (or montage) and has contributed to improvements in EEG interpretation (Levy, Berg, Testa et al., 1998). The EEG is usually read twice, first to describe the activities, and then to review the findings in order to attempt to relate them to the history and the clinical question.

It is important to point out that the process of visual analysis and setting into a clinical context contains a number of potentially serious flaws. The clinical setting and clinical questions arising from it may be ill-posed or not given. Many request forms still do not contain appropriate well-posed questions. Furthermore, the recording conditions may not be appropriate to directly address the question (e.g., when the events in question occur only during sleep and this is not achieved during the recording). Ultimately, the interpreter’s own level of experience may bias the report. They may, for instance, be broadly aware that benign epilepsy with centro-temporal spikes is common in childhood, but may not be clear about the details of the typical clinical setting. An inappropriate report suggesting a condition that the child clearly cannot have mars the outcome of the EEG investigation. Overbreathing is often carried out and the intermittent generalized bursts of often very high amplitude, slow activity continue to be misinterpreted by those unaccustomed to working with children.

This visual approach to analysis has survived in the clinical context despite the presence of many difficulties and inherent frustrations and uncertainties, because it has allowed clearer recognition of artifacts and of patterns of abnormalities with definite clinical associations, particularly in childhood epilepsy. It also facilitates the concurrent use of postacquisition digital signal processing. There is still considerable active debate about the place of particular signal processing algorithms in aiding the reporting of EEG investigations (see p. 242) and this is particularly the case in psychiatric disorders. By combining these approaches to the interpretation of clinical records, it is hoped to reduce the large element of individual interpretation and, perhaps, lessen the need for highly specialized training and experience.

Selecting Neuropsychological Investigations in a Clinical Setting

Determining which neuropsychological investigation is the most appropriate to request depends on a number of factors, of which
by far the most important is deciding the clinical question that is being posed. The most common is as an aid to the diagnosis of epilepsy. Clinicians will be aware that a “normal” EEG at a time when a child is not having seizures does not exclude epilepsy (see chapter 22 for the place of EEG in the investigation of clinical problems). Although an ictal recording documenting the events at the time of an episodic change in behavior may seem (and be) the only possible answer to the question of their underlying nature, much useful information may still be obtained from the interictal recording. Before requesting video-EEG telemetry as a first investigation, on the basis that only the capture of “events” will be significant, clinicians should consider the frequency of the events, whether or not the presence of interictal findings will suffice to permit making a rational clinical management plan (as is the case in many epilepsy syndromes), as well as the relative waiting times for the two types of investigation.

Alternatively, the question may be “Is there evidence of an organic process, such as an acute/subacute encephalopathic process?” This might be answered by finding generalized slow activities suggesting an acute or subacute process, although the finding is itself not specific for any particular diagnosis.

The interplay of EEG abnormalities representing changes related to both pathology and maturation is seen in a number of conditions often encountered in psychiatric practice. These include cerebral dysplasias, the underlying cause of learning difficulties and behavior disorders in many childhood syndromes. When these are extensive, as in the various forms of lissencephaly and pachygyria, EEG abnormalities may appear as distinctive high-amplitude rhythmic generalized activities at a mixture of frequencies in the first year of life, but may later appear as non-specific irregular slowing with or without spikes. However, clinicians will be aware that in many important psychiatric disorders, such as autism, standard clinical neurophysiological investigations are very unlikely to be informative with respect to diagnosis. There are continuing suggestions that children with pervasive developmental disorders and very frequent epileptiform spikes may have clinically detectable differences from those without such spikes (Ballaban-Gil & Tuchman, 2000), but these studies await replication.

Pediatric EEG recording may be regarded as a means of obtaining additional clinical signs, which, like any other sign, must be evaluated in the light of the clinical history and other findings, and which will have false positive and false negative results. If the answers given in the report are unexpected or unclear, there may be several reasons for this. The initial question might not have been well-posed, or posed clearly enough with sufficient clinical information given. It might not be possible to answer the question in the circumstances in which the recording was obtained.

What if the Result is Unexpected?
Some structured approach is called for to avoid missing an important point. The problem might be approached in the following way.

What is the strength and nature of the evidence obtained from the EEG?
If the child did have one of their habitual episodes and this was associated with EEG changes, then the clinical view of their underlying disorder may be confirmed. However, if the EEG is entirely unchanged during a typical event which had been strongly suspected of being epileptic in nature, then two possibilities may have to be considered. The event might indeed have an epileptic basis, but this is not seen in the EEG, either because it arises from a deep structure (as in ictal laughter associated with some hypothalamic hamartomas) or from cortex remote from the electrodes (frontal lobe seizures may often do this). However, the question must then be asked as to whether or not the other clinical features are quite consistent with such an explanation.

Alternatively, it may be that the event does not have an epileptic basis. Once again, the event has to be reviewed for clinical consistency and for what it may reveal about the child’s behavior and attitudes, bearing in mind that children may have both epileptic and non-epileptic events, and that the child may wish to help by displaying what they believe to happen in the events. These clinical decisions may be aided by careful review of video-EEG of the event, particularly with a clinical neurophysiologist.

The discrepancy between the clinical assessment and the EEG report is often less clear-cut, with “abnormalities” being reported in a child in whom a “normal” finding was expected. Once again, it may be useful to consider the context in which the abnormalities were found, with a mild non-specific excess of slow activity in a possibly slightly drowsy child being less compelling evidence than the finding of markedly high-amplitude rhythmic slow activity abnormal for any age and state, particularly if associated with spikes. The EEG report may in these circumstances be seen as giving pointers to areas of the history that might be worth revisiting, or to other investigations that might clarify the diagnosis.

Summing up, the nature of clinical neurophysiological testing is now changing because of developments in other techniques, particularly neuroimaging. Therefore, the emphasis is now rightly more on the physiological and pathophysiological significance of any identified abnormalities (e.g., structural brain lesions). In addition to EEG recording, it can be useful to extend the clinical neurophysiological assessment of the child using EP or ERP techniques (see p. 237).

Finally, the following general points should be kept in mind. Clinical EEG recording will only tell us about the neurological underpinnings of abnormal behavior and cognition, not necessarily about the details of the underlying substrate. Conventional clinical EEG is unlikely to reveal underlying processes when these do not have a grossly organic basis such as epilepsy. In terms of exploring mechanisms of underlying brain function, standard EEG may be useful in defining sleep stages or other “states” but cannot directly illuminate the more intricate mechanisms of human cognition and their aberration in psychiatric disorders. The extent to which it is possible to look at perception, attention, memory and language using
time-resolved EEG methods will be discussed in the final part of this chapter.

**Application of EEG and ERP in Clinical Research**

**EEG – A Quantitative Measure of Cortical Dynamics**

Neurophysiological techniques are currently undergoing a phase of significant innovation after a previous period of major advances that came with the introduction of digital processing capabilities of personal computers. Computerized methods of analysis have become indispensable tools for capturing the complexity of EEG rhythms and dynamics. There is also closer interaction with other neuroscience disciplines, which by now have recognized the intrinsic advantages of EEG and ERP measures as direct correlates of neuronal activity emerging in real time. This interaction builds on advances in functional and structural neuroimaging and computational neuroscience as well as experimental neurophysiology. A better knowledge of the cortical generator sites of EEG and ERP is now based on systematic studies in neurosurgical patients with indwelling electrodes. We examine examples of this interaction and their application in clinical neuroscience research further below. EEG findings in specific developmental disorders are reviewed in the chapters dealing with individual disorders.

**Computerized Analysis of EEG (Quantitative EEG)**

The traditional visual analysis of EEG recorded on paper has been supplemented in recent EEG systems with two innovations based on computer technology. First, digital paperless EEG is now a standard technique used in most EEG settings. Second, a number of computerized quantitative methods of EEG analysis have been introduced, aiding the process of EEG interpretation (see p. 240). One of the first computerized methods to be introduced was *spectral analysis* of brain rhythms using fast Fourier transforms. This method decomposes the time domain EEG signal into a frequency domain signal (sum of sines and cosines), which enables quantification of the spectral content of EEG into distinct frequency bands. Furthermore, the analysis of the spatial distribution of EEG across the scalp can be enhanced using methods of *topographical analysis*, such as scalp potential maps, current source density maps (i.e., the spatial derivative of electrical potential) and electrical source (dipole) modeling. In addition, the coupling of rhythms in different brain regions can be assessed using correlation or *coherence analysis*. This technique enables a quantitative assessment of neural connectivity changes in the brain to be made.

While these quantitative EEG techniques have a major role in research settings, they are used in clinical practice only in adjunct to traditional EEG interpretation by highly skilled EEG physicians (Nuwer, 1997). Certain quantitative EEG techniques are considered established only for specific clinical questions:

1. *In epilepsy* for screening for epileptic spikes or seizures in long-term EEG monitoring or ambulatory recording to facilitate subsequent expert visual EEG interpretation;
2. *In intensive care or operating theatre monitoring* for continuous EEG monitoring by frequency-trending to detect early acute intracranial complications, and for screening for possible epileptic seizures in high-risk patients.

Quantitative EEG analysis is an established technique in psychopharmacology, where affinity of drugs for certain neuromodulatory receptors (e.g., dopamine and serotonin receptor subtypes) is associated with characteristic changes in resting EEG rhythms. This method is therefore being used to characterize drug kinetics and profiles in human studies. Computerized EEG analysis has also become an integral part of sleep research and sleep medicine by providing objective criteria for the assessment of sleep architecture.

**Quantitative EEG Maturation from Infancy to Adulthood**

There are dramatic EEG changes with age that reflect cortical development. EEG can be used to assess cognitive functions and improve our understanding of the relation between brain maturation and behavioral development (for review see Taylor & Baldeweg, 2002). The different EEG rhythms have distinct developmental patterns. In the neonatal period, the waking EEG is dominated by slow frequencies (delta and theta) with the higher frequencies (alpha and beta) emerging with age (Gasser, Verleger, Bacher et al., 1988; Harmony, Marosi, Diaz de Leon et al., 1990b). The decreases in the lower frequency bands occur in the first years of life, whereas the increases in alpha typically continue until early adolescence, while beta continues to mature until adulthood. EEG coherence in childhood shows two types of change: continuous growth processes, and discrete growth spurts in specific anatomical locations and at specific postnatal periods. Using this measure, it emerged that the left and right hemispheres develop at different rates and with different postnatal onset times (Thatcher, 1992; Thatcher, Walker, & Giudice, 1987).

EEG maturation in posterior brain regions is almost twice as fast as that seen at central sites (Benninger, Matthys, & Scheffner, 1984) and is slowest over frontal regions (Gasser et al., 1988), where the process continues until late adolescence. These EEG changes are in keeping with the patterns of cortical maturation derived from quantitative magnetic resonance imaging (MRI) (decreases in cortical thickness or gray matter density (Toga, Thompson, & Sowell, 2006). The latter changes may contribute to the decrease across childhood in the overall amplitude of the EEG signal, in addition to changes in skull thickness.

**Quantitative EEG Findings in Developmental Disorders**

The resting EEG spectral measures have been used in comparisons of children with normal cognitive development with children with learning disabilities (Harmony, Marosi, Becker et al., 1995), dyslexia (Klimesch, Doppelmayr, Wimmer et al.,...
Event-related Potentials – Markers of Cognitive Processing

Introduction and Basic Principles

ERPs are now an established technique in studying neural correlates of specific cognitive operations. We review some general principles of this method and give brief examples of their application in clinical research settings. The reader will find more comprehensive reviews on ERP methodology by Luck (2005) and Handy (2007). ERPs constitute the stimulus-locked part of the EEG elicited by a specific cognitive or motor event or stimulus (cf. EP; see p. 237). Therefore, ERPs are modulated by task instructions (e.g., detection of a specific target event) more than by physical properties of the eliciting stimulus.

Task-specific modulations of the ERP wave shape (i.e., increases or decreases in amplitude) are called ERP components, which are best identified in difference waves. ERPs are direct neural measures of functional integration in the brain which can be elicited at distinct hierarchical processing stages: from sensory perception, attention to specific stimulus features, contextual event integration (e.g., recognition memory, emotional evaluation) to the planning and execution of a motor response (see p. 244).

ERP at the Interface of Neurophysiology and Cognitive Neuroscience

Up to the 1980s ERPs had been used as a physiological addition to behavioral measures such as reaction time which allowed a further dissection of processing stages and their modulation by task instructions. Today, armed with a whole array of new methods, ERPs can be used to answer very specific questions, utilizing the unique properties of this method in comparison with functional imaging. The advantages of ERPs are chiefly their temporal resolution (in milliseconds), their direct neural origin (as opposed to the hemodynamic nature of the fMRI signal) and the relative inexpensiveness of the method. Their low spatial resolution necessitates independent converging evidence from other methods, if inference about activity in specific cortical regions is of interest. It is important to bear this limitation in mind when interpreting ERP studies. ERPs also allow the examination of covert (unattended) processing in the absence of a behavioral response, which is useful in studies of infants and children with behavioral problems.

Methods of ERP Registration and Analysis

ERPs are recorded using similar apparatus as conventional EEGs and EPs, except that different filter settings are used to capture some of the slower event-related changes in ERP signals, called slow cortical potentials. General guidelines and recommendations are available for the recording and analysis of ERPs (Picton, Bentin, Berg et al., 2000).

In addition to ERP activity that is tightly time- and phase-locked to the stimulus, there are also systematic stimulus-related EEG changes that are not tightly phase-locked to the stimulus. These “stimulus-induced oscillations” (event-related synchronization [ERS] or desynchronization [ERD]) can be observed in a variety of experimental conditions and across the entire EEG spectrum, ranging from induced theta changes during memory processes to high-frequency gamma oscillations during perceptual tasks.

Estimation of ERP Generators

Using techniques such as MEG or multielectrode EEG, it is possible to estimate the likely location of cortical electrical generators from the scalp distribution of magnetic fields and electrical potentials, respectively. However, this method of inverse source modeling yields no unique solution and its application is therefore limited to research settings where converging evidence can be obtained from a priori anatomical knowledge, or increasingly obtained from functional neuroimaging.

Intracranial ERP Recordings

A more accurate estimation of cortical ERP generators is possible when electrodes are inserted directly into the brains...
of neurosurgical patients for whom such invasive procedure is performed for localization of epileptic seizure activity (see p. 237). Intracranial ERPs (iERPs) are extracted from the electrocorticogram (ECoG) in much the same way as from scalp EEGs, except that their voltage is much larger (up to 150 μV) as the attenuating influence of skull and skin is removed. Intracranial ERPs have a high spatial resolution, in contrast to scalp ERPs, with components usually visible only in very few adjacent electrode contacts, spanning a few square centimeters, with steep amplitude gradients, suggesting close proximity to the cortical generators.

In addition to providing insights into the functional anatomy of ERPs, this method is also used clinically in neurosurgical patients to provide information about the proximity of functional cortex to the site of surgical resection. For example, iERPs recorded from medial temporal regions are used as diagnostic markers of the functional integrity of the hippocampal formation before temporal lobe surgery. They reveal the laterality of verbal memory processes (Grunwald, Lehnertz, Helmstaedter et al., 1995) and predict the impact of temporal lobe resection on postoperative verbal memory (Grunwald, Lehnertz, Helmstaedter et al., 1998). Intracranial ERPs recorded from the cortical surface help identifying sensory cortices (Liasis, Towell, & Boyd, 1999), as well as eloquent motor and language-related regions.

Cognitive Processing Stages and Functional Anatomy of Associated ERP Components

Our knowledge of the functional neuroanatomy of ERPs has been advanced largely by systematic sampling by intracranial ERPs of a large number of brain sites in neurosurgical patients (Halgren, Baudena, Clarke et al., 1995; Halgren, Marinkovic, & Chauvel, 1998). Two types of task have been used, which are also frequently used in ERP studies from the intact scalp. The first type is a simple target detection task where a sequence of frequent non-target stimuli is presented, and among them occasional (oddball) targets have to be detected. This oddball task gives rise to a well-known sequence of ERP peaks (N1, P2 to non-targets, and additional N2, P3a and P3b and slow wave to targets). Stimulus classification tasks have been used to examine the modulation of long-latency intracranial ERP components (N4, P3b) by emotional and semantic context.

The following basic processing stages can be delineated, characterized by distinct ERP patterns, which follow a hierarchical pattern arising from sensory cortices extending to multimodal, association and premotor cortices (Halgren & Marinkovic, 1995) (Plate 17.1). Examples of their respective applications in clinical research studies are given further below (see p. 245).

1. Perceptual processing in primary and secondary sensory cortices is reflected in a sequence of positive and negative polarity sensory components (P1, N1, P2) from approximately 50 to 200 ms poststimulus.

2. Orienting and attention to surprising or biologically important stimuli is reflected in a triphasic N2–P3a–slow wave complex. This orienting complex is generated concurrently in the cingulate gyrus and connected lateral prefrontal and posterior parietal cortices, known to subserve attentional control. Similar potentials are also elicited in the absence of attention to the stimuli (see p. 245).

3. Event encoding of attended semantic stimulus information and integration within the cognitive and emotional context are reflected in long-latency “endogenous” ERP components N4 and P3b in the hippocampus, amygdala and associated inferotemporal and lateral orbitofrontal cortices.

4. These stimulus-locked ERP components are followed by potentials reflecting response preparation and execution, readiness potentials in the central cingulate gyrus and associated supplementary and premotor cortices. Potentials correlated with response execution are the lateralized motor potentials in sensorimotor regions.

5. ERP components arising immediately after response execution are correlated with performance monitoring of successful or erroneous actions. Error-related negative potentials (ERNs) are generated in medial frontal (cingulate cortex) regions involved in performance monitoring (see p. 246).

6. Sustained slow cortical potential shifts (SCP), recorded mainly over prefrontal regions, reflect the maintenance of a sustained cognitive context during task execution.

7. Among ERPs associated with language processing is a late negativity recorded over central scalp electrodes (N4) elicited by semantic expectations in left anterior medial temporal cortex. Syntactic violations elicit a short latency (300–500 ms) left anterior negativity (ELAN) and a late posterior positivity (P600).

Developmental ERP Changes from Infancy to Adulthood

ERP components reflecting increased processing efficiency and speed; and

3. ERP amplitude changes reflect the number of synaptic elements synchronously activated. These amplitude changes can be non-linear across age, showing distinct peaks during infant development, which may index developmental periods of synapse formation and elimination.
Maturation of Auditory Cortices are Reflected in Auditory ERPs

The maturational changes of auditory ERPs have been well documented in infancy and childhood (Wunderlich & Cone-Wesson, 2006), showing a protracted time course which extends into the second decade of life. The protracted developmental course of auditory ERPs is paralleled by an extended neuroanatomical maturation of human auditory cortex. Maturity of the auditory cortical architecture is not reached until after 12 years of age, which might explain the prolonged development of certain auditory processing skills, such as frequency discrimination and speech recognition (Moore, 2002).

In children and adults, the most prominent auditory ERP component is the N1 wave, which is composed of at least three distinct subcomponents. These N1 components show different developmental changes, and hemispheric differences were found, with one of these components over the left hemisphere maturing earlier than over the right side. This precocious development of the left auditory cortex is even more pronounced for speech stimuli than for pure tones.

ERP Investigation of Developmental Disorders

In the following sections we review examples of ERP studies of auditory perceptual functions (reflected in mismatch negativity [MMN]), attention and event encoding (P3) and response execution (ERN). The objective is to demonstrate the limitations and the nature of insights that can be obtained from ERP studies. The ERP findings are not clearly shown to be specific to the disorders reviewed here, nor do they characterize all people with such developmental conditions.

Aberrent Auditory Cortical Maturation in Developmental Disorders

Some studies using ERPs to simple sound stimuli have suggested altered maturation of auditory cortices in a number of developmental disorders. Dyslexic children showed a lack of hemispheric lateralization in early auditory magnetic fields in a study by Heim, Eulitz, and Elbert (2003), perhaps related to a lack of planum temporale asymmetry. In children with specific language impairment (SLI), ERP evidence points to impaired auditory maturation (Bishop & McArthur, 2004). Furthermore, Bruneau, Roux, Adrien et al. (1999) reported that N1b and N1c are abnormally small in autistic children with poor verbal communication and lack the normal modulation by sound intensity, suggesting dysfunction in auditory association cortex in the lateral part of the superior temporal gyrus, especially in the left hemisphere.

Maturation of Sound Discrimination Reflected in Mismatch Negativity Potentials

When ERPs to frequently presented sounds (standards) are subtracted from those to occasional sounds deviating in any physical feature such as frequency, location or duration (deviants), the difference potentials show an early negative deflection at around 100–200 ms, called mismatch negativity (MMN). MMN indexes an automatic auditory change detection (discrimination) process as it is elicited in the absence of overt attention to the sounds (Naatanen, 1992). Its magnitude and latency correlate well with behavioral sound discrimination performance. MMN potentials emerge early during postnatal development, being robust by about 6 months (Jing & Benasich, 2006). There is further developmental change in MMN latency, magnitude and topography, which can index the acquisition of sound representation for the native language during infancy (Cheour, Čepuniene, Lehtokoski et al., 1998). MMN has proved an important tool in the investigation of children at risk of impaired speech and sound discrimination, such as dyslexia (Maurer, Bucher, Brem et al., 2003; Pihko, Leppanen, Eklund et al., 1999), SLI (Shafer, Morr, Datta et al., 2005; Uwer, Albrecht, & von Suchodoletz, 2002), autism (Gomot, Giard, Adrien et al., 2002; Kuhl, Coffey-Corina, Padden et al., 2005) and non-specific learning difficulties (Kraus, McGee, Carrell et al., 1996).

Despite significant differences being found between clinical and control groups, the application of MMN to developmental disorders on an individual patient basis is still limited by low intrasubject reproducibility. Nevertheless, encouraging clinical utility of MMN has been shown in cochlear implant users (Ponton, Eggermont, Don et al., 2000; Singh, Liasis, Rajput et al., 2004), indicating that MMN can be used to assess the functional status and plastic potential of the auditory system in children with cochlear implants and that it may provide an objective predictor for long-term behavioral outcome.

MMN Potentials as Markers of Aberrent Cortical Plasticity

MMN is also a robust biological marker of schizophrenia (for review see Umbricht & Krijès, 2005), and shows some specificity for this disorder, in as much as MMN generation is normal in patients with bipolar (manic-depressive) illness. MMN is also reduced in relatives of patients with schizophrenia, both in childhood and adulthood, suggesting that it is a trait marker for this disorder. This is also supported by premorbid MMN deficits in children and adolescents at high risk for schizophrenia (Baker, Baldeweg, Sivagnanasundaram et al., 2005; Schreiber, Stolz-Born, Kornhuber et al., 1992). The considerable interest in its application to schizophrenia arose from the observation that MMN is abolished after blockade of N-methyl-d-aspartate (NMDA) receptor dependent synaptic transmission, a receptor system implicated in cognitive symptoms of this disorder. Furthermore, NMDA receptors are also critical for many forms of cortical plasticity. It was therefore not surprising to find that MMN deficits in schizophrenic patients correlate strongly with measures of illness severity and cognitive performance. Indeed, there is a remarkable convergence between the neurophysiological mechanism of MMN generation in supragranular layers (II/III) of the auditory cortex (Javitt, Steinschneider, Schroeder et al., 1996), on the one hand, and the site of most consistent neuropathological abnormality in glutamatergic synapses located in these cortical layers in schizophrenia (Harrison, 1999). MMN is simpler than other ERPs, and can therefore be studied not only in humans but also in experimental...
animals (Umbricht, Vyssotki, Latanov et al., 2005), offering the opportunity to study in more detail the cellular and molecular mechanisms of this important aspect of synaptic pathology of schizophrenia.

Development of Face Processing in Healthy and Autistic Children
Faces are the most important visual stimuli for social interactions and specialized neural modules for processing of human faces have been identified with intracranial ERP in inferior temporal cortex (fusiform gyrus) (Allison, Puce, Spencer et al., 1999). Scalp recorded ERPs show a face-sensitive N170 component at posterior temporal leads. This N170 is sensitive to various types of facial stimuli and the emergence of such expertise has been studied in infants and children, demonstrating a prolonged maturational course of its neural substrate (i.e., shortening of N170 peak latency). Differing developmental curves for upright and inverted faces argue that the development in face processing is brought about primarily by improvement in configurational processing. Of interest are reports of aberrant face ERPs in children with autism: the N170 is slower by about 20 ms and ERPs fail to differentiate between familiar and unfamiliar faces, although recognition for objects is intact. Furthermore, in 3- to 4-year-old children with ASD, ERPs failed to show a recognition effect to facial emotions (fear) which is normally present from 7 months of age (Dawson, Webb, Carver et al., 2004). In summary, face ERPs can offer unique insight into maturation of specific pre-verbal cognitive skills in children and their early developmental aberration.

Deficits in Attention and Event Encoding are Reflected in P3 Potentials
P3 potentials are a family of ubiquitous long-latency positive potentials in response to biologically important or attended stimuli. Surprising and novel stimuli elicit a fronto-central positivity (P3a or novelty P3) at 300 ms poststimulus, while expected target events elicit a posterior parietal P3b (or target P3) component at 300–500 ms. The novelty P3a may be altered in children with autism, especially in response to speech sounds (Lepisto, Kujala, Vanhala et al., 2006). Furthermore, there is considerable evidence that P3b generation is abnormal in schizophrenia (as well as possibly in autism and ADHD; e.g., Mathalon, Ford, & Pfefferbaum, 2000), perhaps reflecting dysfunction in an extended cortico-limbic system, centered on the hippocampus, with top-down feedback from higher level regions. In summary, endogenous ERPs, including P3 potentials, hold promise in identifying abnormally developing brain systems early during child development.

Maturation of Cognitive Control Indexed by Error Negativity Potentials
A number of ERP components are associated with cognitive control functions, such as inhibiting a prepotent response, and monitoring the outcome of actions. The stimulus-locked frontal N2 and P3a ERP components are associated with the former operations (i.e., the initiating of inhibitory control or “braking mechanism”). Performance errors are associated with a distinct error-related negativity (ERN) potential time-locked to the incorrect response. ERN is elicited in medial prefrontal cortex (dorsal anterior cingulate gyrus) within 100–200 ms of the executed motor response, indexing a very rapid comparison process between intended and executed actions (Falkenstein, Hohnsbein, Hoorman et al., 1991; Gehring & Knight, 2000). ERN potentials show a protracted developmental course from childhood to adulthood (Hogan, Varga-Khadem, Kirkham et al., 2005), reflecting the late maturation of executive control functions. Children with ADHD show marked deficits in eliciting ERP responses (N2 and P3a) associated with response inhibition and error detection (ERN) (Liotti, Pliszka, Perez et al., 2005). The ERP data implicate an interconnected network of regions in the frontal lobe and its subcortical projections in dysfunctions of cognitive control in ADHD.

ERP as a Marker of Liability to Disorder
It has been suggested that ERPs might be useful as endophenotypes for the study of genetic factors affecting the risk of psychopathology. Such endophenotypes are thought to reflect the action of risk genes more reliably and directly than symptoms (Gottesman & Gould, 2003). However, it cannot be asserted that ERPs are an endophenotype (see chapter 23), not least because their heritability is not established. One study has found that a functional polymorphism in one of the candidate genes in the deleted region of chromosome 22 (the COMT gene involved in dopamine metabolism) affected both MMN generation and cognitive function (Baker et al., 2005). This polymorphism has also been associated with increased risk of developing psychosis in this population (Gotlib, Eliez, Thompson et al., 2005). Reduced MMN amplitude has been reported in some studies of relatives of schizophrenia patients during both adulthood (Michie, Innes-Brown, Todd et al., 2002) and childhood (Schreiber, Stolz-Born, Kornhuber et al., 1992).

The long-latency P3 component is also changed in schizophrenia (Ford, 1999), as well as in relatives of patients and could also index vulnerability to this disorder (Winterer, Egan, Raedler et al., 2003), perhaps along with genes involved in dopamine transmission (Berman, Noble, Antolin et al., 2006; Gallinat, Bajbouj, Sander et al., 2003). Nevertheless, it is unlikely that even ERPs will directly reflect the action of single genes, given the complexity of brain systems involved in their generation. At best, they offer the potential to study the action of risk genes and their interaction with other factors at the neurophysiological level.

Considerations for the Interpretation of ERP Findings
Because of the limitations of the ERP method (e.g., in localizing activity in specific brain regions), it is necessary to ask: what can be inferred from ERP studies? The following considerations may help in providing some guidance in this complex issue.

The separation of ERPs into distinct processing stages (see p. 244) might imply that neural computations reflected in ERPs
are strictly serial in nature, with activity in higher processing stages beginning after the computations in an earlier lower level stage have been completed. However, endogenous long-latency ERPs with a widespread scalp distribution, such as P3a, P3b and N4, have multiple, concurrently active intracerebral generators. This could reflect parallel and independent processes, or alternatively, interdependent processing. The experimental evidence on P3 potentials supports the notion of parallel but independent processing (Halgren, Marinovic, & Chauvel, 1998). ERP studies in patients with discrete lesions of the medial temporal cortex, dorsolateral prefrontal cortex or posterior parietal cortex showed impaired P3a generation, correlated with deficits in orienting attention to novel events (Daffner, Scinto, Weitzman et al., 2003; Knight, 1996). These findings cannot be explained if the intact cortical P3a generators operate independently of generators in regions affected by lesions; the findings therefore support the notion of at least partial interdependence of the components of the attention network involved in P3a generation. It is therefore more helpful to think of ERPs as providing insight into the neural interaction of brain systems, rather than in localizing dysfunction in specific neuroanatomical systems. We return to this notion further below.

However, ERPs are generated in more widespread areas than are necessary for the performance of a specific task (Halgren, Marinovic, & Chauvel, 1998). For example, lesions of the hippocampus, where the largest P3b potentials are generated, do not interfere with performance in the simple oddball discrimination task used to elicit such P3b potentials (Polich & Squire, 1993). This hints at redundancy in brain activation to engage many potentially useful regions, even though they might not be required to perform the task. In such cases, it is only possible to infer from an ERP deficit in a particular patient group that the neural substrate involved in its generation is compromised. The nature of the compromise cannot be directly inferred, and requires independent evidence.

Indeed, it is necessary to ensure that ERPs are recorded during tasks that can be performed by all patients. Otherwise, interpretation of ERP correlates of a specific cognitive operation of interest is complicated by the possibility of dysfunction in an antecedent process. For example, if the neural substrate for event integration is of interest, as measured with P3b potentials, it is necessary to ensure that the sensory discrimination necessary to identify target stimuli from background non-target stimuli can be performed with high accuracy.

**Future Directions**

**Integration with Other Neuroscience Methods**

Neurophysiological techniques are continually developing and current trends indicate that they are increasingly being applied in combination with other neuroimaging modalities. The application of MEG is likely to increase in specialist research facilities for specific clinical applications. For example, MEG can aid in localization of cortical generators of sensory evoked potentials and epileptic spikes. Furthermore, there is tight coupling between intracortical electrical field potential generation and fMRI signal changes (Logothetis, Paules, Augath et al., 2001), which facilitates the combination of both methods (e.g., in estimating the sources of ERPs using fMRI constrained source modeling). The technology of combined EEG and fMRI measurement is rapidly improving and the first clinical studies were able to identify brain areas activated concurrently with interictal epileptic spikes (Krakow, Woermann, Symms et al., 1999). The combination of EEG and ERP recordings with transcranial magnetic stimulation (TMS) has potential for investigations of pathological spread of activation and in evaluating if cognitive operations can be interrupted or facilitated with focal cortical stimulation. Furthermore, as our understanding of the neurophysiological mechanisms and cognitive correlates of different brain rhythms increases, there will be a need to extend the frequency range of EEG recordings beyond what is currently being used in clinical practice, from very slow (<1 Hz) to very high frequencies (>100 Hz). The latter high-frequency oscillations are of particular relevance to seizure initiation and spread (Traub, Contreras, & Whittington, 2005). In addition, further elucidation of the functional role of rhythmic activity in synaptic plasticity and shaping of neural connections will allow us to make inferences from EEG/ERP time-frequency dynamics about their role in the psychopathology of the developing and mature brain. This endeavor will be critically informed by another recent innovation, the application of methods of computational neuroscience to neurophysiology, which is summarized briefly below.

**Computational Models and Synaptic Plasticity**

We predict that neurophysiological methods will be instrumental in our understanding of the nature of the computations performed by the human brain. Because of the enormous complexity of brain architecture such insights are likely to be informed by theoretical perspectives afforded by computational sciences. Such an approach might enable us to understand disorders of the brain and mind that have so far eluded conventional methods of analysis. A critical step in this direction would be a deeper understanding of the principles of cortico-cortical interactions, thought to be at the core of disorders such as schizophrenia and autism. ERPs are markers of neural mass action in the brain generated concurrently in multiple brain regions and might therefore reveal the nature of cortico-cortical interaction between those distinct generators and their presumed disruption in psychopathology. Indeed, a formalized mathematic model of cortical computation has been proposed which makes direct predictions about the behavior of EEG and ERP components (Friston, 2003, 2005). This biologically constrained computational model is based on knowledge of cortico-cortical connectivity, such as feedforward, backward and lateral connections, well characterized by anatomical studies (Felleman & Van Essen, 1991) and the role of neuromodulators in dynamically shaping synaptic plasticity.

Furthermore, recent developments in statistical evaluation of EEG/ERP responses allow inferences to be made about the
nature and strengths of cortical connectivity between hierarchical interconnected cortical regions. The method of dynamic causal modeling (DCM; David, Kiebel, Harrison et al., 2006; Friston, Harrison, & Penny, 2003) is based on neural mass models representing hierarchically connected cortical areas and makes realistic assumptions about the neuroanatomical nature of cortico-cortical connectivity. A further critical step in understanding aberrant cortical plasticity that might underlie developmental psychopathology is the study of neuromodulation of ERP dynamics. Given the highly heritable nature of interindividual variants of the normal EEG pattern (Vogel & Propping, 1982) and the considerable proportion of neurophysiological variability (EEG frequency spectrum and P3 potentials) that is influenced by genomic variation (van Beijsterveldt & van Baal, 2002), it can be expected that a combination of genetic and ERP markers of disrupted brain physiology could guide and predict individual patient’s response to treatments (Stephan, Baldeweg, & Friston, 2006). Hence, an increasing convergence of neuroscience methodologies, including neurophysiology, will aid the development of an informed view on the pathophysiology of developmental psychological disorders.

CHAPTER 17

In this chapter we provide a selective overview of the field of child and adolescent psychotherapy. We begin with a historical perspective, discuss how treatment of children differs from treatment of adults, note how researchers assess the effects of treatment and then summarize some of the findings of that research. Finally, we note some strengths and limitations of the evidence base, and highlight some critical debates for the field.

### Child and Adolescent Psychotherapy in Historical Context

It is not clear when psychotherapy began, but its roots can be found as early as the classical Greek era, when human discourse was used as a means of exploring and examining the life of the mind. As one example, Socrates’ (469–399 BCE) philosophical dialectic, later labeled the “Socratic method,” involved questioning others in order to stimulate introspection into their beliefs. Socrates believed that the philosopher’s role was to “deliver” truth that resided within others, much like a midwife delivers a baby from within its mother. By asking questions of others – rather than telling them what to think – Socrates sought to plumb their capacity for feeling, desire and reasoning. This ancient “midwife thesis” still informs many modern therapists’ approach to helping others. In addition, Socrates’ belief that the inner life of the mind and outward behavior are inextricably connected foreshadowed a tenet of many modern therapies. Although the term psychotherapy is relatively new historically, the general idea harkens back to the ancient tradition of questioning, discussing and listening as means of nurturing understanding and change.

Centuries of subsequent work in philosophy, religion, medicine and other contemplative and healing traditions have given rise to a myriad of practices encompassing meditation, expert instruction, subtle suggestion, hypnosis and persuasion (Shapiro & Shapiro, 1982). Today, a vast array of non-medical interventions are considered psychotherapies, with the common objective of easing subjective distress, decreasing maladaptive behavior or increasing adaptive behavior.

The notion of psychotherapy as a profession can be traced back about a century (Freedheim, Freudenberger, & Kessler, 1992). A case can be made that contemporary psychotherapy grew out of the work of Sigmund Freud (1856–1939). Important themes in this work were the notions that early experience can be critical, and that even children may be appropriate candidates for intervention. Indeed, child psychotherapy can be credited in part to Freud’s consultation with the father of “Little Hans” and the psychoanalysis of his own daughter, Anna (1895–1982), who became a prominent child analyst in her own right. Anna Freud – and others, such as Berta Bornstein (e.g., 1949) – applied psychoanalytic precepts and methods to children and adolescents well into the mid-1990s.

The rapid growth of child psychotherapy was also fueled by very different models and methods, including a radically divergent behavioral approach. Jones (1924a,b), for example, used behavioral modeling and “direct conditioning” to help a 2-year-old boy overcome fear of a white rabbit, and this helped launch a more structured, environmentally focused approach to child psychotherapy. Such behavioral therapies for young people developed alongside psychoanalysis and humanistic treatments. Later, Beck (1964, 1970, 1971) construed cognition as an antecedent to affect, constructing cognitive therapy, and Meichenbaum and Goodman (1971) helped launch cognitive–behavioral therapy for children. By the late 20th century, child psychotherapy had expanded remarkably in the variety of its forms and the extent of its reach. Recently, Kazdin (2002) identified 551 different named therapies used with children and adolescents. Even this large number greatly underestimates the diversity of approaches employed in practice, given the extent to which hundreds of thousands of practitioners eclectically blend different orientations to form distinctive combinations.

### How Child and Adolescent Psychotherapy Differs from Adult Psychotherapy

Adult and child psychotherapy share a common ancestry, and therefore have many similarities. Nonetheless, some substantial differences warrant attention. First, unlike adults,
children rarely perceive themselves as “disturbed” or as needing therapy. Thus, most treatment referrals for children and adolescents are made by parents, teachers or other adults. Typically, adults contract for therapy, pay the bill and identify some or all of the goals the therapist pursues. Although children may participate to some degree, they often exert less ultimate influence than the adults involved. In short, the child in many therapies is “the patient,” but the parent or another adult is often “the client.” With the therapy initiated and commissioned by adults, it is not surprising that children often begin the process with less motivation for treatment and for personal change, or at least with different objectives, than those of the adults involved. Indeed, in one study in which clinically referred children and their parents were asked separately to identify the problems for which the child needed help, 63% of parent–child pairs failed to agree on even a single problem (Yeh & Weisz, 2001).

A related difference between child and adult therapy resides in the sources of information the therapist uses to plan and monitor treatment. Because the self-awareness, psychological mindedness and expressive ability of children are limited developmentally, child therapists must rely on adults for information about the youngsters they treat, and this can present several unique challenges. The accuracy of parent and teacher reports may be compromised by incomplete opportunities to observe children in multiple settings, by distorted comparison samples of child behavior, by the influence of undetected adult agendas (e.g., help-seeking, leading to high levels of reported problems, or fear of reports to child protective services, leading to underreporting of problems) or by the effects of parents’ own life stresses or mental health problems (Kazdin & Weisz, 1998). Moreover, rates of agreement among different adult informants reporting on the same child tend to be low (Achenbach, McConaughy, & Howell, 1987), further muddling the picture of what most needs attention in treatment. Additionally, adults’ reports of child behavior and identification of reasons for referral are apt to reflect the values, standards, practices and social ideals of their cultural and identification of reasons for referral are apt to reflect the values, standards, practices and social ideals of their cultural reference group (Weisz, McCarty, Eastman et al., 1997). Because child therapy involves multiple stakeholders (e.g., child, parents, school personnel), each of whom may have different motivations, perceptions and goals, establishing the target of intervention – and the outcomes that will be used to index treatment success – may be a complicated process, in comparison with the process for therapy with individual adult clients.

A third remarkable difference between adult and child treatment relates to environmental impact. To a much greater extent than with adults, children are captives of their external engineered environments. The family, school and neighborhood contexts in which children live are typically determined by others. By extension, the “pathology” or “dysfunction” being treated may arise as much from a less-than-optimal environment – which the child can neither escape nor alter significantly – as from processes within the child. The powerful impact of such factors as socioeconomic status, family configuration, family conflict and life stressors on child functioning at home, school and with peers may constrain the impact of interventions that focus on the child as solo or primary participant, highlighting a need to involve key members of the child’s social context in intervention (Henggeler, Schoenwald, Borduin et al., 1998).

Assessing the Effects of Psychotherapy

The child therapist habitually faces a number of obstacles that are much less likely to be confronted by those who treat only adults. It would therefore be naive to assume that an effective adult therapy will automatically succeed with children. Instead, a separate treatment literature with a separate body of treatment outcome research is required. More than 500 named therapies are practiced with youths (Kazdin, 2002), and countless other variations are created by eclectic therapists; however, only a small proportion of therapies in use have been subjected to empirical test, at least in the venerable form of randomized clinical trials (RCTs). In marked contrast to the rapid growth of psychotherapy practice over the past century, research examining the effects of psychotherapy took shape slowly. In 1952, Eysenck published his important review of studies of adult psychotherapy, raising serious doubts about whether therapy was effective. A few years later, Levitt (1957, 1963) reviewed studies that included children and concluded that rates of improvement in the youth were about the same with or without treatment. These early reviews were influential – and distressing – but the methodology of the studies they relied on was not rigorous by today’s standards. Since those landmark reviews, research has grown more stringent and abundant (Durlak, Wells, Cotton et al., 1995; Kazdin & Weisz, 2003). Furthermore, the focus of treatment research with children and adolescents has been honed, shifting from early studies of unspecified “treatment” for often vaguely defined youth problems to trials of well-operationlized therapies targeting specific patterns of dysfunction. Thus, we are now in a position to benefit from a large and increasingly rigorous body of evidence on youth psychotherapies and their effects.

Forms of Evidence

Evidence on the effects of child treatment comes in several forms. The most widely recognized of these is the RCT, an outcome study wherein children with a particular target problem (e.g., antisocial behavior or an anxiety disorder) are randomly assigned to groups that either receive a candidate intervention, a control condition (e.g., waitlist or an attention-only group) or sometimes an alternative intervention. After the intervention phase, outcome measures assessing the target problem are compared across the different groups. It is these RCTs that are most frequently pooled in reviews and meta-analyses (see p. 253) and constitute most of the evidence discussed in this chapter. However, other approaches to outcome assessment should be noted. In circumstances where all the children with a particular condition must receive an
active treatment, multiple baseline designs, ABAB (sometimes called “reversal”) designs, and related designs are useful. In multiple baseline designs, treatment onset is delayed for different periods of time for different youths (or different target problems within the same youth); if the timing of improvements corresponds to the timing of treatment, treatment benefit may be inferred. In ABAB designs, treatments are alternately introduced and withdrawn for the same youth, or the same group; if improvement corresponds to times when the treatment is in place, and improvements disappear when the treatment is withdrawn, then beneficial treatment effects may be inferred. Multiple baseline and ABAB designs – and variations on these approaches – are often used in treatment research with attention deficit/hyperactivity disorder (ADHD) youth (Pelham, Carlson, Sams et al., 1993), in studies where an entire classroom needs to receive an intervention (Wurtele & Drabman, 1984) and in cases (sometimes involving rare conditions) where only one or two children are treated (McGrath, Drabman, 1984) and in cases (sometimes involving rare conditions) where only one or two children are treated (McGrath, Dorsett, Calhoun et al., 1988; Tarnowski, Rosen, McGrath et al., 1987). These alternative outcome assessment designs have generated a rich body of outcome data that, unfortunately, still await an enterprising reviewer. For now, we focus on the clinical trials research, which has been the focus of considerable review.

Narrative and Quantitative (Meta-analytic) Approaches to Evidence Review

The ever-expanding body of RCT research has been examined periodically through both narrative and quantitative reviews of outcome findings. Narrative reviews (Kazdin, 2000; Shirk & Russell, 1996) can bring the perspectives of thoughtful experts to bear on what the outcome findings show, and the strengths and limitations of those findings. As an example, Kazdin’s (2000) scrutiny of the research on youth treatment led to a detailed appraisal of what has and has not been learned, and Shirk and Russell (1996) focused their narrative review in part on what treatment research has told us about pathogenic processes and mechanisms of change in treatment. Both reviews led to useful recommendations for individualizing and improving treatment for children and adolescents.

Another approach to reviewing outcome research is quantitative review, most often in the form of meta-analysis. Meta-analyses provide a synthesis of the evidence, with the effects of multiple studies pooled to generate an overall picture of average treatment impact. The hard currency of meta-analysis is the effect size (ES; for group comparison studies: $ES = [M_{treatment} - M_{control}] / SD_{outcome}$), an index of the strength and direction of treatment effects. Many in the field follow Cohen’s (1988) guidelines for interpretation of effect size, wherein an ES of 0.20 may be considered a “small” effect, 0.50 a “medium” effect and 0.80 a “large” effect. Averaging across the various outcome measures used, meta-analysts can compute a mean ES for each study, or each treatment-control comparison, and in turn an overall mean ES for an entire collection of studies (Mann, 1990). Mean ES may also be compared across groups of studies that differ in potentially important ways (e.g., the types of therapy employed, or the ages of the youngsters treated).

Findings of Meta-analyses

To date, there have been four particularly broad-based youth psychotherapy meta-analyses – that is, meta-analyses in which few restrictions were imposed on the disorders of interest or types of intervention included. Casey and Berman (1985) surveyed treatment trials published between 1952 and 1983, involving children aged 12 and younger. Among the studies that included treatment-control comparisons, the mean ES was 0.71, indicating that the average treated child was doing better after treatment than 76% of the control group children. In a second meta-analysis, Weisz, Weiss, Aliche et al. (1987) included outcome studies published between 1952 and 1983, with youth aged 4–18 years. This synthesis yielded a mean ES of 0.79; following treatment, the average treated child was better off than 79% of control group peers. In a third meta-analysis, Kazdin, Bass, Ayers et al. (1990) included studies published between 1970 and 1988, with ages 4–18. For studies comparing treatment groups to no-treatment control groups, mean ES was 0.88, with the average treated child better after treatment than 81% of the no-treatment comparison group. For the subset of studies comparing treatment groups to active control groups, mean ES was 0.77, with the average treated child functioning better after treatment than 78% of the control group. In the fourth meta-analysis, Weisz, Weiss, Han et al. (1995) included studies published between 1967 and 1993, with ages 2–18; mean ES was 0.71; after treatment, the average treated child was functioning better than 76% of the control group.

These four meta-analyses indicate uniformly beneficial treatment effects. ES values ranged from 0.71 to 0.84 (estimated overall mean for Kazdin et al., 1990), with an average just below Cohen’s (1988) threshold for a “large” effect, and within the range of what has been found in two widely cited meta-analyses of mostly adult outcome studies (Shapiro & Shapiro, 1982; Smith & Glass, 1977). It should be noted, however, that: (a) analyses in Weisz et al. (1995) suggest that, with weighting to correct for sample size and heterogeneity of variance, ES means may be closer to “medium” rather than “large” effects; and (b) findings by McLeod and Weisz (2004) supported the notion that publication bias favoring studies that show beneficial effects may have inflated our picture of the mean impact of treatment. However, even when we focused on dissertation studies, which did not go through journal peer review, the results showed beneficial treatment effects (McLeod & Weisz, 2004).

Two other meta-analytic findings warrant attention here. First, we have found (Weisz et al., 1987, 1995) that effects measured immediately after treatment are quite similar to effects measured at follow-up assessments, which average 5–6 months after post-treatment assessment points. This suggests that the benefits of treatment for youth are reasonably durable. However, a recent meta-analysis that focused specifically on treatment of depression in children and
adolescents (Weisz, McCarty, & Valeri, 2006b) found beneficial effects fading out by 1 year post-treatment among the small number of studies that extended follow-up assessment that far. This may suggest a need for booster sessions to refresh coping skills, but it may also reflect the fact that major depressive disorder is episodic, such that control groups may improve over time, converging with treatment groups after many months have passed. A second point worth noting concerns the “specificity” of treatment effects. Frank (1973) and others have proposed that psychotherapy has general “non-specific” effects on diverse problems (e.g., by making people feel understood and supported). An alternative view is that therapies help in specific ways, doing the most good with the problems they are designed to address. We have found evidence for the latter view; our analyses (Weisz et al., 1995) showed effect sizes about twice as large for the specific problem domains targeted by a treatment than for other, more incidental domains (e.g., anxiety treatments produced bigger effects on anxiety than on depression). Filling out the picture, Shirk and Karver’s (2003) metaanalysis of 23 studies suggested that such non-specific factors as therapeutic relationship may be moderately related to treatment outcomes, particularly for such internalizing problems as anxiety. It is possible that relatively specific treatment effects may coexist with certain non-specific treatment effects; it may also be true that the relative importance of specific versus non-specific factors depends on the nature of the problem being addressed.

While narrative reviews and meta-analyses are useful in many ways, they are generally designed to characterize a body of evidence, rather than to identify specific treatments that are supported by the evidence. For that kind of identification to take place, a different type of review is needed, entailing a search for specific psychotherapies that have been supported in clinical trials. Complementing the broad-based analyses just described, some meta-analysts have addressed rather specific questions by focusing on select subsets of treatment outcome studies.

**Treatments Showing Replicated Success with Commonly Treated Problems and Disorders**

In this section of the chapter we complement the overall picture of treatment benefit provided through broad-based meta-analyses by identifying some specific forms of intervention that have shown replicated success in RCTs. To do this within space constraints, we focus on a manageable range of the conditions for which treatment is provided; however, we emphasize that psychotherapy for children is used to address a highly diverse array of problems and disorders – many of which we cannot discuss here. The concerns addressed in therapy encompass, for example, enuresis, Tourette disorder, bulimia, autistic disorder, learning disabilities, fire-setting, trichotillomania and even headaches. Rather than attempting to include every treated condition within our review, we focus here on four broad clusters that account for a particularly large proportion of youth referrals for clinical care in most western countries (Jensen & Weisz, 2002; Weisz, 2004) and for which a particularly extensive clinical trials literature exists:

1. Anxiety-related problems and disorders (e.g., social phobia, generalized anxiety disorder);
2. Depression-related problems and disorders (e.g., dysthymic disorder, major depressive disorder);
3. Attentional problems, impulsivity and ADHD; and
4. Conduct-related problems and disorders (e.g., oppositional defiant disorder, conduct disorder).

With a focus on these four clusters, we have searched the treatment outcome database in an effort to identify those psychotherapies for which success has been demonstrated in multiple RCTs.

To provide the most reliable evidence, we sought treatment outcome studies meeting rather uniform standards that were important for our particular purposes; this made our study collection somewhat different from those used in previous reviews. We included studies with children aged 3–18, published between 1965 and 2002. We required that the studies:

1. Include a comparison of psychotherapy to a control group (waitlist, no treatment, placebo or other process intended to be inert) or an alternative treatment;
2. Involve a prospective design and random assignment of subjects to treatment and comparison conditions;
3. Use participants selected for having psychological problems or maladaptive behavior (within the problem clusters noted above); and
4. Include a post-treatment assessment of the psychological problem(s) or maladaptive behavior for which participants were selected and treated.

To ensure a focus on psychotherapy, we selected only those studies in which participants in the groups were not assigned psychotropic medications. A total of 298 studies met our criteria for inclusion. Details of the search procedure and the studies can be found in Weisz, Hawley, and Jensen Doss (2004) and Weisz, Jensen Doss, and Hawley (2005).

**Treatments for Internalizing Conditions**

**Anxiety, Phobias and Fears**

Treatment of child anxiety has a long and rich history, and encompasses a large number of RCTs for children. Three forms of treatment have emerged over this history and have shown especially positive outcomes and particularly well-replicated success.

**Modeling**

One of these is modeling, an approach designed to disrupt the self-sustaining sequence of feared object → anxious thoughts → aversive arousal → avoidance → relief. The distress caused by the feared object or situation can be so powerful, and the sense of relief resulting from avoiding the object or situation can be so rewarding, that alternate forms of behavior simply are not tried – often despite the best efforts of parents and peers. One venerable approach that can help relies on observational learning – exposing the fearful youth to a model who violates
the assumptions underlying the fear. The model tries the feared behavior (e.g., approaching a dog and patting it on the head), thus demonstrating that it can be done without the negative consequences the treated youth had feared. When this approach works, the observer emulates the behavior of the model and thus learns that no adverse effects occur. Studies have shown beneficial effects of modeling interventions, in various forms.

In **live modeling**, the anxious youngster observes a peer, the therapist or some other model engaging in the feared behavior in real time. Across the exposures, the model experiences no adverse consequences and often appears to enjoy the experience. A variation of this approach is **symbolic modeling**, in which video (or some other media product) is used to present a model to anxious youngsters. This approach allows the medium to be reused repeatedly with no worry that the model’s behavior may change in some unwanted way. Finally, in **participant modeling**, the fearful youth performs the feared activities in concert with the model. The approach appears to be particularly potent. In Ollendick and King’s (1998) careful review of anxiety treatments, this was the only modeling method identified as “well-established.” The potency of this approach may reflect the fact that it combines observational learning with the added security of a confident partner plus active encouragement to try the exposure. Across the different variations of modeling, a frequent practice is to start at low intensity (e.g., sitting at some distance from the feared object) and add increments (e.g., moving closer, touching the object, picking it up) gradually.

**Reinforced Exposure**

Another approach to anxiety is **reinforced exposure**. This entails graduated steps of exposure to the feared object or situation, with the youngster rewarded for accomplishing each step. It is commonly believed that reinforced exposure is simply one form of contingency management, in which behavior is altered by changing its consequences (Ollendick & King, 1998). A challenge for the therapist is creating graduated steps of exposure that will be appropriately challenging but not so overwhelming that the youth refuses outright. For some fears of situations (e.g., darkness) the graduating procedure may involve increments in time (e.g., the amount of time the child remains in a darkened room) or degree (e.g., degree of darkness tolerated). For other fears, the gradations may involve a series of increasingly lifelike and direct exposures. As one example, Muris, Merckelbach, Holdrinet et al. (1998) treated spider fears in 8- to 17-year-olds by exposing them to a variety of spiders and progressing from looking at the spiders from a distance to letting the spiders walk on the youngsters’ arms. In the various procedures, rewards follow successful exposures, ranging from praise to concrete incentives.

**Youth-Focused Cognitive–Behavioral Therapy**

Cognitive–behavioral therapy (CBT) has been used extensively to address youth anxiety; indeed, it is the most frequently tested treatment for child anxiety in the RCT literature. As the name implies, CBT entails efforts to identify and alter cognitions that contribute to the anxiety, and also to identify and alter maladaptive behavior (such as avoidance of feared situations) that may serve to sustain the condition. Some forms of CBT have been used in treatment focused on individual youths, others with youths and their family members in various combinations. Applications of CBT at the individual youth level have ranged from procedurally simple approaches using self-talk, typically addressing specific fears, to much more complex multisession programs typically used to address multisymptom anxiety disorders.

**Multicomponent CBT** For anxiety disorders that are more complex than simple phobias, more complex packages of CBT procedures may be needed. There are several examples of such programs, including the Coping Cat program (Kendall, Kane, Howard et al., 1990) and the Transfer of Control Approach (Silverman & Kurtines, 1996) designed for children diagnosed with generalized anxiety disorder, separation anxiety disorder or social phobia. Although different programs vary in some important ways, they often follow a similar treatment course, which begins with psychoeducation regarding the nature and course of anxiety, and how to recognize the somatic, cognitive and behavioral manifestations of anxiety. During this phase, the child learns various coping strategies to manage anxious feelings, such as identifying and modifying anxious cognitions, or relaxation exercises which may include progressive muscle relaxation or deep breathing. Often, an easy-to-recall acronym is used to help children remember the sequence of identifying physical symptoms of anxiety and anxious cognitions, devising a behavioral plan to cope with these feelings, and judging the success of their plan. For example, FEAR in the Coping Cat program, (Feeling frightened? Expecting bad things to happen? Actions and attitudes that help, Rate and reward). Similarly, the acronym STOP is used in another program (Silverman & Kurtines, 1996), and serves to remind children to recognize when they are Scared, identify their anxious Thoughts, refute them with Other, more realistic thoughts, and Praise themselves.

In many CBT programs for anxiety (Albano, Marten, Holt et al., 1995; Kendall et al., 1990) children work with their therapist to identify and rank the feared or phobic situations, and this hierarchy serves as a measure of treatment progress and provides targets for the behavioral exposure phase of treatment. Using graduated exposure, the child and therapist collaboratively work their way through the fears on the hierarchy with the goal of decreasing the maladaptive somatic, cognitive and behavioral responses to the imagined threat.

Variations on the kind of core CBT program just described have been used in a number of creative ways to extend the application of cognitive and behavioral training. Barrett, Dadds, and Rapee (1996) created a CBT-oriented Family Anxiety Management Program to address specific youth anxiety disorders through sessions with parents and child together, and separate sessions for parents as a couple. A unique form of individual CBT has been developed to address
post-traumatic stress disorder and other behavioral and emotional problems in sexually abused children (Deblinger & Heflin, 1996); the non-offending mothers of sexually abused children have been trained to play the part therapists had played in the individual child version of the treatment (Deblinger & Heflin, 1996). The general strategies of modifying anxious cognitions and confronting phobic assumptions via exposure have also been applied successfully to obsessive-compulsive disorder in children, with the added component of response prevention – encouraging the child not to engage in the ritual compulsions that reduce the obsession-triggered distress (Barrett, Healy, Piacentini et al., 2004; March, Frances, Carpenter et al., 1997).

**Depressive Symptoms and Disorders**

We turn now to treatment of depression, a form of dysfunction that tends to be highly correlated with anxiety. Given the close association between these two clusters, perhaps it is not surprising to find that some of the procedures used to good effect with anxiety reappear in the list for depression. Readers interested in the effects of psychotherapies for child depression are referred to a recent meta-analysis on the topic by Weisz, McCarty, & Valeri (2006b).

**Cognitive–Behavioral Therapy**

The most extensively tested and supported approach to youth depression treatment is youth-focused CBT. Of the CBT manuals used, the one with the most ample empirical support, to date, is the *Coping with Depression Course for Adolescents* (CWD-A; Lewinsohn, Clarke, & Hops, 1990). In keeping with its cognitive–behavioral pedigree, the CWD-A program treats depression by addressing cognitive, behavioral and affective skill deficits. To address these deficits, CWD-A therapists teach youngsters how their emotions are related to their thoughts and actions, and encourage them to monitor their moods and track mood–thought–action connections. Participants also learn to:

1. Identify activities they find mood-elevating and increase their frequency;
2. Develop and carry out a personal plan for change;
3. Identify unrealistic negative thoughts and practice replacing those thoughts with realistic, positive counter-thoughts;
4. Deal with stress by using relaxation techniques; and
5. Interrupt negative thoughts, to prevent themselves from getting stuck in unproductive rumination.

In some of their work, the CWD-A collaborators have combined treatment of adolescents with a parallel program for their parents.

**Interpersonal Therapy**

Relatively recent evidence points to beneficial effects of interpersonal therapy for adolescents (IPT-A). The IPT approach (Mufson, Dorta, Wickramaratne et al., 2004; Mufson, Weissman, Moreau et al., 1999) is based on the premise that depression occurs in an interpersonal context, and that an improved understanding and renegotiation of this context can be vital to recovery. Therapy focuses on one or two problem areas, which include grief and loss, interpersonal role disputes, role transitions and interpersonal deficits. Initially, the therapist provides education about the symptoms of depression and how depression is connected to interpersonal processes. Then therapist and youth conduct an interpersonal inventory to understand better the nature of the adolescent’s interactions with significant others, in regard to both satisfying and unsatisfying aspects. A treatment contract is established, and the main problem areas are identified and discussed with the adolescent. In the middle phase, therapist and adolescent work directly on the identified problem areas, and the adolescent is encouraged to monitor depressive symptoms, link affect with interpersonal events, clarify conflicts and styles of communication, and use various strategies (e.g., role play) to try out various forms of behavior change. In the termination phase, the therapist and adolescent work to establish a sense of competence to manage future stressors.

**Relaxation Training**

Two studies have found that relaxation training alone produces significant relief from depression, perhaps by reducing tension and stress, or perhaps through some as yet unassessed biological change. In a common procedure, youngsters learn to alternately tense and relax muscle groups, progressing from one body region to another until most of the major muscle groups are relaxed. For tense situations that arise without warning, or situations in which the child only has a few moments to cope, children may learn techniques for quick calming; one example is “the quick Benson,” which is taught as part of the CWD-A (Lewinsohn, Clarke, & Hops 1990). This method, shown in the box below, requires only that the students have a personal “relaxation word” (such as “calm” or “cool”) and that they have a ready-to-use image of a favorite calming place or situation.

**Treatments for Disruptive Conditions**

**ADHD and Related Problems**

Focusing now on the attention and hyperactivity domain, we should note at the outset that a non-psychological intervention is known to show quite positive acute effects. Stimulant medication (e.g., methylphenidate) has been shown to work...
well in scores of RCTs, and forms of stimulant medication that extend effects throughout a full school day (e.g., Concerta) have increased the popularity of this approach to treatment. However, most studies show that: (i) stimulant medication is not effective (or even safe) for all children; and (ii) stimulants do not eliminate all the symptoms associated with ADHD. Moreover, some parents and children are simply not going to choose medication as a treatment option. For all these reasons, the search for beneficial psychotherapies has continued, and with some success; mean effects, however, have tended to be more modest than mean effects for the other three problem clusters addressed in this chapter. Most of the psychotherapies showing significant benefit in RCTs have been behavioral and cognitive–behavioral. Some have focused treatment on children directly, but others have employed parent training, teacher training (e.g., classroom management programs) or multiple foci including child, parent and/or teacher. We provide here some examples of treatments that have shown respectable effects.

**Cognitive–Behavioral Therapy**

Among the treatments administered directly to youths, we found that CBT is the approach whose beneficial effects are the most widely replicated in RCTs (cf. Pelham, Wheeler, & Chronis, 1998, who reached a different conclusion, based on a different approach to evidence review). Although there were several useful precursors to CBT, many experts credit Meichenbaum and Goodman (1971) with launching this approach to youth treatment. These authors used what they then called self-instructional training to help impulsive second-graders reduce their impulsivity and improve their performance on tasks requiring concentration, including even an IQ test. Across multiple activities, the procedures were designed to teach children to identify the requirements of a task, rehearse the task mentally, guide their own performance through self-talk, and give appropriate encouragement and praise to themselves when they did well.

The Meichenbaum and Goodman (1971) article was followed by an explosion of intervention trials using elements of their procedure and contributing to the genre that has come to be called CBT. As an example, Bender (1976) found that training impulsive first-graders to guide themselves using self-talk led to slower (i.e., less impulsive) responses and fewer errors on a letter- and picture-matching task. Kendall and Wilcox (1980) used their own adaptation of self-instructional training with 8- to 12-year-olds referred by teachers for “problematic lack of self-control that interfered with both personal and classroom performance and general classroom deportment” (Kendall & Wilcox, 1980, p. 81). Children were trained across six 30–40 minute sessions to guide their own behavior on various tasks by:

1. Identifying the requirements of the task;
2. Planning a strategy;
3. Focusing attention on the task;
4. Use of coping statements when mistakes were made; and
5. Self-reinforcement for success at the task.

Afterward, blind teacher ratings indicated that this intervention improved self-control and reduced hyperactivity.

**Relaxation Training, Biofeedback, Metronome Training**

We were rather surprised to find that another class of child-focused interventions that showed beneficial effects on ADHD were those focused on calming or relaxation. For example, Redfering and Bowman (1981) reduced non-attending behavior in “behaviorally disturbed” 8- to 11-year-olds by simply playing tapes with relaxation-meditation instructions for the children, across five half-hour sessions. Porter and Omizo (1984) reported that group relaxation training, together with large muscle exercise followed by rest and deep breathing, significantly reduced impulsivity and improved attentiveness in hyperactive first- and second-graders. In two related studies, Omizo and Michael (1982) and Rivera and Omizo (1980) combined relaxation training with biofeedback in their work with hyperactive children. While listening to parts of a relaxation-induction audiotape, youngsters received visual and auditory feedback (e.g., clicks) from an electromyometer that measured muscle activity in the frontalis area. Children were told that their job was to keep their bodies relaxed enough that the feedback would show a sustained pattern of low activity. Just 3–4 sessions, less than half an hour each, were associated with significantly reduced impulsivity and gains in attention on a post-intervention performance task.

**Behavioral Parent and Teacher Training**

A widely practiced approach to the treatment of problems related to ADHD, such as disruptive and disobedient behavior, involves teaching parents to create and maintain environments in which desirable child behavior (e.g., obeying adults, thinking before acting) is rewarded and undesirable behavior (e.g., disobedience, impulsive acts) is not. This basic concept of contingency management is the centerpiece of a number of different behavioral parent training programs. Because so many ADHD-related problems appear in the school setting, an important complement to parent-training programs is teacher involvement, sometimes in the context of classroom-focused training programs designed to establish and maintain contingencies at school that will reinforce self-control, attention to school work and appropriate social behavior with teachers and peers. Because these programs are used for children with ADHD when it co-occurs with other disruptive behavior disorders, such as oppositional defiant disorder (ODD) or conduct disorder, we will discuss parent-training programs in greater detail in the next section.

**Conduct-Related Problems and Disorders**

Conduct-related problems and disorders are matters of genuine concern in most societies, as well they should be. Considerable evidence indicates that such problems and disorders can presage social dysfunction, including antisocial and criminal behavior which often lasts into late adolescence and adulthood (Moffitt, 1993). The good news is that treatment of conduct-related problems and disorders has received a
great deal of attention in the research literature, and that a number of treatments have shown substantial positive effects which have been replicated in multiple RCTs. Here we focus on a few examples.

**Youth-Focused Operant Treatment**

Treatments placed within the operant category are those emphasizing reinforcement contingencies, including response cost and time out. For example, Autry and Langenbach (1985) succeeded in reducing disruptive fourth, fifth and sixth grade boys’ levels of disruptive behavior in class by rewarding the boys with tokens for such reductions; the tokens were redeemable for items from the school store and for special class privileges, such as free time. In a very different cultural context, Moracco and Kazandkian (1977) were able to reduce disruptive behavior among teacher-referred 7- to 11-year-olds in a Beirut, Lebanon, elementary school by using operant procedures. In a series of behavioral counseling sessions, children were reinforced with praise and attention when they behaved appropriately, and were systematically ignored for inappropriate behavior, with the counselor turning her head away and looking uninterested. Another example of behavior change with operant procedures is found in Jessness’s (1975) report on their use with adjudicated boys in the California Youth Authority. This program involved eight living units for 15- to 17-year-olds. Each unit employed a microeconomy in which appropriate behavior earned institutional “dollars” and points. The dollars could be used to purchase objects, services and recreational activities. Points could accumulate to earn a recommendation for parole and release. Charts showing points earned by each boy were placed in conspicuous locations as an additional form of reinforcement. The program had significant effects on both behavior ratings in the institution and recidivism after discharge.

**Cognitive–Behavioral Therapy (e.g., Problem-Solving Skills)**

CBT for youth conduct problems has taken a variety of forms. We illustrate the CBT approach by focusing on a particularly successful example: Problem-Solving Skills Training (Kazdin, 2003). In essence, this approach is designed to teach aggressive youngsters to use their heads before using their fists. The children, aged 7–13, go through about 20 45-minute individual sessions with a therapist to learn basic steps of problem-solving, practiced initially via familiar games. Youngsters then learn to apply these steps to interpersonal situations, including the kinds of situation that often lead to aggression. The core skills of the program are embodied in five problem-solving steps, presented as five thoughts the youth is expected to review when confronting a problem. Through these steps, children learn to identify the problem, brainstorm more than one possible solution, evaluate the proposed solutions in terms of their likely consequences, make a choice, and then evaluate how successful they were in solving the problem. Children first learn to use these steps in simple games like Checkers and Connect Four; over time the skills are applied to more and more lifelike problems, including social conflicts of the type that have caused problems in the past.

**Behavioral Parent Training**

Parent-focused intervention is the most extensively tested and supported form of treatment for youth conduct problems and disorders, and nearly all of the studies involved have tested behavioral parent training. Although each program has unique characteristics, we discuss common features of some of the programs that have demonstrated beneficial effects, including the intervention procedures developed by Patterson, Chamberlain, & Reid (1982) and Barkley’s (1997) Defiant Children: A Clinician’s Manual for Assessment and Parent Training. In these and related programs, parents learn basic behavioral principles relevant to child rearing, such as the role of attention in the recurrence of both positive and negative behaviors. Parents learn how to define, track and record rates of the antisocial and prosocial behaviors they want to target, and are coached in the design, implementation and refinement of behavior modification programs.

A core idea of these interventions is that children generally act the way they do because they have learned to act that way; much of that learning involves identifying what behaviors are rewarded in their environment, and then doing more of those behaviors. As an example, most children show some kind and generous behavior, but if that behavior is not noticed, praised or rewarded, it will decline in frequency. Most children show some aggressive, oppositional or antisocial behavior at some times; if that behavior is rewarded, even if only by increased attention from the parent, it may increase in frequency.

In behavioral parent training, parents use praise and increased attention to positive child behavior to strengthen their relationship with their child, and increase the rewarding consequences that follow appropriate behaviors by means of token or point systems that lead to tangible reinforcers. To reduce the frequency of unwanted behaviors, parents learn ways of making those behaviors less rewarding; one example is time out, in which the child is withdrawn from opportunities for reward.

Parent-training interventions also stress the need to reduce what are called coercive exchanges between parents and children. For example, some parents speak to their child in ways that lead to hurt feelings, resentment and escalation in conflict. Instead of saying, “Heather, turn off that stupid music, and get your d— homework done!” the parent could calmly ask, “Honey, it’s time to turn off the music now and do your homework.” Speaking of homework, because many youth problems extend to school and other out-of-home settings, these programs often include methods of extending intervention to such settings. In school, if the teacher is willing, a school card can be used to provide a simple daily report to parents on issues of importance in the school setting (e.g., staying on-task in class, obeying the teacher, turning in homework). Feedback from the school card can be incorporated into the contract and point system used at home.
Webster-Stratton’s Video-Guided Parent Group Approach A particularly well-tested intervention is the video-guided program through which Webster-Stratton (e.g., 1984) and her colleagues convey behavioral skills to parents of young children. In the Incredible Years BASIC parent-training program, groups of 10–14 parents meet with a therapist for up to 14 weekly sessions lasting about 2 hours. Parents view a series of 1–2 minute video vignettes showing parents dealing with their children in a variety of situations, sometimes successfully, sometimes not. These videos are used to stimulate discussion of basic behavioral principles. Parents practice the principles in homework assignments. Over the series of sessions, four themes are covered: constructive use of play, using praise and reward effectively, setting and enforcing limits, and handling misbehavior. The 1–2 minute video vignettes used in the group sessions show a mixture of successful and unsuccessful parent-child interactions, each designed to prompt a lively discussion by parents. Similar to the behavior parent-training programs described above, the Incredible Years also includes assignments in which the parents try procedures discussed in groups at home and track the results (chapter 64 provides further information on applications of the Webster-Stratton approach and other parenting programs).

Parent–Child Interaction Treatments To round out the picture of the forms that behavioral treatment in a family context can take, we close with a description of parent-child interaction treatments (i.e., interventions that place parents and young children in the same room and have them interact, guided by coaching from a therapist). The general approach grows out of the unpublished work of Hanf and Kling (1974) at the University of Oregon Medical School. Two prominent current examples of the approach are Parent–child interaction therapy (Eyberg & Boggs, 1998) and Helping the noncompliant child (McMahon & Forehand, 2003). Parent-child interaction treatments are used primarily for disruptive and oppositional children in the preschool through early elementary age range. Parent and child interact in a playroom, observed by a therapist from behind a one-way glass or via a videocamera, and the therapist coaches the parent using a bug-in-the-ear device. (In a low-tech version, the therapist coaches in a soft voice from a corner of the playroom.) The nature of the interactions shifts from time to time, with some child-directed interactions in which the child selects the activities and the parent practices attending closely, reinforcing desirable child behavior through labeled praise, hugs, etc., and selectively ignoring undesirable behavior. Other interactions are set up to be explicitly parent-directed, with the parent selecting activities and setting rules for the child to follow; parents are coached to make it easy for children to obey by keeping instructions specific and direct, focusing on one behavior at a time, and waiting 5 seconds or so after instructions to give the child time to comply. When instructions follow these guidelines, most children oblige most of the time. When they do not, parents are taught procedures for addressing non-compliance—they practice the best way to give the child a “time-out,” for example.

Overview and Highlights of the Findings

The treatments represented in this selective review—illustrating a much larger array of interventions—have evolved over more than four decades. Although we focused only on problems and disorders in four broad clusters—anxiety, depression, ADHD and conduct—we found 298 acceptable RCTs, encompassing 326 different treatment programs that showed at least some significant benefit relative to a control group or alternative treatment group. Neither studies, treatment programs nor treatment impact were evenly distributed across the four problem clusters. In the depression domain, we identified only 23 studies and 26 beneficial treatments; the scarcity of such studies and treatments is partly because of a late start; no youth depression trial was published until 1986. This may be partly attributable to the fact that for many years depression in children was considered an impossibility (Hammen & Rudolph, 1996).

By contrast, anxiety (94 articles, 111 beneficial treatments) and conduct problems (135 articles, 136 treatments) have been long-standing foci for treatment researchers, with considerable pay-off in terms of trials and treatments. The treatments identified (including those not detailed in this chapter) were not only numerous but diverse, crossing continental, national, cultural and ethnic boundaries. The treatments also spanned a range of targets, including youths seen individually and in groups; parents seen individually, in couples and in groups; teachers alone and with parents; whole families and parent-child combinations; and multiple systems encompassing up to a half-dozen intervention targets. Amid all this diversity, certain targets and modalities were clear favorites in certain domains. Among anxiety and depression treatments, for example, youth-focused treatments predominated, particularly those following CBT principles. Somewhat surprisingly, we also found this to be true of ADHD treatment. This prominence of CBT in randomized trials of ADHD treatment complements findings of an important previous review (Pelham, Wheeler, & Chronis, 1998) which included numerous within-group study designs and identified behavioral parent training and behavioral procedures in the classroom as the dominant forms of evidence-based intervention. Finally, we found that behavioral
parent training was the most common form of empirically supported treatment for disruptive behavior problems, with the Patterson Parent Management Training – Oregon Model (PMTO) approach and Webster-Stratton’s video-guided approach particularly influential.

There was also some diversity in the treatment models employed. Although youth psychotherapy may have begun with psychoanalysis, as suggested at the outset of this paper, we found that behavioral treatments, including CBT, now dominate the list of supported treatments. However, the list covered a rather broad range, encompassing interpersonal therapy for depression in adolescents and relaxation training and biofeedback for ADHD in children. This suggests that there may be considerable room for innovation in the development of beneficial treatments.

Strengths of the Evidence Base
Magnitude, Durability and Specificity of Treatment Effects
While there is much to appreciate in the evidence base on youth treatments, there are also some gaps. On the plus side, meta-analytic reviews point to mean effects of tested treatments that:

- Fall within the “medium” to “large” range (as per Cohen, 1988);
- Are relatively specific to the problems and disorders targeted in treatment, not just general improvements in overall adjustment; and
- Show substantial holding power, at least over the 5–6 month periods characteristic of most follow-up assessments.

Task force reviews by child specialist teams (Brestan & Eyberg, 1998; Kaslow & Thompson, 1998; Ollendick & King, 1998; Pelham, Wheeler, & Chronis, 1998) have identified 27 specific treatments as either “well-established” or “probably efficacious.” Because some problems and disorders have not yet been addressed by task force review, and because new evidence has accumulated since these reviews, it seems likely that additional treatments now exist that would meet task force criteria.

Diverse Models of Treatment Delivery
Another strength is the increasingly rich array of treatment delivery models employed. The traditional weekly office visit model still predominates in the research base, but investigators have pushed the boundaries, with tests of more intensive approaches geared to school breaks and summer camp programs (Pelham, Greiner, Gnagy et al., 1996), treatments in which core skills training is embedded in videotaped vignettes (Webster-Stratton & Reid, 2003), interventions providing behavioral training and support for foster parents (Chamberlain & Smith, 2003), treatment supplements in the form of post-therapy booster sessions (Clarke, Rohde, Levinsohn et al., 1999) and a peripatetic therapist in the youth’s environment model (Henggeler et al., 1998).

Breadth and Practical Relevance of Outcomes Assessed
Measurement of outcomes across the evidence base shows a relatively healthy range of approaches and content. We have found (Weisz, Jensen Doss, & Hawley, 2005) that, while 60% of the randomized trials we examined used youths themselves as informants on outcome measures, 33% also used parent reports, 29% used teacher reports and 78% used various other sources of outcome information, including trained observers. As for measurement content, in addition to a primary focus on measures of the target disorder or problem addressed in treatment, 78% of the studies we examined included at least one measure of non-target disorders or problems (thus permitting assessment of generalization of treatment effects), 28% included some measure of real-world functioning (e.g., school grades, disciplinary incidents, arrests), 8% assessed consumer satisfaction and 5% included an assessment of environmental impact of treatment (e.g., parenting stress).

Limitations of the Evidence Base Suggest Directions for Future Research
In addition to significant strengths, the evidence base on child treatment shows several limitations, highlighting directions for emphasis in future research (Table 18.1).

Strengthen the Control/Comparison Conditions against which Treatments are Tested
Our reviews of the evidence base suggest that the most common form of treatment-control group comparison in the research is arguably the weakest experimentally: active treatment versus inactive waitlist or no treatment. Passive control groups control only for the passage of time, not for attention, discussion of problems and solutions, a therapeutic relationship or various other non-specific factors that may enter into an episode of therapy. Fewer than 40% of the randomized trials we have reviewed used an active intervention control condition. Moreover, fewer than 8% used standard case management or some form of treatment-as-usual as the comparison condition. This presents a significant inferential problem which we discuss later in this chapter.

Address Gaps in Coverage of Important Forms of Dysfunction
The evidence base also reveals significant gaps in coverage of youth problems. As one example, the annual mortality rate in 15- to 24-year-old females diagnosed with anorexia is

Table 18.1 Research on child and adolescent psychotherapy: Directions for the future.

1. Strengthen the control and/or comparison conditions against which treatments are tested
2. Address gaps in coverage of important forms of dysfunction
3. Identify necessary and sufficient conditions for treatment benefit
4. Clarify the effective range of treatments (moderation)
5. Identify mechanisms of change (mediation) underlying treatment benefit
6. Make treatment research conditions more like real-world practice conditions
   • Shift to a deployment-focused model of treatment development and testing
   • Build the evidence base on comparisons to usual clinical care
more than 12 times the rate for this age × gender group from all other causes (Sullivan, 1995). Yet, there have been only a handful of controlled treatment trials for anorexia nervosa (for reviews see Fairburn, 2005; Le Grange & Lock, 2005) and none for the treatment of bulimia nervosa (Wilson & Sysko, 2006) in adolescent populations. Although Stice, Shaw, Burton et al. (2006) have shown preventive effects of psychosocial interventions on eating pathology in adolescent girls, tests of treatment protocols with clinically relevant populations are lacking, despite increasing rates of eating disordered attitudes among adolescents (Bearman, Presnell, Martinez et al., 2006). In addition, with few exceptions (e.g., Azrin, Donohue, Besalel et al., 1994), potent treatments for substance abusing youth are rare, particularly for users of harder drugs such as cocaine. Also with few exceptions (e.g., Borduin, Henggeler, Blaske et al., 1990), the literature lacks successes in the treatment of youthful sex offenders. And despite attempts by several research teams, we still lack interventions for suicidal youth that clearly reduce the risk of further attempts (Weisz & Hawley, 2002). Finally, most of the psychosocial treatment success with ADHD has been with preadolescents, and some of the behavioral treatments that work within that age range may not travel so well up the developmental ramp into adolescence. Indeed, the author of a widely used behavioral parent program argues that adolescents should not be considered candidates for the program, as their poor responses may exacerbate family conflict (Barkley, 1997). Limited success of psychosocial treatments with ADHD in teens could make stimulant medication the evidence-based treatment (EBT) of choice for this age group, by default (Weisz & Jensen, 1999). To put the coverage issue more starkly, there are at least 150 disorders in the current DSM-IV (American Psychiatric Association, 2000) that can be applied to children and adolescents, and many more problems of living for which youngsters need help; our list of EBTS to date encompasses only a modest percentage of these.

Identify Necessary and Sufficient Conditions for Treatment Benefit

Many of our treatments are omnibus in style – packing a variety of procedures and training a variety of skills, but without a clear picture of which ones really matter. Despite a long tradition of “dismantling” research, we have only begun the process of identifying the specific components of our multisession, multiconcept, multiskill treatments that are necessary for good outcomes. The full monty nature of so many manualized treatments often renders them a poor fit to the current emphasis in real-world clinical care on session limits and maximum efficiency. There is almost certainly some excess baggage in some treatments (i.e., elements that do not actually contribute much to the outcomes achieved). Making treatment programs leaner and more efficient could enhance their attractiveness to practitioners, render the procedures more teachable, increase treatment viability in the marketplace of clinical care and thus perhaps reach more of the children who need their benefits.

Clarify the Effective Range of Treatments (Moderation)

For each treatment in the armamentarium, we need to understand the range of youth clinical and demographic characteristics within which the treatments produce benefit and outside of which benefit diminishes. Even the best-supported EBTS are good for some individuals but not others, with most clinical trials reporting substantial percentages showing poor response. It is relatively common in trials to see that 30% or more of treated children are not helped much by the treatment. One possible reason is that treatment benefit is constrained by such potential moderators as age, gender, socio-economic status (SES), comorbidity, family income, ethnicity, family configuration or other clinical and demographic factors. With relatively few exceptions (e.g., Brent, Kolko, Birmaher et al., 1998; Curry, Rohde, Simons et al., 2006; Kazdin & Crowley, 1997), research to date has left us rather poorly informed about such constraints. Racial, ethnic and cultural factors, for example, are embedded but unexamined in most of our treatment outcome research (Weisz, Jensen Doss, & Hawley, 2005), and this makes it difficult to know how robust most treatment effects are across various population groups. At this early stage in youth treatment development research, it is understandable that most tested treatments have not been designed to take into account the broad variations associated with different cultural traditions. However, many would agree that the interplay between such factors and treatment characteristics may influence the outcome of the treatment process, and that an understanding of these processes would enrich efforts to produce treatments that can be applied across a broad spectrum of individuals and groups (Weisz, Huey & Weersing, 1998). While there is great interest in the impact of cultural variations and other potential moderators, our reviews suggest quite variable findings across studies, without much evidence of robust moderators that are consistent in their impact across studies.

Identify Mechanisms of Change (Mediation) Underlying Treatment Benefit

We also need sustained inquiry into the change processes in treatment that account for observed outcomes. At present, we know much more about what outcomes our treatments produce than about what actually causes those outcomes (Kazdin, 2000; Shirk & Russell, 1996). If we fail to identify core causal processes, we risk a proliferation of treatments administered rather superstitiously because studies show they work, but without an understanding of the change processes therapists actually need to set in motion to produce results. To understand how the treatments work, we need a generation of research testing hypothesized mediators of outcome. Mediation testing procedures have been well described (Baron & Kenney, 1986; Holmbeck, 1997; Judd & Kenny, 1981), and the use of randomized clinical trials to test mediators and mediators of therapeutic change has been thoughtfully addressed by Kraemer, Stice, Kazdin et al. (2001) and Kraemer, Wilson, Fairburn et al. (2002). Some treatment researchers have already applied mediation testing procedures to good effect. Huey, Henggeler,
Brondino et al. (2000), for example, found that decreased affiliation with delinquent peers mediated reductions in delinquent behavior in youths treated with multisystemic therapy. Eddy and Chamberlain (2000) found that improved family management skills and reduced deviant peer associations mediated the effects of their behaviorally oriented treatment foster care program on adolescent antisocial behavior. Other investigators have probed change processes associated with other treatments (Weersing & Weisz, 2002), although not always with complete mediation test methods. We need more studies in which proposed mediators are identified a priori, measured well and tested with care (Kazdin, 2000; Kazdin & Weisz, 2003). Failure to test rigorously for mediation leaves an information vacuum that may be filled by faulty assumptions about the nature and causes of treatment benefit. Increased understanding of the actual processes underlying therapeutic improvement will improve prospects for:

- Understanding and addressing impediments, stalls, and failures in treatment;
- Training therapists by teaching them what change processes they need to effect rather than simply what techniques to use; and
- Identifying cross-cutting principles that can be used in designing, refining and perhaps combining interventions.

**Make Treatment Research Conditions More Like Real-World Practice Conditions**

For a variety of reasons, the conditions under which most EBTs have been developed and tested tend to differ markedly from the conditions under which treatments are provided to clinically referred children in everyday mental health care settings (Southam-Gerow, Weisz, & Kendall, 2003). The gap between research and clinical conditions includes:

1. Psychological and social characteristics of the treated individuals (e.g., with clinic-referred youths more severely disturbed, more likely to meet criteria for a diagnosis, more likely to have comorbidities and more likely to drop out of treatment than youths recruited for RCTs);
2. Reasons for seeking treatment (e.g., referred youths not recruited from schools or through advertisements, but referred by caregivers because of unusually serious problems or family crisis, or even court-ordered);
3. The settings in which treatment is carried out (e.g., more financial forms to complete, more bureaucracy and sometimes a less welcoming approach in the clinic);
4. The therapists who provide the treatment (e.g., not graduate students or research assistants hired by and loyal to the adviser and committed to her or his EBT program, but professionals with years of experience and their own treatment preferences);
5. The incentive system (e.g., therapists not paid by the treatment developer to deliver her or his treatment with close adherence to the manual, but paid by the clinic to see many cases and with no particular method required); and
6. The conditions under which therapists deliver the treatment (not graduate students’ flexible time, but strict productivity requirements or payment per therapy hour, paperwork to complete and little time to learn a manual or prepare for each session in advance).

The gap between RCT conditions and practice conditions has contributed to the concern of many practitioners and some clinical scientists that the treatments emerging from RCTs may not be well-suited to the rigors of real-world practice (Addis & Krasnow, 2000; Westen, Novotny, & Thompson-Brenner, 2004; Weisz, 2004). Two possible responses to this concern warrant attention in this chapter.

**Shift to a Deployment-Focused Model of Treatment Development and Testing**

It is possible that these many differences between therapy in most RCTs and therapy in actual clinical practice are too pronounced to be bridged as simply the final step at the end of a long series of traditional RCTs. Perhaps the number of dimensions along which treatment would need to be changed to bridge the research–practice gap makes the task of moving so complex that the task needs to be made an integral part of the treatment development process. Indeed, the very real-world factors that experimentalists might view as a nuisance (e.g., child comorbidity, parent pathology, life stresses that produce no-shows and dropouts, therapists with heavy caseloads) and thus attempt to avoid (e.g., by recruiting and screening cases, applying exclusion criteria, hiring their own therapists), may in fact be precisely the factors that need to be included in research designs if researchers are to develop psychosocial treatment protocols that fit well into everyday practice. Treatments that cannot cope with these real-world factors may not fare so well in practice, no matter how beneficial they are in efficacy trials.

To address this challenge, one proposal has been that traditional RCTs exercising tight control over diverse real-world treatment factors give way to a model of treatment development and testing that brings treatments into the crucible of clinical practice early in their development and treats testing in the practice setting as a sequential process, not as a single final phase. This approach has been called the deployment-focused model (DFM) of treatment development and testing. The model (detailed in Weisz, 2004) outlines a series of steps by which the creation and testing of treatments can encompass representative practice conditions and contexts. Central to this model is the notion that to create interventions that work well in the crucible of everyday professional use, treatment developers and researchers will need to focus their work on precisely the kinds of individuals, treatment providers and clinical care contexts for which the treatments are ultimately intended.

**Build the Evidence Base on Comparisons with Usual Clinical Care**

Another possible response to the gap between traditional research conditions and everyday clinical practice conditions focuses on the question of which comparison groups to include in research. Largely absent from the treatment research literature are comparisons that address what is
arguably the most critical question for those concerned about the research–practice gap (i.e., how helpful are EBTs in comparison with the treatment that children would otherwise have received in usual clinical care?). In some respects, this is the touchstone question. Indeed, if EBTs cannot outperform the treatments children would otherwise receive in clinical care, one could question the point of all the time, effort and funding used to create those EBTs. Our evidence review (Weisz, Jensen Doss, & Hawley, 2005) found that fewer than 8% of all child RCTs used standard case management or some other form of usual care as the comparison condition, and some of these comparisons lacked the precise control (e.g., for treatment dose, or for whether usual care was in fact a “treatment”) that would be needed for ideal inferential power. In a recent analysis, Weisz, Jensen Doss, and Hawley (2006a) focused on the 32 RCTs identified that compared an EBT for children to some form of usual care (e.g., everyday psychotherapy with no protocol, case management, structured community program that had not been previously tested). On average, EBTs outperformed usual care interventions, but not to an overwhelming degree. The mean effect size across all the EBT versus usual care comparisons was 0.30, falling within the small to medium range. Notably, the range of effects was quite wide across individual studies, with some showing impressive superiority of EBTs but others showing EBTs to be less effective than treatment as usual. This suggests a need for caution on the part of potential consumers of EBTs. The fact that an intervention has been tested and shown to work in clinical trials – say, in comparison to a waitlist condition – may not necessarily mean that the intervention is superior to current forms of clinical care that are untested. To address this question requires a genre of research that is quite rare to date; direct comparisons of EBTs with the most common forms of usual care to which the EBTs are potential alternatives. In our view, the next era of research in the field should include a large component of EBT versus usual care testing, encompassing the creation of a taxonomy of usual care interventions and a growing body of evidence on the relative advantage (or disadvantage) of various EBTs in comparison with various forms of usual care, in the context of various child problems, disorders, and combinations thereof.

Critical Tensions and Unanswered Questions

Beyond its strengths and limitations, research on child psychotherapy can also be characterized by tension around some critical questions about which there is no consensus answer. Here we focus on a few of the questions that seem particularly central to the field (Table 18.2).

Efficacy versus Effectiveness of Child and Adolescent Treatments

Although we have advocated increased emphasis on treatment research that encompasses real-world characteristics, and we have proposed a deployment-focused model to guide that process, we must acknowledge that not all researchers agree on this issue. In the treatment literature, both psychotherapeutic and medical, a distinction is drawn between two very different forms of outcome research. In efficacy designs, experimental control is used to test treatment impact under carefully arranged idealized conditions, described above. In effectiveness designs, intervention effects are assessed under ordinary clinical conditions, with treatment delivered to “average” or representative patients or clients, by “average” or representative practitioners, working under conditions that reflect typical practice realities. In a recent review of youth clinical trials, Weisz, Jensen Doss, & Hawley (2005) found that about 13% of study samples consisted of clinically referred youths (many were recruited, e.g., through advertisements, or identified through screening procedures in schools); about 19% of the studies used at least one practicing clinician to deliver treatment; and only about 4% of the studies provided treatment within a clinical practice setting. In fact, only 1% of the studies involved all three elements (i.e., clinically referred youths, treated by practicing clinicians, in clinical practice settings). So, elements of effectiveness research are not very common in the treatment outcome literature. Should we be concerned about this? Some researchers believe that, at this stage in treatment development research, energy is best devoted to research that uses well-controlled conditions to generate the strongest possible treatments for specific forms of dysfunction – and thus that efficacy research needs special emphasis. Others believe that what is most needed are treatments that can address the complexity and severity of mental health problems as they appear in everyday practice, and that doing this will require increased emphasis on effectiveness research. The debate has important implications for the funding of research and, in turn, for what will be learned about treatments and the conditions under which treatments have their effects.

Precision versus Breadth in Individual Treatment Focus

Another important debate in the field concerns the degree to which treatments should be narrowly focused on single problems or disorders, versus designed to address problems in clusters, or even the “whole child.” Most manual-guided treatments designed for children and teens have been focused on single problems or disorders, or at least relatively homogenous clusters. In fact, in much of the research on these treatments (but certainly not all), youths who have comorbidities that might undermine treatment success have been excluded from study samples. Even when comorbidities have been

CHAPTER 18

included in study samples, the treatments being tested have most often had a relatively narrow problem or diagnostic focus. On the plus side, this procedure may provide a useful context for testing treatments without interference from unwanted conditions.

However, the longer treatment development and research focus on single conditions, the longer the field is delayed in addressing a widely recognized fact about child psychopathology. Extensive evidence (e.g., Angold, Costello, & Erkanli, 1999) shows that co-occurrence of disorders and problems is quite characteristic of the youngsters seen in everyday clinical care. For example, ADHD is frequently found in concert with ODD, and often also with depressive or anxiety disorders. Rates of comorbidity, striking even in community samples, are markedly higher in clinical samples (Angold, Costello, & Erkanli, 1999). A case can be made that we need to understand: (i) the extent to which comorbidities of various kinds moderate the effects of treatments that are focused on single conditions; and (ii) the potential benefits of treating multiple conditions concurrently. More than a decade ago, Kendall and Clarkin (1992) referred to comorbidity as the "premier challenge facing mental health professionals in the 1990s" (Kendall & Clarkin, 1992, p. 833). The 1990s have now come and gone, and the challenge remains largely unaddressed by youth treatment researchers.

Linear Treatment Manuals versus Modular Approaches

A closely related debate centers on the merits of using full treatment manuals—which typically describe a linear sequence of steps, with one lesson or skill to be covered in session 1, another in session 2, etc. Some see an inherent logic in such sequences, with the information or skills covered in earlier sessions needed for movement to subsequent sessions, and with the full package required for full treatment benefit. Indeed, most treatment manuals for which there is support in RCTs have taken exactly this linear form. However, many professionals outside the world of research object to the idea of standardized intervention protocols with a series of sessions in a predetermined sequence (Addis & Krasnow, 2000; Addis, Wade, & Hatgis, 1999; Havik & Vanden Bos, 1996). We should note that manuals come in a variety of forms and formats, and that the manuals for some of the best-tested treatments (e.g., multisystemic therapy; Henggeler, Schoenwald, Borduin et al., 1998) emphasize treatment principles and guidelines, not a lock-step sequence of session topics, and clinicians have considerable flexibility to use their own creativity and judgment to achieve desired clinical outcomes.

However, for some professionals, full treatment protocols of any kind may not be appealing. A more appealing application of evidence-based interventions may involve incorporating new practice elements into their work selectively, using their own experience and skills to decide which elements are worth trying, rather than replacing their traditional approaches wholesale. This conflicts with the extent evidence base, in which empirically supported interventions have almost always come in the form of full manualized programs, and in which some evidence from both prevention and treatment research (Durlak & Wells, 1998; Huey et al., 2000) indicates that fidelity to the manual enhances outcomes.

Thus, a case can be made that, at this time and for a number of interventions, the most “evidence-based” practice involves the application of full programs in the specific forms tested in research trials. In principle, though, it seems possible that certain elements of these programs, combined in ways that fit distinctive characteristics of individuals targeted for intervention, might produce genuine benefit. The problem is that the research to date provides little guidance on how to extract specific best practices from full protocols, and lacks information as to which of these – alone or in combination – might lead to good outcomes. To compile such knowledge in the most systematic way will require that we find reliable ways of identifying separable elements of treatment protocols, logically and theoretically sound ways of turning these elements into separate modules, and clinically sensitive ways of selecting modules and combinations to fit various individuals and groups targeted for intervention. At least one approach to these steps has been documented, and a resulting “modular protocol” created, to encompass intervention for youth anxiety, depression and/or conduct problems (Chorpita, Daleiden, & Weisz, 2005a,b). Tests of the resulting modular protocol are under way. It seems likely that many years of refinement and testing lie ahead before researchers can begin to assess whether separating “best practices” and organizing them in modular fashion will match or improve on standard manuals as we now know them. The questions of interest include not only what kinds of outcomes the modular treatments produce, but also what their prospects are for dissemination to and effective implementation by practitioners in real-world clinical practice, where standard manuals face significant challenges.

Common Factors (e.g., Therapeutic Relationship) versus Specific Techniques

The current array of EBTs is strong in describing (through manuals) principles and specific procedures to apply in treatment. This is a strength to the extent that the manuals document the steps therapists need to follow to replicate treatment procedures that have been successful in randomized trials. However, it is a limitation to the extent that aspects of treatment other than the specific procedures may have played a part in treatment success. As an example of what may be missing, many who study therapy process believe that “non-specific” “common factors,” such as the quality of the therapeutic relationship, account for a large proportion (even most) of the variance in outcomes (Luborsky, Rosenthal, Diguer et al., 2002). Indeed, many child therapists rate the therapeutic relationship as more important than the specific techniques used in treatment (Kazdin et al., 1990; Motta & Lynch, 1990; Shirk & Saiz, 1992), and some treated children may agree, even those treated by EBTs. Kendall and Southam-Gerow (1996) found that children treated for anxiety disorders using the Coping Cat program rated their relationship with the therapist as the most important aspect of treatment. Given these
A broader question concerns the extent to which therapeutic relationship-building is a teachable skill and, if it is, how much of that skill can be captured and taught via a written treatment protocol. Many would perhaps agree that the best therapeutic relationship is a teachable skill and, if it is, how much of that skill can be captured and taught via a written treatment protocol. Operationally, this means coding whether therapists cover the material (e.g., role plays, in vivo exercises, quizzes). Fidelity to the treatment manual, and sometimes whether they use the techniques that are recommended in the manual (e.g., role plays, in vivo exercises, quizzes). Fidelity to the treatment model is important, of course, and it may be necessary for success in many treatments. But is it sufficient? Again, probably not.

Our experience in assessing fidelity over the years has convinced us that it is possible to achieve relatively high fidelity but in ways that seem unlikely to be very effective in producing good treatment outcomes. Something more is needed, and for most treatments that “something” is not very well-defined and not easy for experts to code from treatment videotapes. Examples include ability to engage the child’s interest and motivation, to bring the treatment concepts and skills to life in ways that are meaningful, and to use real-life concerns or crises presented by the child as opportunities to illustrate and practice key skills of the treatment program. In our view, identifying such “keys to effective use” of EBTs should be central to the agenda for research in the years ahead.

Relation between Science and Practice
A debate of sorts has emerged between some in the research community who favor dissemination of EBTs into clinical practice and some in the clinical practice community who favor studying everyday clinical practice to identify the most effective practices. In a sense, the debate overlooks an important fact about EBTs (i.e., that many of them emerged from successes in everyday clinical practice). As we noted earlier, the Hanf and Kling’s parent training program in Oregon, which grew out of Hanf’s everyday practice and supervision, led to the development of three EBTs: separate parent training programs authored by Barkley (1997), Eyberg and Boggs (1998) and McMahon and Forehand (2003). Indeed, the interplay between everyday practice and science has been quite rich at times, and quite often ordered in such a way that practice leads science. We believe there is a great deal of room for continued interaction. Science can be good for practice, helping us identify which forms of care are in fact helpful to children, and – in the best circumstances – what causal mechanisms have a role. Practice can likewise be good for science, helping us identify areas in which new knowledge and improved treatment are most needed, and grounding science in the realities of everyday clinical care.

Acknowledgments
Some of the evidence review reported in this chapter was supported through the Research Network on Youth Mental Health (Bruce F. Chorpita, Robert Gibbons, Charles Glisson, Evelyn Polk Green, Kimberly Hoagwood, Peter S. Jensen, Kelly Kelleher, John Landsverk, Stephen Mayberg, Jeanne Miranda, Lawrence A. Palinkas, Sonja Schoenwald and John Weisz), funded by the John D. and Catherine T. MacArthur Foundation. The authors were supported by the National Institute of Mental Health (R01 MH 547347). We are grateful to Abby Wolf for their help in various aspects of this project.

CHAPTER 18

Clinical Assessment
There are many challenges for families, clinicians and researchers in the evaluation of clinically significant mental health problems in children and adolescents. These include distinguishing normal, temperamental and biological variations from signs of pathology, and assessing mental health in the context of transitions and developmental change, particularly in the early years. It is also important to be able to assess relevant environmental influences, including parenting and the wider family and social contexts as experienced by the child or adolescent. This chapter reviews the current use of some research-based structured interviews (SIs) and observational methods including their advantages and limitations in clinical settings. These are not fixed properties of the instruments, but depend closely on the purpose of the assessment. SIs and observational methods provide specific standardized information but do not replace clinical judgment. This is important to bear in mind when considering any assessment method.

Service Context

Best clinical practice in child and adolescent mental health (CAMH) services takes an evidence-based, multidisciplinary (MD) multiagency (MA) approach to both direct and indirect work. Clinical practices change over time in response to a variety of pressures including the prevailing theoretical knowledge base, revisions of diagnostic classification systems, local resources, referral practices and available treatment modalities. Multiple sources of information are needed to gain a realistic picture of the child’s development over time (Grills & Ollendick, 2002; Silverman & Kurtines, 1996). Similarly, quality of parenting is usually assessed using a combination of systematic interviews with parents and children coupled with observations of family interactions (Mrazek, Mrazek, & Klinnert, 1995).

Children and adolescents rarely present with single disorders but rather a range of problems. Once a referral has been made, direct interviewing of parents, children and relevant adults together with specific assessments such as direct observations in different settings are necessary. However, informants do not necessarily all agree on the nature, extent and severity of the difficulties (Grills & Ollendick, 2002; Simonoff, Pickles, Meyer et al., 1997). Previously, parents were thought to be the best informants regarding a child’s behavior, with information from the child considered secondary (Edelbrock, Costello, Dulcan et al., 1985). This view has changed significantly in the last several decades (for recent review see Grills & Ollendick, 2002). Direct observations provide a very different window on functioning, where information is not filtered through the perceptions of the involved parent, teacher or child. We show how observational methods can complement other aspects of assessment and provide specific information for treatment planning. Standardized procedures (irrespective of whether or not research-based instruments have been used) are needed to combine all available information into a clinical formulation and intervention plan. Unfortunately, this will not always resolve the problem of discrepancies between sources of information (Goodman, Yude, Richards et al., 1996; see also chapter 21).

Purposes of Clinical Assessment

A common set of information is necessary as part of an initial assessment, for subsequent follow-up reviews and for reassessment. A detailed description of the child’s current functioning, abilities and behavior (including frequent and infrequent behaviors and skills) is required to establish a current baseline of capacity and need. Parents and/or principal caregivers and the child (depending on the context) are likely to welcome an opportunity to express early on their concerns, describe how they understand the “problem(s)” and share any other information they believe is relevant. The form of the assessment and choice of assessment methods need clinical judgment to consider the context of the referral, the specific questions or concerns raised, the needs of the family, the chronological and developmental age of the child, any history or evidence of existing special needs, and any circumstances that might mean the child is at particular risk or considered a “child in need” (Department of Health, 2004). Judgments will also need to be made about the frequency of particular types of referral to a clinical service and the relevance and

Structured Interviews in Clinical Settings

“Interviewing has long been the standard method of assessing children’s emotional, behavioral, and social functioning . . . Yet, it is one of the least trustworthy assessment procedures, subject to broad variations in content, style, detail and coverage” (Edelbrock & Costello, 1990).

Interviews with structure have developed for two main purposes (Del Carmen-Wiggins & Carter, 2004): contributing to the diagnostic assessment and obtaining descriptive data on children’s emotional, behavioral and social problems.

Historically, structured clinical interviews with an adult informant have been considered the “gold standard” in terms of comprehensiveness and psychometric properties (Cox, Rutter, & Holbrook, 1981; McClellan & Werry, 2000). Cox, Rutter, & Holbrook (1981), investigating different interviewing styles in a clinical setting using individual interviews with the mother of the referred child, found that a high frequency of clinically important information was unique to individual interviews with the mother of the referred child, found that a high frequency of clinically important information was unique to individual families and that all techniques if mastered well were equally effective in eliciting emotions. However, when the interviewing styles were compared for their efficiency in eliciting good quality factual information, a process of systematic questioning was shown to be superior.

For research and clinical groups to share findings and experience, it is essential that all use the same terminology to minimize information variance. This was not possible prior to the publication of agreed international diagnostic classification systems, criteria and thus standardized measures (American Psychiatric Association, 2000; Spitzer, Endicott, & Robins, 1978; World Health Organization, 1996). The SI schedules developed over the last 20 years are mostly based on internationally agreed classification systems (DSM-IV and ICD-10), and use categorical diagnoses rather than a quantitative dimensional approach to levels of psychopathology (see chapter 20). Studies investigating the relationship between these two approaches have found only moderate convergence (Bird, Gould, & Staghezza, 1993; Boyle, Offord, Racine et al., 1993).

The form and content of published interview schedules vary, but overall there is a trend for more specialization of focus such as specification of coverage, modification for different informants or for age range (for detailed reviews see Del Carmen-Wiggins & Carter, 2004; Grills & Ollendick, 2002; Shaffer, Lucas, & Richters, 1999). Such modifications are driven in part by the emphasis on evidence-based practice and disorder-specific funding for treatment services in some healthcare systems. This emphasis on specific diagnoses may not be appropriate for day-to-day clinical practice where a broad-based assessment to investigate the comorbidity of presenting problems for the child and family is the priority (Angold, Costello, & Erkanli, 1999). Moreover, individual and family vulnerabilities and strengths also show little apparent specificity between diagnostic groups (see chapters 23–33).

Current diagnostic boundaries will be revised as our understanding of the causal mechanisms for mental health disorders increases (see chapter 4). The differentiation of Rett syndrome from autism within the currently defined group of Pervasive Developmental Disorders is a recent case in point (Kerr, 2002). Furthermore, research and clinical findings have identified a broader spectrum of behaviors that extend beyond currently accepted diagnostic boundaries. These may represent milder and subclinical traits within the general population (Brugha, 2002; Melzer, Tom, Brugha et al., 2002). This awareness of a broader spectrum of difficulties and the limitations of current diagnostic criteria emphasizes the need for systematic recording of clinical information irrespective of the use of existing standardized instruments.

The decision about whether to use a standardized procedure(s) in clinical practice must take into account the specific concerns and needs of the referred child and family as well as the clinical context. It is this individualized approach to clinical practice that is so important for a comprehensive assessment and for intervention planning.

Structure may be defined in a variety of ways. Traditionally, the treatment plan and therapeutic outcomes determined the interview structure. More recently, the interview style and format (respondent or investigator based), the method for recording and coding of information (paper schedule or computer), whether a live recording is made (audio or DVD), as well as the diagnostic classification system (American Psychiatric Association, 2000; World Health Organization, 1996), and the final procedures for interpreting the information and making appropriate clinical judgments about the data all determine the structure of the assessment. Some SIs use a prespecified diagnostic algorithm (e.g., Autism Diagnostic Interview [ADI-R]; Le Couteur, Lord, & Rutter, 2003) or a final rating scale (such as the Children’s Yale-Brown Obsessive Compulsive Scale [CY-BOCS]; Storch, Murphy, Adkins et al., 2006; see chapters 20 & 43) or the Child Global Impression (CGI) scale. Most research studies do not rely on SI generated data in isolation but as a contribution, alongside information from other standardized assessments (such as cognitive and other testing) with observation across settings to produce a “best estimate” clinical judgment. This procedure is often defined as the gold standard in research and clinical guidelines (Dunn, G., 2000; Le Couteur, 2003).

Respondent-based Interviews

Respondent-based interviews are highly structured in both the format of the interview and how the interview is delivered. The interviewer is trained to use the questions as specified in the interview and the informant is required to respond whether the symptom/behavior is present, absent or meets the criterion for a prespecified severity. There is no opportunity for clarifying the concepts used by the informant when answering the questions. It works well (in terms of inter-rater reliability of administration and codings) as long as both
interviewer and informant/respondent have the same conceptual understanding of the definitions of the symptoms/behaviors considered and the distinctions needed for accurate coding. Such interviews are relatively quick to administer and interviewers require little training. Administration by trained lay people without clinical expertise can be used to collect precise data; a definite benefit for large research studies (Meltzer et al., 2002; Shaffer, Fisher, Dulcan et al., 1996). However, because this type of interview requires minimal clinical judgment, one of the risks when compared with investigator-based SIs is the tendency to overdiagnose disorders (Boyle et al., 1993; Shaffer, Fisher, Lucas et al., Reich, 2000). There is no opportunity to adapt the interviewing style, for example to expand on a response to a question to take into account specific concerns for that family. Examples of respondent-based interviews administered to parents include the Diagnostic Interview Schedule for Children (DISC-IV, current version; Shaffer, Schwab-Stone, Fisher et al., 1993; Shaffer, Fisher, Lucas et al., 2000); and the Diagnostic Interview for Children and Adolescents (DICA; Reich, 2000). Both have been extensively revised over the last 20 years, with new teacher versions, translations and the development of computerized instruments (Lucas, 2003). The Children’s Interview for Psychiatric Syndromes (ChiPS) (Weller, Weller, Fristad et al., 2000) is a highly structured interview designed to be used by trained lay interviewers with children of normal intellectual ability aged 6–18 years to “diagnose” 20 common psychiatric disorders. As with all SIs, it relies on a cooperative informant. A parent version is also available. Administration time is described as relatively brief and Weller et al. (2000) report encouraging psychometric conclusions.

Investigator-based Interviews

Investigator-based interviews provide a semistructured “guided conversation” with the informant. These are more like the clinical situation but with some loss of reliability when compared with respondent-based interviews (Rijnders, van den Berg, Hodiamont et al., 2000). The structure lies in the precision of the definitions of the behaviors and the codings described in the schedule or glossary. The interviewer is required to use compulsory opening questions and supplementary open-ended questions in a flexible but systematic manner, to gather sufficient detailed information to make each coding judgment (Richardson, Dohrenwend, & Klein, 1965). These detailed descriptions of actual behavior contribute to the interview diagnoses and also provide accounts of individual functioning in specific situations that can contribute to the clinician/team’s formulation and intervention planning. However, SIs are usually designed for a particular purpose and thus are unlikely to cover all the aspects considered important when dealing with a clinical referral.

Some examples of investigator-based interviews (with a broad focus and others with a narrower focus of study) will be reviewed. Other broad-based interviews such as the Parent Account of Child Symptoms (PACS; Taylor, Schachar, & Hepstinall, 1993) and with a narrower focus such as the Adolescent

Advantages of Structured Interviews in Clinical Settings

SIs provide a standardized framework for obtaining information from different informants according to defined criteria and the psychometric properties of most SIs are published, so standards can be set for reliability of these measures. Most implement current diagnostic criteria, thus minimizing the risk of information variance (such as the potential for individual practitioners to ascribe differing degrees of clinical significance to particular symptoms). Overall results from reliability studies demonstrate that diagnostic consistency is enhanced with the use of SIs (McClellan & Werry, 2000; Silverman, 1991, 1994). The standardized information can also be used for treatment planning. However, there is no evidence in favor of recommending a particular interview for specific applications (Angold, 2002). If no instrument seems suitable, it might be tempting to create one. However, this process is fraught with difficulties and is not for the amateur.

Drawbacks and Limitations

SIs only provide a structure for gathering the information predefined for that instrument. Used in isolation, SIs are unlikely to provide sufficient information for a comprehensive assessment and for planning interventions.

Training staff to administer structured assessments means the investment of significant time and resources with the inevitable impact on other aspects of the service (such as length of waiting lists). However, for some SIs, accessing appropriate training can be problematic (see p. 275) and once training has been completed, achieving the required levels of accuracy and reliability may not be achievable for all trainees. Resources are also necessary for provision of protocols and other equipment (e.g., for recording), for dedicated funding for continuing post-training supervision and longer term for the maintenance of reliability to prevent interviewing and rating “drift.” This level of investment is only worthwhile if the use meets a service need of the local population. For example, in the UK there are no recommendations that SIs should be included in the protocols for all care pathways as part of a comprehensive CAMH service (National Service Framework, 2004). However, training in the use of SIs (such
as Kiddie-Schedule for Affective Disorders and Schizophrenia [K-SADS] and Child and Adolescent Psychiatric Assessment [CAPA] or ADI-R; see p. 276) can enhance interviewing skills, knowledge and accuracy of CAMH professionals identifying particular problems, although the instruments may require modification for regular use in busy routine CAMH settings (Le Couteur, 2003; NICE, 2005). Further, if a service provides specialist clinics for particular client groups, or for some other reason requires standardized information to be recorded, SIs provide standardized assessment procedures.

Research studies are required to report the procedures employed to achieve reliability in the use of instrument administration, how the results of administration are reviewed and what arrangements are made to maintain reliabilities between interviewers and across research sites. Similar resource-intensive precautions are also needed in clinical practice. Most published SIs have been developed in English. Several have been translated into other languages, but the reliability and validity of the instrument needs to be established for the different client groups, and for particular ethnic and cultural settings.

Finally, most SIs have specified time frame definitions (e.g., “current episode” might be defined as the last week, 4 weeks or 3 months; or the “worst episode” is over last year or a lifetime/ever rating). This may not be appropriate for an individual patient, family or clinical setting. Further, the methods used to “assist” retrospective recall of behaviors are likely to influence the recorded timing of onsets and lifetime diagnoses.

### Considerations When Deciding to Use an SI and Examples of Interview Assessments

There are no specific SIs recommended as “gold standard” tools for clinical practice. The decision to use an existing SI will depend on both the clinical question and whether there is an SI “fit for purpose.” This section reviews some of the most well-known and widely used SIs, but is not a comprehensive review of available interviews. The examples chosen will be used to illustrate different types and highlight the psychometric considerations and constraints (Del Carmen-Wiggins & Carter, 2004). The use of disorder-specific headings is to assist the reader and does not imply that problems for a child and family should necessarily fit a particular diagnosis. Where possible, links will be made with equivalent observational assessments.

### Structured Interviews Used in General Child and Adolescent Psychiatric Practice

#### Diagnostic Interview Schedule for Children (DISC-I to DISC-IV)

This is an example of a highly structured respondent-based diagnostic instrument in two forms: parent and/or teacher, covering 4–17 years; and a child form for 9–17 years. It was originally developed by Costello, Edelbrock, & Costello (1985) following the development of the US National Institute for Mental Health Diagnostic Interview Schedule for adults (Robins, Helzer, Croughan et al., 1981). Revised and translated over the years (Shaffer et al., 1996, 2000), it takes 70–120 minutes to administer. The interview has a branching tree format with 358 “stem questions.” The expectation is that the informant will answer “yes” or “no” to the questions.

DISC-IV covers more than 30 different non-hierarchical mental health disorders (in line with ICD-10 and DSM-IV), together with an assessment of impairment based on responses to six sets of questions about the effects of symptoms on the child’s relationships with his or her caretakers and family, peers and school. The timescale covered has changed across the different versions. DISC-IV covers the last 4 weeks, the past year and can generate lifetime diagnoses in some formats.

Psychometric properties of DISC-IV and previous versions have been published (Shaffer et al., 2000) including the performance of the instrument for children of different developmental ages, use in different study populations, and discrepancies between parent and child interviews (Bravo, Ribera, Rubio-Stipec et al., 2001; Jensen, Roper, Fisher et al., 1995).

The interviews are usually audio-taped. Once completed, the scores are entered electronically and DSM-IV and ICD-10 research diagnoses generated for the parent and child versions. The DISC has been used in both clinical and community-based studies, some of which have involved high-risk youth such as those in juvenile justice settings (Teplin, Abram, McClelland et al., 2002).

#### Voice Diagnostic Interview Schedule for Children (Voice DISC)

A self-administered computerized version of the DISC-IV has been developed. It is recommended by some authors because the error rate for scoring and algorithm calculations is said to be less and the preliminary data show that the reliability of the Voice DISC is comparable to other versions of the DISC (Lucas, 2003). It generates provisional diagnoses of disorders present in the past month. As a self-administered comprehensive psychiatric assessment it may have advantages for certain client groups (Wasserman, McReynolds, Lucas et al., 2002; West, Sweeting, Der et al., 2003).

#### Kiddie-Schedule for Affective Disorders and Schizophrenia (K-SADS) (Ambrosini, 2000; Kaufman, Birmaher, Brent et al., 1997)

This is a widely used, semistructured investigator-based SI for use with children aged 6–18. There are adult and child versions. It was originally published by Puig-Antich and Chambers (1978) as a modification of the Schedule for Affective Disorders and Schizophrenia (SADS; Endicott & Spitzer, 1978). The interview was primarily developed to identify children with major depressive disorders, but has been shown to be useful...
in assessing a broader range of psychopathologies. Several revisions have been undertaken (Ambrosini & Dixon, 1996). However, some diagnoses, such as specific and pervasive developmental disorders, are not covered. The interview is published in English (Kaufman et al., 1997) and other languages (Ghanizadeh, Mohammadi, & Yazdanshenas, 2006; Kim, Cheon, Kim et al., 2004; Kolaitis, Korpa, Kolvin et al., 2003).

There are three DSM-IV compatible versions (K-SADS-P IVR; K-SADS-E and K-SADS-Present/Lifetime [P/L]; Ambrosini, 2000; Kaufman, Birmaher, Brent et al., 1997). All provide a current diagnostic assessment. K-SADS-P IVR covers the worst episode in the last year; K-SADS-E and K-SADS-P/L provide a lifetime diagnosis. Each version has separate sets of score sheets (for details see Ambrosini, 2000). The K-SADS-P IVR score sheet has specific diagnostic domain scores that might be useful for evaluation outcome studies.

For the K-SADS-P/L, the authors recommend that parent(s) and child are interviewed separately: parent first, then child. Each interview takes approximately 1.25 hours. After the child interview, the Summary Lifetime Diagnoses Checklist and Children’s Global Assessment Scale (CGAS) ratings are completed by the interviewer/clinician after synthesizing all the data and resolving any discrepancies in the informants’ reports (undertaking further interviews if necessary).

The interview begins with an unstructured introductory session with opportunities to develop rapport and obtain an account of the problem. The diagnostic screening review covers 20 diagnostic areas and 82 symptom areas (for current and past episodes) using a modular interviewing technique with screening questions and a “skip structure” for symptom areas that are of insufficient intensity. It is the interviewer’s responsibility to ascertain range of symptoms, types of treatments and interventions received, if any, and severity of impairment.

The final diagnoses made are based on the clinician/interviewer’s overview of the interview, not an algorithm. Both K-SADS and CAPA (see below) provide detailed (DSM-IV and/or ICD-10 compatible) definitional glossaries (Angold & Fisher, 1999). However, most studies use the K-SADS diagnoses as part of a best estimate procedure.

The interviews can be downloaded from the University of Pittsburgh website for clinical and research purposes. To use the K-SADS reliably requires specific training in the use of the interview(s) and in the DSM diagnostic classification system. Recent studies have reported the use of the K-SADS with a variety of interviewers including research clinicians and lay interviewers (who attended a 4-month training program and received at least weekly supervision throughout the study; Axelson, Birmaher, Strober et al., 2006). Inter-rater and test–retest reliability data are available for the English language versions of the K-SADS (for details of the reliability data and discussion of the validity studies see Ambrosini, 2000). Recent papers have reported preliminary data on psychometric properties for different translations and use in different populations (Ghanizadeh, Mohammadi, & Yazdanshenas, 2006; Kim et al., 2004; Kolaitis et al., 2003; Shanee, Apter, & Weizman, 1997).

**Child and Adolescent Psychiatric Assessment (CAPA)**

(Angold & Costello, 2000; Angold, Prendergast, Cox et al., 1995; Angold, Costello, Erkanli, 1999)

This is a more recently published, investigator-based, semi-structured diagnostic interview (originally developed at the Institute of Psychiatry, London, UK) which has been used in international research studies and some clinical settings. The current CAPA 4.2 (2001) has versions for use with children aged 9–18 years.

The interviews take approximately 2 hours to complete. The child version does not contain an attention-deficit/hyperactivity disorder (ADHD) section. The overall structure has a number of features in common with other currently available SIs such as the K-SADS (Ambrosini, 2000). The interview is divided into three sections: introduction, overview of presenting problems and current functioning; detailed symptom review; and incapacity ratings. There are 1401 emphasized compulsory probes and 2571 discretionary probes. Interviewers are required to take notes and encouraged to make an audiorecorded recording. Each section has an initial screening part and “skip” rules apply if no symptoms are reported for that section. The interview covers 30 different categorical disorders (according to ICD-10 and DSM criteria, including certain uncommon symptoms – e.g., suicidal attempts – but omits neurodevelopmental disorders such as the pervasive developmental disorders), together with sections focusing on family, peer and academic functioning, life events and service utilization (Child and Adolescent Services Assessment [CASA]; see below).

There is a current (“primary 3 month period”) and a lifetime version for major episodes of certain disorders. Further developments include new Lifetime Child and Parent versions used in specific research studies (Rutter, Silberg, Colvert et al., 2004; Silberg, Simonoff, & Rutter, 2003).

The authors report test–retest reliability for diagnoses. Their website refers to a 1-month course, provides a contact for enquiries about training and emphasizes the need for regular supervision and fidelity checks. No information is available about translations.

The CASA assesses the use of mental health services by children (Ascher, Farmer, Burns et al., 1996; Farmer, Angold, Burns et al., 1994). It has four parts and takes up to 20 minutes to administer using a mixture of respondent- and investigator-based approaches.

**Preschool Age Psychiatric Assessment (PAPA)**

(http://devepi.mc.duke.edu)

This is a newly developed, investigator-based, semistructured parent interview for diagnosing psychiatric disorders and symptoms in preschool children aged 2–5 years (Egger & Angold, 2004; Egger, Ascher, & Angold, 1999). It is derived from the CAPA (with mandatory and supplementary probes.
A detailed developmental history is an essential component of a multidisciplinary and/or multiagency assessment for the differential diagnosis of pervasive developmental disorders (PDD)/autism spectrum disorders (ASD). A professional with recognized ASD training usually undertakes this. The three instruments described below all provide a standardized interview format for the systematic collection and recording of this information while providing different approaches to the topic. Although there is no evidence to date for a particular framework for history-taking within a CAMH service, the history-taking format should use ICD-10 and/or DSM-IV criteria (Le Couteur, 2003).

**Structured Interviews for Specific Disorders**

Described in this section are four exemplars of the types of SIs in current use in some clinical settings. They contribute to the assessment of two different specific types of disorder: pervasive developmental disorders and anxiety disorders.

**Pervasive Developmental Disorders**

The interview covers DSM-IV disorders relevant to younger children and symptoms that do not feature in current diagnostic systems. PAPA also assesses disability, family environment and relationships, family psychosocial problems and life events. The time focus is the 3 months immediately before the interview and a lifetime framework for some symptoms. The interview is said to take 1.5–2 hours to administer.

The interview begins with a brief developmental assessment to orient the interviewer to the developmental level of the child. The sections cover topics such as family structure and function, play, peer and sibling relationships; day care/school experiences and behaviors; food-related behaviors; sleep behaviors; elimination problems; somatization; accidents; reactive attachment; life events; parental psychopathology; marital satisfaction; socioeconomic status and diagnostic modules including conduct problems, ADHD, separation anxiety; anxious affect; tics; stereotopies; depression; mania, etc. At the end of each section/domain an evaluation of resultant disability is made. Once the interview is completed it is coded and entered into a computerized database. Computerized algorithms generate various symptoms, impairments, life events and family functioning scores and diagnoses for DSM-IV disorders (Chrisman, Egger, Compton et al., 2006).

The authors report test–retest reliabilities for PAPA diagnoses and scale scores and no significant differences by age, sex or race (Egger, Erkanli, Keeler et al., 2006). To date, the PAPA has been used as a research diagnostic tool. If it is acceptable to families and clinicians, this modularized general diagnostic interview for preschool children may have clinical utility for practitioners working with preschool children and their families.

Diagnostic Interview for Social and Communication Disorders (DISCO, version 9) (Leekam, Libby, Wing et al., 2002; Wing, Leekam, Libby et al., 2002)

This is a semistructured, investigator-based schedule for use with parents and carers. It was designed to collect information on development and behavior for individuals of all ages and levels of ability, to assist clinicians in the diagnosis, differential diagnosis and management of autism spectrum and other developmental disorders affecting social interaction and communication. Unlike most published SIs it was not designed to provide a particular diagnostic category related to current international classification systems (ICD-10 and DSM-IV), but rather to cover a wide range of developmental skills and behavioral features including diagnoses beyond ASD. The interview is used in some clinical settings to help in the assessment of need and guide recommendations for interventions. The authors have reported initial inter-rater reliability data and provisional algorithms to facilitate the research use of the interview (Leekam, Libby, Wing et al., 2002). The information collected can be used to make a clinical diagnosis within the autistic spectrum, a developmental disorder on the borderlines of the spectrum and a psychiatric disorder. It takes approximately 3 hours to complete. Training is required and is available in the UK through the Center for Social and Communication Disorders, National Autistic Society.

**Autism Diagnostic Interview-Revised (ADI-R)** (Le Couteur et al., 2003; Rutter, Le Couteur, & Lord, 2003)

This investigator-based interview was designed to provide a developmental history framework for a lifetime differential diagnosis of PDD and information about current functioning (over the previous 3 months), for individuals (with a mental age of 2 years or above) from early childhood to adult life (American Psychiatric Association, 2000; WHO, 1996). It was originally developed to form part of a multidisciplinary research-based diagnostic assessment in combination with a parallel observation measure: the Autism Diagnostic Observation Schedule (ADOS; Corsello, Spence, & Lord, 2003; Lord, Risi, Lambrecht et al., 2000; Lord, Rutter, DiLavore, 2001).

The interview has been used extensively for research and for some clinical purposes. Clinicians might consider using it when more information is required for a complex case including a diagnostic query regarding possible ASD or related disorders, or to assess syndrome boundaries. However, currently there are no published standard algorithm cut-off scores for “non-autism” ASDs. The ADI-R does not cover the more subtle or milder symptoms that might be considered clinically as part of the extended ASD broader phenotype but further measures are under development (Bailey, Palferman, Heavey et al., 1998).

The ADI-R contains over 100 items in five main sections: early development; communication; social development and play; repetitive and restricted behaviors; and related problems. There is a standard format with behavioral definitions for each item both on the schedule and within the published manual (Rutter, Le Couteur, & Lord, 2003). Each item or section has an initial compulsory question but the interviewer needs to
record detailed descriptions of behavior and activity directly onto the schedule to justify each coding decision.

The ADI-R takes 1.5–3 hours to administer and score (Rutter, Le Couteur, & Lord, 2003). The ADI-R diagnosis is not a clinical diagnosis but the result of combining coded information from the interview.

Training is essential for the reliable administration of the interview. Video training tapes and training manuals are available in English for clinical training purposes. Additional reliability training is required for the research use of the interview. The ADI-R has now been translated into several languages. At present these translations have been primarily for research purposes.

Psychometric data on the ADI-R are available (for summary see Rutter, Le Couteur, & Lord, 2003). The authors have reported good inter-rater and test–retest reliability and shown that the interview is effective in differentiating autism from intellectual disability and language impairment in people with a range of chronological ages and developmental levels. Further studies by other groups have reported both good psychometric properties (de Bildt, Sytema, Kraijer et al., 2004; Lecavalier, Aman, Scabill et al., 2006) and the usefulness of the ADI-R in research studies (Berument, Rutter, Lord et al., 1999; Constantino & Todd, 2003; IMGSAC, 2001; South, Ozonoff, & McMahon, 2005). Recent studies have confirmed high sensitivity (83–91%) but lower specificity (56–72%) for autism (Risi, Lord, Corsello et al., 2006). Recent studies have investigated the relationship between the ADI-R and the observational assessment of the ADOS (de Bildt et al., 2004; Le Couteur, Haden, Hammad et al., 2007; Risi, Lord, Corsello et al., 2006). With increasing awareness of the broader autism spectrum, the original authors and a number of other ASD research groups are currently reanalyzing the diagnostic algorithm(s) for the ADI-R (Buitelaar, Van der Gaag, Klin et al., 1999; IMGSAC, 2001; Tadevosyan-Leyfer, Dowd, Mankoski et al., 2003).

Developmental, Dimensional and Diagnostic Interview (3di)

This is a recently published, computerized procedure devised for administration by trained interviewers with a parent informant using a laptop computer that generates symptom and diagnostic profiles for autism and non-autism conditions (Skuse, Warrington, Bishop et al., 2004). It is an investigator-based SI with opportunities to expand the questions used depending on the parental account. It focuses mainly on current functioning. Parents can be sent a pre-interview package of questionnaires to complete. This information is entered onto the computer and allows an abbreviated interview lasting 45 minutes, compared to 90 minutes for a full interview. The 3di was primarily devised to assess autistic traits and comorbidity in normal ability range children, but may be used with those with moderate or severe intellectual disability. It has 183 items on background child and family information, 266 autism-specific items and 291 questions about current mental state. Algorithms automatically weight and sum responses within domains, and adjust scoring for age and for non-verbal subjects. A structured computer-generated report is available at the end of the interview. The authors, using comparisons with the ADI-R and DISCO to assess content and criterion validity, have published initial reliability and validity data. Training is required. The authors recommend both that the 3di is used in combination with independent observational assessments (such as the ADOS; see p. 281) and the facility to download automatically the 1300 variables to investigate dimensions of ability and impairment within clinical and non-clinical groups. This automated instrument claims to provide new opportunities for the assessment of individuals, particularly those with a range of symptoms including social impairment. The facility to generate automatic reports is likely to appeal to busy clinicians.

Anxiety Disorder

The final example of an SI is the Anxiety Disorders Interview Schedule IV (ADIS-IV), used for the investigation of anxiety disorders. These disorders are common in childhood and, given the high rates of comorbidity, a careful thorough diagnostic evaluation is necessary to establish an accurate diagnostic profile and baseline for planning intervention (see chapter 39). Such considerations are relevant for most child and adolescent assessments and many diagnostic interviews (e.g., K-SADS and DISC-IV) cover the specific symptoms of these disorders (Langley, Bergman, & Piacentini, 2002). These recent DSM-IV-based interviews, including the ADIS-IV, demonstrate acceptable to good psychometrics for these diagnoses (Langley, Bergman, & Piacentini, 2002; Silverman, Saavedra, & Pina, 2001; see chapter 39).

Anxiety Disorders Interview Schedule (ADIS-IV) (with both Child and Parent versions) (Silverman & Albano, 1996a,b; Silverman & Nelles, 1988)

This was first published in 1988 and revised in line with DSM-IV in 1996. There is a lifetime version (ADIS-IV-L) to establish past diagnoses. It also contains a timeline to assist charting onset, remission and temporal sequences of disorders. This investigator-based interview is designed specifically for the diagnosis and functional analysis of anxiety and related disorders including ADHD, phobic disorders and obsessive-compulsive disorders (OCD) in children and adolescents aged 6–18 years. The interview takes 1–1.5 hours, with initial sections for most diagnoses that can be used to screen for disorder. It is able to assess comorbidity and screen for other disorders including psychosis, selective mutism and substance misuse. There is some evidence that the interview is useful in other cultural settings (Rapee, Barrett, Dadds et al., 1994). The parent version contains probes for disruptive disorders and requests greater detail. The child version provides a simpler format and wording. A visual prompt in the form of a 9-point scale “feeling thermometer” is used to assist parents and children judge the degree of impairment (Silverman & Albano, 1996a). Composite diagnoses are made by clinicians based on level of severity and agreement between the two interviews (Grills & Ollendick, 2002; Stallings & March, 1995).
CHAPTER 19

Structured Observational Methods in Clinical Settings

Observational methods involve watching and systematically recording the behavior of others directly as it occurs rather than retrospectively. This contrasts with interview techniques, which typically involve recalling or making judgments about one’s own behavior and that of others over a longer time period. Observational methods can be used to assess child behavior and social interactions in a range of contexts. One of their great strengths is that they provide a window on these processes in their natural setting. They can also be used in settings that are intended to mimic aspects of a natural setting, such as in a laboratory or clinic.

Observational methods have a wide range of research and clinical uses (e.g., assessing the nature and extent of a clinical problem, formulating hypotheses about social influences on behavior, evaluating treatment outcome and investigating basic research questions). Observations can be informal and unplanned, such as when observing parent–child interaction in a clinic waiting room, or they can be highly structured, such as those used in clinical research studies.

This chapter focuses on observational methods that entail imposition of some degree of structure in terms of the setting and the way in which behavior is recorded and coded. In order to understand what constitutes good-quality measurement for a given purpose, the principles behind formal structured observation will be covered. However, it is important to note that there is a continuum from highly structured to more informal methods. Although methods that are closer to the informal end of the spectrum may be more useful in clinic settings, formal principles may be helpful in applying these techniques with greater rigor and validity to everyday clinical questions. For more detailed coverage, readers are referred to general reviews (Bakeman & Gottman, 1997; Gardner, 2000; Hartmann, Barrios, & Wood, 2004; Hops, Davis, & Langoria, 1995; Patterson, 1982; see chapter 4). Margolin, Oliver, Gordis et al.’s (1998) paper is particularly useful on practical considerations in using observational methods.

First, what is meant by “structure”? In this context it refers to two things: the nature and specification of the setting in which behavior is observed; and the formal method of measuring behavior. A highly structured setting would be one that involves a series of precise instructions to those being observed (Gardner, 2000). Sometimes these are referred to as “analog” settings (Heyman & Slep, 2004; Roberts, 2001). For example, parent and child are asked to interact in a particular way during the “strange situation,” or during a parent–child task. However, other methods specify that the setting will be as natural as possible (Gardner, Ward, Wilson et al., 2003; Patterson, 1982). A highly structured measurement method would be a formal reliable coding system, used to describe and quantify behaviors or interactions of clinical interest. For example, many parenting intervention studies have used Eyberg, Bessmer, Newcomb et al.’s (1994) “Dyadic Parent–Child Interaction System” to quantify behavior in the home or clinic. High degrees of structure in task and measurement may go hand-in-hand (e.g., in the “Strange Situation,” where both are highly specified). In contrast, many parent–child interaction observation schemes have flexible tasks but highly systematic measurement.

This distinction between types of structure has a clear parallel in interview methods: earlier, a distinction was made between the structure of the stimulus (questions) presented to the interviewee, and the structure of the coding definitions for the reported behaviors to quantify the clinical phenomena of interest. We focus primarily on formal structured observational methods that might be used in clinical research or practice, but we attempt to consider how elements of these methods might be applied realistically and more informally in practice. As with interview methods, the usefulness and feasibility of a particular method of assessment will depend to a very great extent on the purpose of the assessment and the type of question being asked.

Advantages of Observational Methods

Observational methods have a number of advantages. The first two of these are to some extent shared with interview techniques, the other two are more distinctive. First, they have a wide range of uses (e.g., to assess child problem behavior and social skills, or parenting skill, in a natural or contrived setting). They can be used to measure environmental conditions (e.g., the social interactions surrounding problem behavior, or the physical surroundings of the home, classroom or neighborhood).

Second, observational measures appear to be sensitive to treatment change (Dishion & Granic, 2004), and thus are suited to assessing outcomes of interventions for individuals, or as part of group treatment designs. They complement other measures that draw largely on participants’ perceptions, and these in combination provide a “gold standard” of measurement of treatment mechanisms and outcomes in randomized controlled trials for some clinical problems, particularly where observable behavior is central (e.g., for measuring conduct problems or social skills; Gardner, Burton, & Klimes, 2006; Webster-Stratton, 1988).

Third, observational methods have high face validity; some have suggested that “what you see is what you get” (it is not this simple). Behaviors are normally observer-defined, and hence can be applied consistently across individuals, relatively uninfluenced by respondent biases, which may result from low mood, expectancy and definitional idiosyncrasies (Richters, 1992). Instead, observer bias can be a problem (Patterson, 1982), but steps can be taken to minimize this (e.g., the expectancy that behavior will change following treatment).

Fourth, observations in structured situations may be arranged so as to “press” for (elicit) clinically important behaviors or emotions (e.g., response to separation or to parental demands). This is particularly important for assessing young or socially impaired children, who cannot report on their own behavior.
Finally, observations are the only way of assessing in detail the nature of fast-moving social interactions. These are hard for participants to access themselves, yet they may be central to understanding social influences on a clinical problem. Observations provide an account of these interactions, independent of the perceptions of those taking part. This has been particularly important in understanding family processes, exemplified by Patterson’s (1982) work on conduct problems and Gottman’s (1993) on marital problems. Observational measurement of processes such as dyadic reinforcement, peer contagion and responsiveness has helped to build major causal theories of clinical problems, to develop interventions and to test mediating mechanisms (Gardner, Shaw, Dishion et al., 2007; Rutter, 2005). This approach to observation can also be very helpful in clinical assessment, to aid formulation of parent influences on child behavior and affect.

Drawbacks and Limitations

The first drawback is shared with SIs. The time and expertise needed to learn a coding system, and collect and analyze data means that complex observation systems may be impractical for clinic use (Margolin et al., 1998). However, validity depends on purpose. Brief, informal use of a parent–child observation system is helpful for generating hypotheses about family influence, providing feedback to parents on interaction style, or generating discussion and goals for intervention (Dishion & Kavanagh, 2003; Hartmann, Barrios, & Wood, 2004). Non-systematic observations may be less useful for making accurate comparisons of behavior before and after treatment, or between families. Observations can only sample small segments of behavior, measured in minutes or hours. They cannot easily measure infrequent events or summarize across multiple settings and over time. This is an important caution, given that many behaviors vary a great deal by context. Representativeness of these segments becomes a critical issue. A consequence of brevity of observations is that sampling error can also be a problem. Observer bias and reactivity can present considerable potential threats to validity (what you see is maybe not what you normally get), although these problems also affect other assessment methods. However, these problems are not insurmountable, and much thoughtful work in the field has focused on assessing the extent of error and bias, and on attempting to overcome them (Gardner, 2000; Haynes, 2001; Patterson, 1982; Stoolmiller, Eddy, & Reid, 2000). Finally, these methods can only tap observable aspects of clinical phenomena, such as behavior, emotional expression, social interaction or the physical environment. They cannot assess feelings or perceptions of a problem.

Reactivity to Being Observed

Reactivity refers to the phenomenon whereby the process of being observed affects participants’ behavior, which in turn may affect generalizability from observation data to other situations. The extent to which there is an observer effect is likely to depend on several factors, including: conspicuousness of the observer; opportunity to habituate to their presence; participants’ understanding of the purpose of observation; and demands and setting of the task. These factors are least likely to affect observations of young children. However, even adults may be less affected by being observed than common sense would suggest. Thus, Johnson and Lobitz (1974) found that parents in clinical samples were unable to alter their own behavior during observation (Patterson, 1982). It is encouraging that evidence from other approaches to measuring reactivity has led to a similar conclusion (for reviews see Gardner, 1997, 2000; Patterson, 1982). Nevertheless, it is worth taking steps to minimize reactivity, by allowing time for familiarization with procedures, by having the same observer for repeat observations, by limiting the number of observers present, and minimizing obtrusiveness of their behavior and equipment.

Considerations in Selecting an Instrument or Method

General Considerations

When designing a coding system, Hartmann, Barrios, & Wood (2004) suggest three golden rules: begin with a clear question; conduct pilot observations; keep coding simple. This advice equally applies to choosing from among existing systems. Every aspect of selecting a method is closely driven by the question or purpose of assessment, as well as practicality and resources. Is it for diagnosis, baseline and outcome comparison, case formulation, treatment planning or several of these? What phenomena are of interest? It is important that the purpose is thought through carefully, and that feasibility of observations is tested through piloting. Two very common problems can be revealed through piloting. First, many coding systems are too complex to be of practical use, except in large research projects. Second, many clinically interesting phenomena have a low base-rate of occurrence. Piloting helps clarify which behaviors are possible to observe and code in the context and time available.

Idiographic or “Off the Shelf”?

For research purposes, where comparability among participants is vital, it makes sense not to reinvent the wheel but to use a well-validated instrument with a manual, if there is one that fits the purpose. However, for many clinical purposes, such as to develop hypotheses about factors influencing problem behavior, or to evaluate individualized outcomes, it may be useful to design observations specially for a given clinical situation, which may be entirely idiographic ones, to suit the clinical goals for that individual. There is a lively literature within the field of behavioral assessment on the reliability and validity of individually designed observational methods (Haynes, 2001; Heyman & Slep, 2004; Mash & Foster, 2001),
suggesting that rigor need not necessarily be sacrificed in order to answer individualized clinical questions.

**What Behaviors to Observe?**

In addition to the practical considerations above, selection of behavior to observe will depend on which clinical phenomena are of interest. It may also be linked to the theoretical underpinning of interventions. Thus, within an attachment framework one would focus on different aspects of parenting compared to a cognitive-behavioral framework. Dowdney, Mrazek, Quinton *et al.* (1984) provide a rare thorough discussion of how behaviors were selected, and for what purposes, in developing a parent–child interaction coding system. Many of the systems reviewed below can be adapted to carry out simple counts of a few common behaviors for clinical purposes (e.g., non-compliance, parent negative commands, praise and affection).

Given a particular content area of interest, the stream of social interaction may be described and split up along a number of different dimensions (e.g., a system for measuring harsh parenting might code content, affect or timing of behavior, or all of these). Two considerations are of particular importance: the level of complexity of the codes and the unit of analysis employed.

**Complexity of Behavior Codes**

Observed behavior can be described and coded in terms of relatively simple, discrete behaviors (e.g., hit, command, smile), or in terms of more complex, higher-order constructs (sensitive parenting, avoidant attachment, play, ritualistic behavior). More complex constructs generally need more inference to code, and as a result may be harder to learn and to code reliably. However, simpler codes may have the drawback of not adequately representing phenomena of clinical interest. Interobserver reliability, validity and resources are key considerations in deciding whether to use complex codes. It should be noted that even apparently simple behaviors require a good deal of inference to code, as social behaviors are rarely captured by definitions based on motor behavior alone.

**Unit of Analysis: Splitting the Stream of Behavior**

The behaviors selected will guide the process of identifying the most appropriate unit of analysis. For example, event-sampling methods, which count the frequency of behaviors of interest, are suitable for measuring occurrence of discrete events. Behaviors that tend to occur continuously over time (e.g., crying, arguing, task concentration, elaborate rituals) are more suited to timing duration, although this is hard to do for several behaviors at once. Many observational systems record neither real frequency nor duration, instead they make coding simpler by using some kind of time-sampling. This involves recording occurrence or absence of a given behavior in a set time interval. Piloting and consulting the literature are crucial, to check that the time interval is appropriate for the behaviors and the context. Many systems use 30-second intervals (e.g., Dyadic Parent–Child Interaction Coding Scheme [DPICS]); however, this may be too short for rare behaviors and too long for very frequent ones. Much work has gone into assessing the utility of these sampling methods for different purposes (Bakeman & Gottman, 1997; Hartmann, Barrios, & Wood, 2004). Many systems do not count or time behaviors, but make systematic global judgments about qualities of behavior (e.g., Deater-Deckard, Pylas, & Petrill’s 1997 Parent Child Interaction System (PARCHISY); Dishion’s Coder Impressions Inventory – Jabson, Dishion, Gardner *et al.* (2004)).

**Selecting Task and Setting**

Observational methods necessarily involve sampling only a small fraction of the tasks, settings and occasions in which interaction normally take place. They may also require families to be observed during unusual tasks or settings (e.g., playing with new toys in a laboratory, or being asked to plan a party together). Yet observational data are normally intended to be representative of the underlying base-rate or style of the given behavior. Thus, it is important to consider and choose carefully the task, setting and duration of observations, as all these have implications for how generalizable, or ecologically valid, the data may be. Caution is needed, given that there are few studies to inform us about whether observations collected in the laboratory and clinic, or during tasks imposed by the observer, are representative of interactions that typically take place in the home (for reviews see Gardner, 1997, 2000; Mori & Armendariz, 2001). This is all the more important because social behavior is strongly influenced by context. It is also vital to choose behaviors that are common enough to be observed during a brief session; otherwise the session will need lengthening. Researchers should avoid designing a system that appears clinically relevant, but where behaviors (e.g., mother “follows through” on threats; uses time-out) are unlikely to occur in a 30-minute home session.

Many different observation tasks have been used to study parent–child interaction in the home and clinic, including common mildly stressful events such as mealtime (Patterson, 1982), problem-solving tasks, tidy-up tasks (Gardner, Sonuga-Barke, & Sayal, 1999; Roberts & Powers, 1988) and tasks where the mother is busy and the child has nothing to do (Gardner *et al.*, 2006, 2007). Others include structured and free play (Forehand & McMahon, 1981). Many minimize imposition of tasks by carrying out naturalistic unstructured observation at home (Gardner *et al.*, 2003; Patterson, 1982). The selection of tasks has important implications for which behaviors will be generated. Employing brief structured tasks is more economical, and has the benefits of increasing the consistency of sampling across individuals or time, and increasing the likelihood of certain key behaviors arising. However, artificiality of tasks that “press” for particular behaviors can mean that behavior is not representative of that seen elsewhere. Although we need to be cautious about their validity, for certain purposes observations carried out in highly artificial situations may still generate sufficient information to demonstrate underlying behaviors or processes of interest (Margolin *et al.*, 1998).
Examples of Observational Assessments

Examples of observation approaches and instruments will be classified by the purpose of assessment, rather than by the diagnostic problem. This is because differences of purpose lead to markedly different kinds of assessment. It is not possible to provide an exhaustive list of instruments; instead, commonly used exemplars will be described briefly, with references to other instruments.

General Classes of Clinical or Research Purpose

To Assess Discrete, Clinically Important Parent or Child Behaviors in their Relevant Setting

For example, in order to measure their frequency before and after intervention; to compare families.

Parenting and Child Problem Behavior

The Dyadic Parent–Child Interaction Coding Scheme (DPICS; Eyberg et al., 1994) is commonly used for assessing parenting and child oppositional behavior in clinical trials and practice, and has a full manual (www.hp.ufl.edu/~seyberg/measures.htm). The system captures common clinically relevant behaviors that can easily be observed and counted in the home or clinic, including child non-compliance, yelling, aggression, and parent behaviors such as praise, clear/vague/negative commands, threats, yelling, hitting. Although there are 28 categories, these can be collapsed into summary codes, or relevant behaviors selected, to reduce complexity and training time. It can be used during unstructured interactions and tasks such as clear-up or parent-directed play. The system has been validated extensively in clinical trials by Eyberg and by Webster-Stratton (see Brestan & Eyberg, 1998) and is sensitive to treatment change. It captures most basic information about positive and negative parenting and child behavior needed to evaluate interventions aimed at these targets.

Others have developed similar systems, described in an accessible way; for example, Forehand and McMahon’s (1981) Behavioral Coding System (BCS), which has been used more recently in the FastTrack trial of conduct disorder prevention (Conduct Problems Prevention Research Group, 1999). Some-what more complex systems, from which behaviors could be selected for clinical purposes, include systems by Dishion, Nelson, Winter et al. (2004; see Oregon Social Learning Centre www.oslc.org) and by Gardner et al. (1999, 2003, 2006, 2007).

Social Communication and Stereotyped and Repetitive Behaviors

Repetitive and stereotyped behaviors occur intermittently and so may not occur during the defined observation period. In the field of autism/ASD research and increasingly in clinical practice, methods of standardizing direct observations including ratings of repetitive behaviors have been used to complement information from other sources. There are several checklists and observation schedules that can be used for observing individuals. The Childhood Autism Rating Scale (CARS) provides a framework for characterizing behaviors associated with autism (DiLalla & Rogers, 1994; Schopler, Reichler, & Rochen Renner, 1986). It is widely used but was developed as an initial screening assessment and not a diagnostic tool. The ADOS was first developed together with the Autism Diagnostic Interview (ADI) as a “package” of instruments for research diagnosis. It has been revised and published in four modules (Corsello, Spence, & Lord, 2003; Lord, Rutter, DiLavore et al., 2001). It provides through the specification of “social presses,” standard contexts for observation of behavior in individuals (across the ability range) suspected of having a possible autism spectrum disorder, ranging from toddlers to adults. This is one of the strengths of this standardized measure. The ratings cover aspects of social behavior, communication, play and restricted and repetitive behaviors.

Until recently these latter items had not been included in the diagnostic algorithms (Gotham, Risi, Pickles et al., 2007). The ADOS is widely used in research and clinical settings, is translated into several languages and takes about 30–45 minutes to administer. Training and regular reliability checks are necessary (for psychometric data see de Bildt et al., 2004; Lord et al., 2001). Inter-rater reliability of items across modules is good (kappa ≥ 0.6). The exception is coding of some items such as some repetitive behaviors and sensory abnormalities. These occur less frequently and are therefore more difficult to code reliably. The diagnostic validity of the ADOS algorithm across modules for autism versus non-spectrum disorders, controlling for expressive language, is excellent (specificity score range 0.93–1.00). However, as expected, the distribution of item and algorithm scores between autism and the broader grouping of ASD shows considerable overlap. Differentiation of autism from Pervasive Developmental Disorders Not Otherwise Specified (PDD-NOS) is moderate (specificities 0.68–0.79; see chapter 46).

Fearful and Anxious Behavior

Various observational systems have been devised for assessing children’s approach/avoidance and signs of anxiety in response to phobic or fear-provoking situations. Melamed and Siegel’s (1975) Observer Rating Scale of Anxiety rates 29 possible behaviors in response to feared situations (e.g., crying, hair pulling, trembling, and behaviors assumed to indicate lower fear, including smiling, chatting). Behaviors are sampled as present or absent in each 3-minute time-sample. The system has been validated in a range of medical and dental settings, but could also be applied to other phobic situations. Another commonly used observational measure is the behavioral avoidance test. This is not a specific test, rather a set of principles for measuring approach or avoidance to a phobic situation, individualized for the child. It has also been used in a standardized manner, where all patients have the same circumscribed phobia (e.g., in a spider phobia trial; King, Muris, & Ollendick, 2005).
CHAPTER 19

Social Skills
Social skills are frequently assessed in analog tasks (Spence & Marzialli, 1981; Van Hasselt, Hersen, & Bellack, 1981), for example, by asking children to role play the situations they find difficult, and coding their behaviors in a standardized manner.

To Assess Factors in the Social Environment that Influence Child Behavior
Most systems for counting parent-child behaviors can also be used to examine relationships between behaviors. This is particularly useful for formulating hypotheses about immediate functional relations between parent behavior and child symptoms. Thus, DPICS can be used to assess whether parental praise or other attention follows contingently from appropriate child behavior, or whether they tend to be elicited by child problem behavior. Gardner, Sonuga-Barke, & Sayal (1999) used observations of a parent-child clear-up task to assess timing of parental control strategies (e.g., incentives or reasons), that is, whether they “pre-empted” child non-compliance, or simply reacted to its occurrence. The pre-emptive sequence was found to be predictive of fewer conduct problems 2 years later. Such observations can be used to generate hypotheses or agree targets for intervention, as well as to monitor treatment progress or outcome, examining whether these contingencies change following intervention.

There is a considerable literature on the use of idiographic observational methods tailored to the particular presenting problems and contextual factors relevant to that child, in relation to emotional and behavioral problems (Haynes, 2001; Heyman & Slep, 2004) and challenging behavior in learning disability (Oliver, 1995). These techniques can be used to analyze behavior in their presenting context (e.g., bedtime, mealtime, school refusal). Some clinicians make use of home videos to assess and analyze influences on these symptoms, which can be filmed by staff or parents and brought into the clinic for discussion if home visits are not feasible (Juffer, Hoksbergen, Riksen-Walraven et al., 1997; Shaw, Dishion, Supplee et al., 2006).

To Assess the Physical Environment Around the Child
The HOME Inventory (Caldwell & Bradley, 1984) measures the physical and social environment in home through a combination of observer ratings of resources (e.g., books, toys, general chaos) and of parent-child interaction, and an interview with the parent.

To Make Global Judgments about Qualities of Behavior or Relationship
These may be used for various purposes, including clinical description of a parent-child relationship; and comparing families in clinical research; and setting goals for intervention or evaluating change.

Global coding schemes are ones that do not count individual behaviors, but instead make global judgments about complex behaviors, in a pre-set time interval, or across an entire observation session. PARCHISY (Deater-Deckard, Pylas, & Petrill, 1997) is a global coding scheme with 13 parent and child categories rated on Likert scales. It can be used in home or clinic during brief “free play” sessions, or in structured play tasks. In a study of 62 twin-pairs, behaviors measured by the scheme were associated with children’s social-emotional adjustment based on parent-report (Deater-Deckard, Pike, Petrill et al., 2001). However, PARCHISY’s validity has not been formally evaluated, and it uses generalizability theory approaches to assessing interobserver reliability (alpha range, 0.78–1.0). There is no published manual for PARCHISY; however, its format suggests it would be an accessible scheme to use, as it is designed to be self-explanatory. Although global ratings generate rich information, they carry the drawback of being more open to bias compared to frequency counting methods (Patterson, 1982), making it particularly important for research – or for objective monitoring of treatment progress – that observers are blind to other information.

The “strange situation” (Ainsworth, Blehar, Waters et al., 1978) is a well-known example of a highly structured observation task used primarily as a research instrument for assessing attachment security. It involves observing the child’s response to a series of separations and reunions with mother and with a stranger in the clinic setting. The high degree of structure has raised questions about its validity in relation to attachment behavior in more natural settings (see chapter 55).

To Give Feedback on Presenting Problems
A number of interventions involve using direct observational assessments of family interaction and child behavior in order to give feedback to families on the presenting problems. Examples where the intervention has been tested in randomized controlled trials (RCTs) include Dishion’s Family Check-Up (Dishion & Kavanagh, 2003; Shaw et al., 2006) and Juffer et al. (1997) Video Home-Training. Another example not tested in RCTs is Puckering et al. (1994) Mellow Parenting. Dishion’s Family Check-Up uses feedback from video home observations, as well as other parent-report assessments, to motivate parents for change. This is carried out by comparing the child’s behavior with norms, and with the parents’ own stated goals, using motivational interviewing strategies. Video feedback is also used to decide intervention goals and stimulate collaborative discussion of effective parenting strategies. It has been used with young children and adolescents, in both preventive and treatment settings.

To Assess the Therapy Process
Systematic observations have been used to examine therapy processes (e.g., as an aid to clinical supervision and training, and more formally in order to assess treatment fidelity). Examples of coding schemes include Forgatch’s Fidelity of Implementation (FIMP), which involves rating content and therapeutic skills during parent management training. Construct validity of the system is assessed by examining predictions from FIMP score to treatment outcome. Forgatch, Bullock, & Patterson (2004)
found that higher adherence to the treatment model predicted better treatment outcome.

Reliability and Validity of Interview and Observational Measures

As with any measuring instrument, there are several facets of reliability and validity assessment to consider. Interobserver (or inter-rater) reliability is most commonly assessed for standardized interviews and observations (Dorsey, Nelson, & Hayes, 1986; McClellan & Werry, 2000; Rijnders et al., 2000). The nature of the instrument, its clarity and complexity influence how reliable raters can become (Dunn G., 2000; Jensen & Edelbrock, 1999; Weinrott & Jones, 1984). For SIs there is also the need to consider multiple informant reliability (for review of parent–child discordance see Grills & Ollendick, 2002). Human error and bias, as well as contextual variation in behavior, limit reliability and validity (Gardner, 2000). With suitable training, bias is unlikely significantly to alter observational findings (Patterson, 1982). Nevertheless, it is good practice to keep raters blind to participant status, although this is not easy in clinical settings. Global observation ratings are particularly susceptible to influence of expectations (Lord et al., 2000; Patterson, 1982). In contrast, for SIs higher reliabilities are usually obtained for ratings of global psychiatric status than for ratings of specific symptoms (Charter & Feldt, 2001; Edelbrock & Costello, 1990; Rutter, Le Couteur, & Lord, 2003). Awareness of these issues can inform the use of standardized methods, and interpretation and critical appraisal of research and clinical findings.

There are several indices of agreement, including kappa, intraclass correlation and percent agreement, which can yield different results. Thus, their choice depends on the nature of the data produced and the questions posed (Dunn G., 2000; Repp, Deitz, Boles et al., 1976). Likewise, acceptable agreement level depends on the purpose of measurement and the data properties. However, in practice, many reviewers would regard a kappa or correlation of 0.7 or above as acceptable (Hodges & Cools, 1990). The intraclass correlation coefficient calculates agreement between observers on overall frequency of each behavior observed, and requires continuous data sets, such as frequency counts. For categorical data, Cohen’s (1960) kappa considers point-by-point agreement, taking into account the probability of chance agreement, especially important if there is only a small number of categories. In research studies where comparability between participants is crucial, reliability should be checked periodically to prevent rater “drift” away from the original coding definitions (Patterson, 1982). Regular checks will also be important for enhancing diagnostic reliability (McClellan & Werry, 2000) and ensuring comparability across services.

Also important, although seen less frequently, are measures of test–retest reliability. These refer to the relationship between data collected on the same individual on different occasions. If a system produces consistent results across consecutive interviews or observations for the same individual it is considered to show short-term stability, or test–retest reliability. Few observational systems are subjected to evaluations of stability across sessions (Patterson, 1982), although there is evidence that increasing the number of sessions may increase the power to detect change, important in intervention studies (Gardner, 2000; Stoolmiller, Eddy, & Reid, 2000). With SIs there is the complication of attenuation of symptom reports. This is the tendency for participants to report fewer symptoms on retesting and has been seen in most forms of repeated psychiatric inquiry (Lucas, Schaffer, & Richters, 1999).

While reliability assesses if an instrument is consistent in its measurement, validity considers if it is actually measuring what it purports to measure and, with observations, is affected by issues of task and setting discussed above. Most SIs use operationally defined criteria for presence of a disorder based on existing classification systems. The investigation of content and construct validity of an SI is therefore directly linked with the validation of childhood psychiatric disorders, itself an extensive and continuous process (see chapters 2 & 4). Predictive and concurrent validity of observational and interview systems is also very important to assess. Concurrent validity assesses the relationship between different measures of the same behavior, while predictive validity reflects the extent to which measures produce information that predicts a future criterion (e.g., arrest, response to treatment, risk for recurrence of disorder).

Integrating Structured Interviews and Observational Measures in Clinical Practice

SIs and observational methods have many complementary strengths and weaknesses. Using both in combination is seen as the gold standard in clinical research assessments, for example, in randomized trials of conduct problem treatment (Gardner, Burton, & Klimes, 2006; Scott, Spender, Doolan et al., 2001). However, in everyday practice, clinicians use information from different sources such as parent interview, observations of child behavior and reports from school, when assessing new referrals. How the information is then brought together to understand the presenting problem and plan intervention requires clinical skill and judgment.

The level of detailed information obtained through standardized instruments may not be appropriate for everyday practice where what is required is a broad-based assessment including the individual’s and family’s view(s) of a problem(s), information about personal circumstances and their views about interventions and solutions. However, for CAMH services to be comprehensive and for services to be guided by best available evidence, some professionals will need higher level skills in assessment, intervention and evaluation. Training in the use of standardized measures is one way of increasing the knowledge base and clinical competencies of staff. CAMH professionals with this additional expertise can undertake more
intensive assessments of complex cases and apply the broad principles of reliable and valid measurement to everyday practice through the support and supervision of other members of staff. Even for staff who rarely use standardized instruments, critical clinical skills can be gained from specific training, which are generalizable to everyday clinical assessment. Thus, training may develop their style of systematic detailed questioning; rigorous approach to observation; critical consideration of the validity of their findings. These ways of thinking critically about assessment are likely to be important for enhancing the quality of clinical assessment and intervention.

Finally, the development of robust mechanisms for the integration of different sources of information is a crucial next step for both research and clinical practice. Two recent very different approaches to this dilemma are the Development and Well-Being Assessment (DAWBA; Goodman, Ford, Richards et al., 2000) and the Child and Adolescent Functional Assessment Scale (CAFCAS; Hodges, 2000). Further work in this area will allow us to advance personalized clinical care within an evidence-based approach to CAMH practice.

Conclusions

Consistent clinical assessments and the evaluations of interventions in child and adolescent mental health settings require the collection of standardized information. SIs and standardized observations provide reliable data and, importantly, may help clinicians to improve their generic assessment skills. However, they are unlikely to meet the broader-based needs of individuals seen in everyday practice. Future developments in CAMH will include an increasing emphasis on standardizing measures and the evaluation of staff skills using direct ratings of observed practice and testing of clinical competencies for professional revalidation. In this context, training in the use of specific SIs and standardized observational measures lends itself to this type of professional skills recognition. Future developments in computerized administration and coding of interviews or observations are also likely to make standardized assessment more efficient.

CHAPTER 19

USE OF STRUCTURED INTERVIEWS AND OBSERVATIONAL METHODS IN CLINICAL SETTINGS

There has been an increase in the use of rating scales to assess child and adolescent psychopathology in routine clinical practice. (For brevity henceforward in this chapter the term child will include the adolescent age range.) This is not surprising because rating scales can assist by obtaining and organizing information on children’s problems and strengths in a cost-effective way. Rating scales can aid in various decisions once a patient has been referred to a clinic, including whether assessment at this particular clinic is the most appropriate way of proceeding; if it is, what sort of diagnostic assessment should be undertaken, what type of treatment should be provided for how long, what type and degree of improvement should be expected with intervention, and what should be done after treatment? Thus, the role of rating scales to assess child psychopathology in clinical decision-making pertains to screening, treatment planning, monitoring of treatment progress and to outcomes assessment.

We consider issues specific to the use of rating scales for child psychopathology, discuss some psychometric issues and outline other criteria by which to judge which instrument best suits a particular purpose, discuss issues related to the multicultural use of rating scales in clinical practice, and consider the purposes for which rating scales may be used in routine clinical practice.

The main focus will be on scales to measure a broad spectrum of psychopathology; those for a narrower spectrum of disorders/behaviors and for psychosocial features are considered in the relevant chapter elsewhere in the book. We focus on the criteria to be employed in the evaluation of rating scales rather than discussing the pros and cons of the many scales that exist. For a detailed summary of descriptions of the most widely used rating scales to assess child/adolescent psychopathology, we refer to Verhulst and Van der Ende (2006), where over 100 rating scales are summarized.

**Issues Specific to Rating Scales for Child Psychopathology**

**Multisource Data**

Diagnostic assessment should be based on information from different sources. Diagnostic evaluations will comprise clinical observations as well as interview information. Clinicians can obtain information on the child’s behavior, emotions, rapport and fantasies, as well as estimate the severity and acuteness of problems and the child’s motivation for treatment. However, clinicians are capable of sampling only a small subset of behaviors that children readily show in office settings. For example, behaviors such as fire-setting, stealing or bedwetting, and even behaviors such as tics or hyperactivity will not always be observable by clinicians. Therefore, informants such as parents and teachers, who see children in different situations (home, classroom and playground), are needed to obtain a comprehensive picture of the child’s functioning. Parents are usually familiar with their child’s functioning in many situations and across time. Teachers have the opportunity to compare a child’s functioning with that of large groups of peers. Teacher reports may reveal difficulties in a child’s academic and social skills that may not be evident to parents. Also, adolescents may sometimes take the teacher into confidence and reveal significant problems to the teacher that the parents are unaware of. In addition to adults as informants, adolescents’ self-reports are indispensable, especially on their own affective and other emotional problems.

However, each informant will have a different relationship with the child in different conditions; consequently they often vary in their response to the child’s behavior. In a meta-analysis of 119 published samples, the average correlation between pairs of adult informants who had different roles with respect to the child was 0.28 (Achenbach, McConaughy, Howell et al., 1987). The mean correlation between self-reports and reports by parents, teachers and mental health workers was even lower (0.22). In contrast, the mean correlation between pairs of similar informants (e.g., father and mother; teacher and teacher aide) was 0.60. Correlations were significantly higher for 6- to 11-year-olds than for adolescents, and for disruptive versus emotional problems, although these differences were not large. No significant differences in correlations were found for boys versus girls.

The informants’ differing standards for judging the child’s functioning, as well as their specific impacts on the child and the situational specificity of the child’s behavior, are all reflected in cross-informant variation. Children’s behavior is often much more variable than that of adults, and children are more susceptible to environmental influences.

Instead of viewing the generally low agreement between different informants as a nuisance, or discarding certain sources
of information, it is important to regard each informant as a potentially valid source of information (De Los Reyes & Kazdin, 2005). For example, in a twin study using mothers’ and fathers’ ratings to determine the genetic and environmental contribution to children’s problem behaviors, it was concluded that mothers and fathers validly assess different aspects of the child’s behavior (Van der Valk, Van den Oord, Verhulst et al., 2001). Unique interactions between parent and child, or differences in duration and contexts in which one parent but not the other interacts with the child, might allow each parent to provide additional information about a child’s behavior, apart from the information on which they both agree. Another twin study by Arsenault, Moffitt, Caspi et al. (2003) extended this finding by showing that mothers, teachers, examiner-observers, and children themselves each reported unique and meaningful information beyond the information that was agreed upon.

Disagreement among informants can be valuable (Jensen, Rubio-Stipec, Canino et al., 1999). For example, children who are reported to be hyperactive by both parents and teachers have poorer prognoses than children who are reported to be hyperactive only by parents or only by teachers (Schachar, Rutter, & Smith, 1981). Often, agreement between informants signifies poorer prognosis. However, evidence suggests that discrepancies between information from different informants may also indicate poor prognoses. For example, Ferdinand, van der Ende, & Verhulst (2004b) studied a general population sample of 15- to 18-year-olds prospectively across a 4-year period with parents’ and children’s self-report rating scale scores as information sources. In general, outcomes were worse if parents and children agreed about the presence of significant problems. However, for some types of problems, discrepancies between parent and child were a strong indicator of poor outcomes. For example, the larger the discrepancy in delinquency scores by parents versus child, the greater the likelihood for police/judicial contacts in young adulthood. Likewise, attention problems discrepancy scores were an important predictor of future use of mental health services, and aggressive behavior reported by parents but not by children themselves was a strong predictor of later substance abuse. Also, children who indicated problems with anxiety or depression of which their parents were not aware, had a poor prognosis. Evidence thus suggests that for most problems information from multiple sources seems to be needed.

As yet there are no fixed rules, such as the use of computer algorithms (Bird, Gould, & Staghezza, 1992), to resolve discrepancies between informants. Instead, clinicians need to evaluate whether differences in information reflect important variations in the child’s functioning or differences between informants’ views of the child who in fact behaves similarly in each context. Most rating scales for the assessment of child psychopathology have parallel versions for parents and teachers. Some rating scales have versions for adolescents’ self-reports, although for some rating scales the self-report version is not parallel to the parent and teacher versions and may tap other domains such as personality. The advantage of rating scales with parallel parent, teacher and self-report versions is that the scores across the different informants can be compared. By comparing the level of agreement between different informants’ reports on an individual child’s problems with the level of agreement between similar informants typically found for large reference samples, it is possible to decide whether the reports by a particular pair of informants agree better, worse, or about the same as typically found between these informants.

An important question is how the clinician should proceed once it is known if discrepancies between informants on a particular child’s problems deviate from the typical level of disagreement between similar informants in reference samples. For the clinician to decide how to proceed, it is important to acknowledge that discrepancies between reports may shed light on the children, on the informants themselves, and on the interactions between the children and informants (Achenbach, 2006). Because there are no fixed rules for deciding which informant is best in each individual’s case, it is the clinician’s task to interpret discrepancies between reports and to decide how to proceed. For example, where certain problems are reported by only one informant and not by others, the clinician might want to ask each informant in an interview to describe the problems in greater detail. Some informants may exaggerate certain behaviors, or they may interact with the child in ways that trigger or enlarge certain problems. Consequently, the clinician may decide to make a particular informant’s views of the child, or the interaction between this informant and the child a focus for intervention, for example in order to reach a problem definition that is shared by parents and child.

**Developmental Considerations**

Longitudinal studies have provided evidence for developmental changes both in level and in type of problems. Assessment has to take account of developmental changes in the level of problems. For example, problems such as temper tantrums or separation anxiety are common and therefore normal at a young age, but much less frequent and more likely to indicate psychopathology at older ages.

Because rating scales are inexpensive they can economically be applied to large normative samples of children from different ages. For young people within the normal range for cognitive and physical development, comparisons with normative samples of children of the same age (and sex) provide guidelines for evaluating behaviors. If the ages of children to be studied differ substantially from those in the standardization sample for the scale, valid comparisons are not possible. Although age effects on overall indices of problems usually are rather weak, they can be larger for specific syndrome scales or for individual problem items, and they are usually larger for clinical samples than for general population samples. Some rating scales employ the same version for different age groups. This has the advantage that scores obtained for children at one age can be compared with scores obtained for the same children at a later age. Provided that there are age-standardized norms, comparisons can also be made on the relative levels of problems at different ages.
Assessment also has to take account of developmental changes in the patterning of child psychopathology. For example, anxiety problems in childhood are often followed by depressive problems (Roza, Hofstra, Van der Ende et al., 2003) and oppositional problems are often followed by conduct problems (McMahon & Frick, 2005). Instead of regarding these developmental changes as indicating categorical changes from one disorder into another, it may also be that etiological factors are responsible for continuities underlying such phenotypic changes. If this is the case then assessment procedures should be capable of tapping continuities. Most rating scales for assessing general psychopathology can be scored on continuous scales. Because these scales are often derived through statistical techniques, such as factor analysis, which determine the ways in which problems tend to statistically co-occur, they are independent of the relatively inflexible criteria for diagnostic categories such as employed by the DSM. Instead of either present or absent diagnostic categories, rating scales are capable of assessing problems in ways that take account of etiological continuities despite phenotypic changes.

For example, the Achenbach System of Empirically Based Assessment (ASEBA; Achenbach & Rescorla, 2001) — including the Child Behavior Checklist (CBCL) — and the Strengths and Difficulties Questionnaire (SDQ; Goodman, 1997) have scales designated as Anxious/Depressed (ASEBA) and Emotional Problems (SDQ), respectively, which consist of a combination of problems of anxiety and depression. The suggestion that vulnerabilities to a chronic disposition of anxiety and depression are closely related is supported by findings of genetic studies showing that anxiety and depression are influenced by the same genetic factors (Kendler, 1996). Using rating scales with overlapping anxiety and depression problems has the advantage that developmental changes in anxiety and depression can be assessed without losing important information, and without assuming that changes in problems are interpreted as indicating categorical changes in disorders.

It is also possible to use separate narrow-spectrum rating scales to assess developmentally related problems such as anxiety and depression. For example, the Mood and Feelings Questionnaire (MFQ; Angold, Costello, Messer et al., 1995) and the Multidimensional Anxiety Scale for Children (MASC; Marsh, 1997) can be used to assess depression and anxiety separately. Likewise, the Eyberg Child Behavior Inventory (ECBI; Eyberg & Pincus, 1999) and the ADHD Rating Scale IV (DuPaul, Power, Anastopoulos et al., 1998) can be used to assess disruptive behavior and attention deficit/hyperactivity disorder (ADHD) problems, respectively. This has the advantage that more detailed information of a specific problem area can be obtained. A problem with the use of separate narrow-spectrum rating scales is that although these scales are intended to assess separate problem areas, they often have overlapping items. For example, rating scales that assess depression may contain items on sleeping problems or somatic complaints that are also present in anxiety rating scales, so that viewing separate rating scale scores as information on separate disorders or problem areas may therefore be partially artifactual.

**Abnormality and the Use of Norms**

Clinicians spend a great deal of their time distinguishing the normal from the abnormal and between different grades of abnormality. They are confronted with many questions, such as: “Is unhappiness in this adolescent a sign of depression or is it an affective state that is normal for his or her age?” “Is this body weight a sign of anorexia nervosa or is it part of normal dieting?” Patients who are referred for specialized mental health services have been selected for special attention. As a consequence, clinicians’ concepts of normality and abnormality are usually derived from experiences with small subsets of patients who do not provide representative data for quantifying abnormality. Nevertheless, a great deal of a clinician’s work ends in decisions for situations such as: “Can treatment be started or does this child need further evaluation?” “Does this child need treatment or can we reassure the parents?” “What kind of treatment is best for this particular child?”

The prevailing DSM nosological approach lacks normative reference points and uses similar diagnostic criteria and cut-points for both genders and diverse ages, regardless of the source and type of information. Rating scales that have published norms can be of great help in distinguishing the normal from the abnormal, and between grades of abnormality. These norms should be specific for each gender within certain age periods, as assessed by different informants (parent, teacher and self-report). Using norms in this way makes it possible to determine whether and in what ways a child’s functioning deviates from that of his or her peers.

Deviation from what is normal does not automatically signify impaired functioning. For example, a child who walks much earlier than the average child will evidently not be regarded as impaired. However, most rating scales to assess child psychopathology consist of problem items reflecting behaviors that may be a reason to seek help, and higher scores on these items usually reflect greater impairment.

**Categorical and Quantitative Approaches**

Many clinical phenomena such as heart rate, blood pressure, height, weight or serum chemistries are best measured on continuous scales. Likewise, most (problem) behaviors in children can best be regarded as quantitative variations rather than present/absent categories. This approach allows for inter-individual differences that are normal. Abnormality can be regarded as the quantitative extreme of the normal distribution. This quantitative approach makes it possible to assess the degree to which an individual child’s problems deviate from those that are typical of the individual’s age and sex. In other words, instead of asking whether a particular child has ADHD, the quantitative normative approach enables us to determine the degree to which the child’s scores deviate from those of other children of the same sex and age.

In most behavioral genetic research, child psychiatric disorders are regarded as quantitative variations. Behavioral geneticists view most common psychiatric disorders as complex traits that are affected by multiple gene systems. Because multiple genes are responsible for variation throughout distributions...
of traits, they are apt to yield quantitative continua rather than dichotomous disorders (Plomin, DeFries, Craig et al., 2003).

Despite the fact that many psychopathological phenomena in children can best be regarded as quantitative variations, the dilemma of the clinical reality is that dichotomous decisions need to be made. The use of quantitative rating scale scores does not preclude the use of categories, which can be defined by cutpoints for distinguishing between cases and non-cases. Although dividing lines for caseness may be rather arbitrary, there are methods for selecting cutpoints that serve certain purposes best. However, there is as yet little basis for perfect categorical distinctions between abnormality and normality. How can we determine which children are most likely to need help? For most rating scales this is done by comparing the distribution of scores for non-cases with the distribution of scores for cases. In the absence of an ultimate criterion for caseness, a frequently used morbidity criterion for general rating scales is whether a child has been referred for specialist mental health services. Other morbidity criteria include expert clinical judgment of caseness, diagnoses based on structured interviews, impairment (Angold, Costello, Farmer et al., 1999) or highly specific criteria for certain problem areas such as movement monitor information to assess hyperactivity (Ho, Luk, Leung et al., 1996).

Empirical Versus A Priori Approaches
Guided by psychometric principles, rating scales use multiple items which are aggregated into scales or syndromes. There are two main approaches, the empirical or bottom-up, and the a priori or top-down approach, to select and group items. The empirical approach employs multivariate statistical techniques, such as factor analysis and principal components analysis, which are used to identify sets of problems that tend to occur together. These co-occurring items constitute syndromes. Each syndrome can be quantified by summing the scores of the items that comprise the syndrome such as “hyperactivity,” “anxiety” or “conduct problems.” This approach starts with empirical data derived from informants who describe the behavior of children, without any assumptions about whether these syndromes reflect predetermined diagnostic categories. The empirical quantitative approach forms the basis of the empirical syndromes of most general rating scales. Before applying specific syndromes to samples that are much different from the ones from which the factor structure was derived (e.g., in other cultures or in different populations such as twins), it is important to test the factor structure in the different populations (Ivanova, Dobrean, Dofnner et al., 2007).

The second, a priori, approach is to take the diagnostic categories of one of the two international nosological systems: DSM-IV (American Psychiatric Association, 2000) or ICD (World Health Organization, 1996) as the basis for scoring rating scales. This approach starts with assumptions about which disorders exist and about which symptoms define them.

Instead of disregarding one approach for the other, we hold the view that both approaches are needed, and that combining both approaches by adding information from one approach that is not captured by the other, may aid in increasing our knowledge of psychopathology (Ferdinand, Heijmema, Visser, Hoogerheide et al., 2004a; Jensen, Salzberg, Richters et al., 1993; Kasius, Ferdinand, Van den Berg et al., 1997). For example, problems in social interactions reflected by high scores on the CBCL scale designated as Social Problems are strong predictors of later psychopathology, even across 14 years, whereas the Social Problems scale does not have a clear DSM counterpart (Hofstra, Van den Berg, & Verhulst, 2000). As a consequence, if we know that an individual has significant problems in areas of functioning that are captured by empirically based assessment procedures, and that are not captured by nosological systems such as the DSM, this information may be an important addition to clinical diagnoses.

Rating Scales or Interviews
One of the great advantages of rating scales over clinical interviews is that they can be applied in a flexible, easy-to-administer and economical way. Administration time is usually modest. Most rating scales will take 10–20 minutes to be completed. They can be administered in various locations such as home, school or (mental) health settings. Rating scales are also characterized by great flexibility in the way they can be administered: in person, by telephone or by mail. Some rating scales have a computer-assisted client entry program which can facilitate administration.

Rating scales need not be administered by expensive, clinically trained professionals. These characteristics make it possible to obtain uniform data across different populations and different settings in a relatively easy and economical way. For example, rating scales can be routinely administered in (mental) health settings prior to or at intake, or can be used in large-scale epidemiological surveys. Thanks to their practicality, many rating scales have good data on reliability and validity (Verhulst & Van der Ende, 2006). This gives us detailed information on the variation that can typically be expected.

Rating scales have disadvantages too, some of which are shared by other measurement procedures. Rating scales are limited to the informant’s perspective. Characteristics of the informant and the tendency toward response biases are sources of variation in ratings (Fergusson, 1997; Sawyer, Streiner, & Baghurst, 1998). Rating scales are limited to the structured scores for standardized items. Information that may be relevant but that is not covered by the items of the scale may be missed. It is not possible to explore the informant’s responses and subjective experiences, nor is it possible to observe behavior directly. Misunderstandings and ambiguous answers that may be clarified in a clinical interview are missed when using rating scales. Also, slight changes in the wording of instructions, or the wording of the items themselves, may have large effects that limit comparability (Woodward, Thomas, Boyle et al., 1989).

Of course, the main aim of any diagnostic assessment tool is that it measures what it is designed to measure. This is an issue of the validity of an assessment approach. If the aim of
a rating scale is to determine the presence or the absence of psychiatric disorders then it is necessary to have a definitive criterion. However, given the present state of the art in the field of child psychopathology there is no infallible criterion that can serve as the “gold standard” for definitively establishing the presence or absence of most disorders, and the boundaries between them.

One way to test the validity of a rating scale is to test the relationship between rating scale scores and DSM diagnoses derived from structured or semistructured interviews (Jensen et al., 1993; Kasius, Ferdinand, Van den Berg et al., 1997). However, there is little empirical ground for assuming that one approach is intrinsically superior to the other. The view that we cannot a priori assume that greater diagnostic accuracy or objectivity can be obtained by using (semi)structured interviews is supported by a meta-analysis of 30 studies with information on the agreement between structured interviews and typical clinical diagnostic evaluations (Rettew, Doyle, Achenbach et al., 2006 unpublished data). This metaanalysis showed that overall diagnostic agreement between (semi)structured interviews and clinical evaluations was poor, with a mean kappa of 0.21. This study could not determine which method was more problematic. Both methods have strengths and weaknesses.

Another study supporting the view that fully structured, as opposed to semistructured, psychiatric interviews cannot be regarded as superior over other assessment approaches is by Boyle, Offord, Racine et al. (1997), who compared the associations of a rating scale (the Ontario Child Health Study scales) versus a psychiatric interview (the revised version of the Diagnostic Interview for Children and Adolescents; DICA) to external validators. They concluded that differences between the two assessment procedures in validity were small, and where present they showed somewhat better performance for the rating scales than for the interview.

Ferdinand, Hoogerheide, Van der Ende et al. (2003) studied the 3-year predictive value of parents’, teachers’ and clinicians’ judgment of problems in a clinical sample of 6- to 12-year-olds. Parent and teacher information was superior to clinical judgment regarding the prediction of prolonged out-patient treatment, school problems and police/judicial contacts. However, clinicians’ observations of attentional problems in children during a semistandardized interview were needed to obtain an optimal estimation of the prognosis. Clinical observations were especially strong predictors of later use of in-patient services. Clinicians who performed the diagnostic interviews were not involved in later treatment decisions. Each of the three informants provided unique information to the prediction of outcomes. It could be concluded that none of the informants was superior to the others in all instances and all three information sources were needed to optimize the prediction of outcomes.

**Multicultural Issues**

Multicultural populations containing minorities, immigrants and refugees characterize many contemporary societies. When evaluating children of different cultures within one country, mental health professionals must determine whether problems merely reflect cultural differences or whether they reflect needs for professional help (Bengi-Arslan, Verhulst, van der Ende et al., 1997). To help children from various cultural backgrounds we need:

1. Assessment instruments that are available in various languages;
2. Assessment procedures that generate results that are comparable across cultures; and
3. Norms based on representative samples of children living in the original home countries.

If this is the case, rating scales for identifying variations in behavioral and emotional problems can be applied by professionals under diverse conditions.

Because many cultures lack well-standardized indigenous instruments for assessing children, instruments developed in one culture are often translated and adapted for use in other cultures. To apply such instruments to other cultures, they should be tested in various ways to maximize the equivalence of data obtained in the different cultures (Bird, 1996; Canino & Bravo, 1999). Norms derived from epidemiological samples can be used for evaluating a child’s problems in relation to those of peers in the child’s specific culture. Children whose problems significantly exceed the norms may need more detailed assessments. Norms thus provide clinicians with information with which to evaluate each child’s problems.

An important question is whether the clinician who evaluates children of different cultures should compare a child’s problem scores to norms derived for representative samples of children living in the original home countries, or to norms derived for majority groups of children living in the host country (see chapter 15). Comparisons of parents’ reports of problems for children in 31 cultures, of teachers’ reports in 21 cultures and of youths’ self-reports in 24 cultures (Rescorla, Achenbach, Ivanova et al., in press; Rescorla et al., 2007a; Rescorla, Achenbach, Ginzburg et al., 2007b) have indicated that, when the same standardized assessment procedures are used to assess children from different cultures, cultural differences per se do not lead to big differences in reported problems. Although it was found that individual differences within each cultural group are larger than differences between cultures, differences between some cultures may be too big to disregard. For clinicians this means that decisions on whether a child needs help and, if so, what kind of help, need to be based on appropriate norms.

Obtaining information from multiple informants is especially important when there are cultural differences between mental health professionals and those who are being assessed. For example, it was found that parent-reported and self-reported problem scores for Moroccan youths were similar or even lower than scores obtained for Turkish youths and for Dutch youths in the Netherlands (Stevens, Pels, Bengi-Arslan et al., 2003). However, Dutch teachers reported substantially higher levels of externalizing problems for Moroccan
youths than for Turkish and Dutch youths. If parents from a particular culture systematically underreport their children’s problems, clinicians may need to obtain fuller evaluations from other informants and to explore issues that may be responsible for this under-reporting, such as the parents’ lack of awareness of their child’s problem behavior outside the home.

**Use of Rating Scales in Clinical Practice**

After referral to mental health services, the clinician and patient go through a sequence of steps. Although this clinical process will vary, the typical sequence has six steps: referral, diagnostic assessment, diagnostic formulation, treatment, treatment efficacy monitoring and outcomes evaluation. Rating scales can be useful for obtaining and organizing the information needed for making decisions during the clinical process. When we base decisions on explicit rules that follow assessment data on individual cases, we may improve our ways of helping children and adolescents. The process from first contact of a parent with the clinic to the termination of treatment consists of a chain of decisions. Assessment data need to be tailored to the specific needs for each step that precedes a decision.

**Referral and the Use of Rating Scales as Screening Tools**

When parents contact a clinic about their child’s behavior, the first decision is whether assessment at this particular clinic is the best way of proceeding, or whether the child and the parents should seek help elsewhere. Baseline information about the behavioral and emotional functioning of the child can be obtained in a cost-effective way by having parents and other informants complete rating scales as screening tools, for instance by mailing them. Broad-spectrum rating scales can quickly identify children in need of mental health services. Narrower spectrum rating scales may then be used for more detailed assessment of specific disorders or behaviors.

Distributions of problem scores for cases typically overlap with distributions for non-cases. As a consequence, every possible cutpoint results in some degree of misclassification (Fombonne, 2002). The effectiveness of a cutpoint can be described in terms of the rate of true positives (sensitivity) and the rate of true negatives (specificity) (Rothman & Greenland, 1998). Any cutpoint that is chosen is a trade-off between sensitivity and specificity. The accuracy of a measure can also be expressed as the extent to which being categorized as a case or as a non-case predicts the presence of the disorder. The predictive value of a positive test (PV+) reflects the proportion of those with a positive test who have the disorder. By contrast, the predictive value of a negative test (PV–) reflects the proportion of those with a negative test who do not have the disorder. These measures estimate the probability that a particular score means that an individual has a certain disorder. The predictive value of a test is strongly influenced by the prevalence of the disorder. In a sample with relatively few disordered individuals, the PV+ of even a very specific test will be low, because a “positive” result on the test will yield many false positives. If the same test is used in a sample with a much higher prevalence, the PV+ will be much higher. Although the problem of low base rates for predicting rare conditions, even with highly valid tests, was observed long ago (Meehl & Rosen, 1955), Clark and Harrington (1998) showed that few child mental health professionals who regularly use rating scales in clinical practice were aware of this problem.

However, the generally modest PV+, even for valid rating scales, shows that a single measure should not be the only source of information when important decisions must be made for individual patients. Clinicians should make decisions for individual patients after evaluating all available information, including psychiatric parent and child interviews, psychological and physical test data, and information on social competence.

The utility of a rating scale does not depend only upon its classification efficiency (Maruish, 2004). It is equally important that:

1. Rating scales are easily integrated into an agency’s daily regimen of service delivery;
2. Clinicians know how to use the information obtained from the rating scales; and
3. The agency’s staff are committed to the screening process.

**Diagnostic Assessment**

After obtaining referral data and rating scale scores on the child’s emotional and behavioral problems, the next step in the sequence of clinical case management is the interview with the child, with the parents and with other relevant informants.

Interviews with parents are essential for most mental health evaluations of children. Such interviews are needed not only to obtain information for making diagnoses, but also to accomplish other important tasks that cannot be fulfilled by rating scales, such as: forming a therapeutic relationship to promote collaborative problem-solving; establishing effective communication between clinicians and parents; and formulating ideas about what the parents have done or can do to help their child. Interviews with parents also lay the groundwork for the next steps, including decisions about further evaluation and implementation of interventions. Interviews with the children themselves are also essential, while interviews with teachers and other informants may be helpful as well.

The findings to date suggest that neither interviews nor rating scales are intrinsically better for all assessment purposes. In one of the few studies on the effects of combining interview and rating scale data, Ferdinand et al. (2004a) tested the ability of DISC/DSM-III-R diagnoses and CBCL scores to predict poor outcome variables longitudinally. The combination of both assessment procedures provided better predictions of outcomes than either procedure separately.

**Diagnostic Formulation**

The next steps in the clinical process are to form an integrative conception of the case, including etiological and prognostic
hypotheses, and to come up with a comprehensive diagnostic formulation (see chapter 4). The clinician not only formulates a picture of the important phenotypic features, the school situation and the environment of the child, but also formulates hypotheses about risk and prognostic factors affecting the child’s functioning, and how these factors can be modified by treatment. The clinician will usually decide whether criteria are met for particular DSM or ICD diagnoses. The integrative conception of a case also involves weighting the child’s competencies that may affect the outcome. The diagnostic formulation should thus ideally contain information that will facilitate the planning of specific therapeutic interventions.

**Treatment Planning**

After formulating a diagnosis, the clinician needs to identify targets for intervention and to determine which treatment works best for a particular type of problem. In children with multiple problems, it should be decided which aspects of the child’s functioning should be treated first. Treatment planning consists of the development of a set of goals for a child and his or her family and the specific means by which the therapist will work toward those goals. In clinical practice, interviews will play an important part for targeting major goals for treatment. Rating scales for the assessment of psychopathology can aid in the treatment planning process by providing information on secondary but significant problems that might otherwise be overlooked. Because a categorical diagnosis only indicates the presence of a specific condition, it does not give us information on the severity of the problems. An estimate of the severity of problems will be made by the clinician using different sources of information, including information obtained through the clinical interview.

**Impairment Measures**

Another important aspect of a child’s functioning that can help the clinician in a number of decisions, including the appropriate level of care, the appropriate therapeutic approach and the need for medication, is the extent to which the child’s problems affect functioning in the family, in school, with peers, and activities such as sports or hobbies. Some broad band rating scales such as the CBCL and the SDQ contain items reflecting social competencies or prosocial behaviors which can be used as an index of general impairment. A number of scales are specifically designed to assess functional impairment (Verhulst & Van der Ende, 2006). The most commonly used scale is the Children’s Global Assessment Scale (CGAS; Shaffer, Gould, Brasic et al., 1983). The CGAS correlates well with other clinician-rated measures of impairment and is found to be sensitive to response to treatment in a variety of studies. Another impairment scale, the Child and Adolescent Functional Assessment Scale (CAFAS; Hodges, 2004), discriminated well between children and adolescents receiving different levels of care. Higher scores on the CAFAS were associated with more restrictive care, higher cost, more bed days and more days of service.

**Treatment Effect Monitoring**

After selecting a treatment, it is important to determine whether an intervention produces the desired improvements. Treatment goals can be set prior to treatment and can be defined as a certain decrease in problem scores on a rating scale from pre- to post-treatment, or as the absence of DSM diagnoses that were present prior to treatment (Hayward, Varady, Albano et al., 2000). A problem with using DSM diagnoses as improvement criteria is that significant improvements within the clinical range will remain undetected. When using pre- to post-treatment rating scale scores, decisions should be made about the magnitude of change that will be regarded as sufficient improvement. A reliable change index tests whether pre- to post-treatment score differences surpass the boundaries of the standard error of measurement, usually defined as the 95% confidence interval based on test–retest reliability data. Most manuals of commonly used scales give readily available guidelines for evaluating individual children’s change in scale scores.

Of course, the least costly intervention should be chosen if several interventions are equally effective (see chapter 10). If improvement is insufficient, other interventions should be tried. Actuarial tests of relations between diagnostic data and outcomes for large samples of cases may provide useful evidence.

The utility of a rating scale for treatment monitoring will depend on its sensitivity to possible changes in response to treatment. Specific information on sensitivity to change has been published for only a few broad-spectrum scales. However, in the literature numerous examples of the utility of rating scales to assess therapeutic effects are reported. The Conners’ Rating Scales–Revised (CRS; Conners, 1997) have been shown to be sensitive to the effects of drug treatment of hyperactive children (Kollins, Epstein, & Conners, 2004). Both the SDQ and the CBCL have been found to be sensitive to change and to be useful for evaluating the clinical significance of therapeutic interventions (Kendall, Marrs-Garcia, Nath et al., 1999). Recently, brief measures have become available which require only minutes to complete and provide information on multiple domains of functioning for evaluating treatment (Lambert, Whipple, Hawkins et al., 2003). These measures can be used for ongoing assessment and monitoring of patients from the beginning to the end of treatment and using the information to chart progress and make decisions about treatment (Kazdin, 2005).

A well-known but poorly understood phenomenon that complicates the evaluation of the effects of therapeutic intervention is the repeated finding that problem scores decline from the first to the second administration of rating scales and interviews (Edelbrock, Costello, Dulcan et al., 1985; Helzer, Robins, McEvoy et al., 1985). This is called test–retest attenuation. For example, it was found that for some CBCL scales read-ministration resulted in a decrease in problem scores across a 1-week interval (Achenbach & Rescorla, 2001). However, the magnitude of the decline in scores was small and only present for a minority of the specific scales. It has also been found
CHAPTER 20

that the longer the interval between administrations, the weaker
the effect of test–retest attenuation is likely to be (Verhulst &
attenuation is a general tendency for reports of problems to
decline from a first to a second assessment regardless of
whether many or few problems are reported. Thus, test–retest
attenuation differs from regression toward the mean, which
reflects the tendency of extremely high or extremely low scores
to subsequently become closer to the mean of the entire
sample at a second assessment than at an initial assessment.
Both test–retest attenuation and regression toward the mean
can contribute to declines in problem scores for children who
initially obtain high problem scores. Of course, this com-
plifies the assessment of intervention effects. Consequently,
children should be reassessed on more than one occasion,
and evaluations of interventions should employ designs that
include random assignment to an intervention and control group
which is assessed repeatedly in the same ways as the inter-
vention group before and after the intervention conditions.

Outcome Evaluations
To evaluate outcomes of child mental health services, baseline
rating scale measures obtained at the time of referral can
be compared with measures obtained after services have been
provided. The intervals for monitoring treatment effects
should be geared to the type of problem, the type of inter-
vention and the effects that are found. By contrast, outcome
evaluations are most useful when they are carried out at
uniform intervals across all cases seen in a particular clinical
setting. This makes it easier to draw generalizable conclusions
about whether the interventions were effective. Outcomes can
be determined by repeating the intake assessment measures
at regular intervals, for instance after 4, 6, 12 and 18 months.
Outcomes need not only pertain to problem behaviors, but
may include all kinds of areas important for the child’s func-
tioning, including physical health, social functioning, school
functioning and family functioning.

Research on treatment outcomes makes use of statistical
analyses that differ from analyses that help clinicians decide
whether sufficient treatment progress has been made. For
many rating scales, information is provided that clinicians
can use to judge whether changes in scale scores exceed the
error of measurement. For example, if the standard error
of measurement (SEM) is provided separately for samples of
children by age and gender, it is possible to evaluate whether
a change in scale scores exceeds the change expected by
chance (Sheldrick, Kendall, & Heimberg, 2001).

Criteria for Selecting a Rating Scale
The suitability of a rating scale for certain purposes can be
judged by a number of characteristics: applicability, accept-
ability, practicality, reliability, validity and sensitivity to change.
There are many similarities between the different rating
scales. Some scales cover roughly similar contents, most have
evidence of adequate reliability and validity, most are user-
friendly and most can be scored in a comprehensive way.
However, there are some differences that may be relevant for
some purposes. Answers to the following questions may aid
in making a choice of which scale to use.
1 Do I need a broad- or narrow-spectrum rating scale, or both?
For example, in a specialist clinic for children with eating
disorders, one might need a narrow-spectrum rating scale
with detailed questions on eating behaviors such as food pre-
occupation, dieting, vomiting and preoccupation with body
weight. However, because patients with eating disorders
often have other problems, it might be equally important to
use a broad-spectrum scale to assess behavioral and emotional
problems in addition to the narrow-spectrum scale.
2 Do I need multiple informants? If so, a scale that has
separate versions should be chosen.
3 Do I need a rating scale for early assessment or screening
of every individual who comes into a service, or do I need
one for more extensive clinical evaluation, and will the
instrument be completed for one individual or for many indi-
viduals by the same informant (e.g., all children in one class-
room by one teacher)? Most scales take 10–20 minutes to
complete, but there are shorter scales available.
4 Do I need a brief rating scale for monitoring treatment
progress?
5 Do I need to assess problems only, or do I need a scale that
has competence or adaptive functioning items as well?
6 Do I want to obtain ratings that can be scored on DSM-
oriented scales, on empirically derived scales, or on both?
7 Are translations of the instrument available in the lan-
guages that I need?
8 Are there local norms available for the assessment scale to
allow comparison?

Conclusions
Over the last decades, advances have been made in the
development and evaluation of rating scales to assess child psy-
chopathology. Knowledge of developmental psychopathology
has benefited from the application of measures to assess
child psychopathology in systematic research. More recently,
rating scales are being increasingly applied in clinical contexts.
They are not a short-cut to clinical diagnosis, but an aid in
obtaining and organizing information on children’s problems
and strengths in a cost-effective way throughout the process
of case formulation, treatment planning, treatment monitor-
ing and outcome evaluations.

Child psychiatric practice is moving away from the use of
unfocused lengthy diagnostic procedures of unknown reliability
and validity towards brief, problem-oriented, reliable and
well-validated diagnostic procedures (see chapters 18 & 71).
At the same time, the field is moving from the use of therapeutic
strategies with unknown effectiveness towards evidence-based
treatments with proven effectiveness. Rating scales can greatly
assist in more cost-effective diagnostic assessments and treat-
ment planning by aiding clinicians addressing referral complaints, relevant diagnostic issues and characteristics of children, parents and families. Also, rating scales can be economically used for treatment monitoring and outcome assessment.

The use of instruments that require minimal clinician time is not only cost saving, it also enables clinicians to focus on diagnostic and treatment aspects that cannot be replaced by standardized procedures. An upcoming trend is the use of computer- and Internet-based assessments. Rating scales can be completed by parents, teachers or children themselves by Internet and scored prior to the first appointment in a clinic.

Influenced by cost and time considerations, the change in the field towards more evidenced-based practice, as well as developments towards more pluralistic societies, there are a number of future challenges. There will probably be an increase in the need for brief, disorder-specific, symptom- or problem-focused narrow-band rating scales to be used for treatment monitoring and outcome assessments. Second, the increasing availability of computer-assisted techniques will result in time saving. A major challenge for the near future will be to integrate Internet-based assessments into daily clinical practice. Third, rating scales can have a role in providing closer linkage between assessments at the different stages of the clinical process, including diagnostic assessment, treatment planning, treatment monitoring and outcome evaluations. Fourth, for children from multiple cultures who live together in one society, the availability of norms based on representative samples of children living in the original home countries can greatly aid in the assessment of such children who are in need of professional help.

CHAPTER 20

21

Psychological Assessment in the Clinical Context

Tony Charman, Jane Hood and Patricia Howlin

The notion that psychological assessment involves just the administration of psychometric tests is no more accurate than the definition of intelligence as being simply “what IQ tests measure.” Whereas the accurate use and valid interpretation of psychometric tests serve an important function in establishing children’s levels and profiles of ability, it is unusual for children to be referred solely for the purpose of establishing their IQ. Rather, psychological assessment is usually requested because of wider concerns about a child – for example, why is his or her behavior giving rise to so many problems within the classroom? Why is he or she falling behind the rest of the class, or is unable to relate to peers? The present chapter explores not only the importance of skilled psychometric assessment, but also the much wider role that psychological assessment can have in the identification and resolution of the many different types of problem that present to clinicians.

Psychological Assessment within the Broader Context

Rutter and Yule (2002) pointed out that clinical psychology training requires expertise in experimental psychology, developmental psychology, psychopathology, neurophysiology, neuroscience and biology. Psychological assessment is not merely the administration of a clinical test, but involves the identification of key clinical issues pertaining to each individual case; the formulation of clinical issues into testable hypotheses; the implementation of hypothesis-driven intervention strategies; the evaluation of the outcome of these strategies; and the reformulation of both the original hypotheses and intervention procedures if the predicted improvements are not achieved. They stress the role of all clinicians, including psychologists, as being that of “scientist-practitioners” (Drabick & Goldfried, 2000; Kennedy & Llewelyn, 2001). This does not imply that all clinicians should be involved in large-scale treatment or research trials. Even though these are sometimes possible within clinical settings (see chapter 64), service demands usually preclude research of this kind. However, on an individual client basis, the skilled practitioner will constantly be learning from past experience and applying scientific thinking to his or her practice. As Rutter and Yule (2002, p. 114) noted, this can range from “something that is little more than thoughtful questioning clinical enquiry, to a scientific investigation that approximates to a piece of research that can be applied to individual cases.” In relation to clinical diagnosis, the same authors suggested that this may involve a combination of “pattern recognition” or “the ability to put together very complex sets of data, weighting different elements appropriately and considering possible interactions among risk and protective factors” (p. 105). Very similar processes also form the basis of psychological assessment and intervention.

Pre-assessment Assessments

Psychological assessment should begin long before the child sits down to complete a cognitive test. The referral letter and reports from parents, school or other professionals, are all important in describing the presenting nature of the child’s problems and identifying factors that may need special consideration. For example, are there inconsistencies in the various reports of the child’s behavior? It is not unusual, especially in the case of children with developmental disorders, to find very different accounts of behavior in different settings. Thus, a young child may be reported as highly disruptive at school, but not at home. Alternatively, a child who is described by parents as very difficult to manage may show few problems at school. In addition to these anecdotal accounts, brief standardized questionnaires (e.g., Conners’ 1997 scales; Development and Well Being Assessment [DAWBA], Goodman, Ford, Richards et al., 2000; Strengths and Difficulties Questionnaire [SDQ], Goodman, 1997), which can be completed independently by teachers and parents, can help to pinpoint areas of discrepancy. If previous assessments are unavailable, brief postal questionnaires relating to possible developmental delays or abnormalities as well as general family circumstances can provide valuable information which helps to focus the initial assessment. If a specific disorder, such as autism, is suspected parents might also be asked to complete an appropriate screening instrument (e.g., Social Communication Questionnaire [SCQ]; Rutter, Bailey, & Lord, 2003).

Clinic-based Assessment

Informal observations of the child in the waiting room can also prove an important part of the psychological assessment. Who has accompanied the child – one parent or two? If a single parent, has he or she come with another relative, such
as a grandmother? Have other children also come along? How does the child relate to the accompanying family members – and how do they respond in turn? Is the child obviously disruptive, distressed, sullen, talkative, clingy, aloof? How does the child react when first approached by the clinician? The interpretation of such observations must, of course, always take into account the developmental level of the child. Screaming, clinging to the mother and refusing to accompany an unknown professional are entirely appropriate in a 3-year-old child. Taking the clinician’s hand and leaving the parent without a backward glance is certainly not! Sitting well away from parents and adopting a sullen uncommunicating look is unusual in a 7-year-old, but typical of many adolescents.

Careful observation of the child should continue throughout any more structured cognitive assessment, and should be documented during formal testing. Degree of cooperation with the examiner, general behavior, activity and concentration levels, social and communication skills, specific areas of difficulty or competence all need to be monitored, summarized and reported. Do these tally with the referral reports – thereby helping to clarify the nature of the presenting problems – or does the child’s behavior in the assessment setting seem very different to that described? It is not unusual, for example, to find that more able children with autism or Asperger syndrome, far from being socially withdrawn, may appear relaxed, confident and highly cooperative in a formal testing session. This does not suggest that reports of difficult behavior at home or school are inaccurate, but indicates that, in a highly structured, predictable and relatively impersonal setting, the child is able to perform at his or her best. In turn, such observations can be extremely important in planning appropriate interventions.

Informal, but informed, psychological assessment will also have an impact on the way in which testing is conducted. As is stressed later in this chapter, choice of well-standardized tests and adherence to testing protocols are important elements of the assessment procedure. However, when assessing children for whom the tests were not specifically normed (i.e., most children with moderate–severe intellectual disability, or children with specific developmental, physical or sensory impairments), some deviation from the prescribed format may produce findings that are of greater practical value. After all, it is rare that the ultimate aim of testing such children is to confirm their IQ score per se; rather, the general aim is to obtain an overall estimate of their potential level of functioning. Many years ago, Clark and Rutter (1979) reported that alterations to the ordering of test items, or allowing “non-standard” forms of response, resulted in improved cooperation amongst children with autism. Moreover, longer-term follow-up of children with autism assessed under somewhat modified testing conditions indicates that results can be highly predictive of performance 20 or more years later (Howlin, Goode, Hutton et al., 2004).

The need for modifications to conventional protocols may also have implications for intervention. One 8-year-old boy with autism was referred because his school felt that his intellectual ability was too low for him to be appropriately placed there. At the assessment he refused all tests with a verbal component but finally showed an interest in the Ravens Progressive Matrices. However, instead of simply identifying the correct item he listed only the numbers of items that were not correct! This greatly extended the time taken for testing but did produce a much higher IQ score than expected on the basis of teacher reports. However, it was apparent that his functioning was significantly affected by his very stereotyped and rigid behavior and an individual intervention program was designed largely on the basis of the information gleaned during this unstandardized testing session. This consisted of making school staff aware of his potential ability, helping teachers to reduce his very fixed behavior patterns, reducing the verbal content of tasks as far as possible, using computerized teaching methods, providing him with novel tasks (on which he had had no opportunity to develop stereotyped responses) and allowing him to finish off certain tasks in his own idiosyncratic fashion once most of his work was complete.

It should also be recognized that when assessing “unusual” children, the use of a less well-standardized test may be appropriate. The Merrill–Palmer scale (Stutsman, 1948), for example, has outdated (USA-based) norms, and would be unsuitable for most typically developing children. However, long experience with lower ability children with autism indicates that there is something about the materials that can generate interest and cooperation where other tests have failed. The long-term reliability of scores from early testing on the Merrill–Palmer (as long as the child is able to complete more than one or two isolated test items) has also been shown to be good (Howlin et al., 2004). One 3-year-old non-verbal child with autism was thought by his parents to be very bright because of his ability with constructional toys; in contrast, at nursery, where he showed no interest in any of the equipment available, it was felt that he should be moved to a unit for children with severe intellectual impairments. In the assessment session he showed no inclination to do anything other than spin objects on the floor; he threw the contents of the Wechsler tests across the room and although he showed some interest in the book form of the Ravens Matrices he clearly disliked the feel of the Velcro™ pads required to place the pieces. An old Merrill–Palmer test was also rejected. However, his mother pointed out that he hated any equipment that was obviously used or dirty; indeed, she believed this was the reason he ignored the nursery equipment. The family was asked to return at a later date, after a new Merrill–Palmer had been ordered. The child completed the whole test, well above the 6-year level ceiling, within minutes. On the basis of the assessment (which also illustrated the importance of parental information) the boy was moved to a specialist autism unit, where he continued to make good progress, initially in visuospatial skills and later in computing and mathematics.

Prior knowledge about specific clinical conditions may also be a crucial part of the assessment process. For example, one young girl with Williams syndrome was referred by her
mainstream school because of disruptive behavior in class and highly inappropriate social interactions with male teachers. In addition to concerns about her academic progress, staff suspected that she might have been sexually abused. Her parents were outraged by this suggestion. According to them their daughter was a delightful, friendly child who, apart from mild intellectual difficulties, had no problems at all. During the initial assessment three things became clear. First, the girl’s IQ was much lower (around 45) than originally thought. Second, she showed the very typical pattern of indiscriminate overfriendliness that is characteristic of children with Williams syndrome. Her superficial chattiness, especially her constant questioning, did much to disguise her lack of social understanding and her profound language problems. Third, when questioned about her special interests, it became apparent, as is not uncommon among young people with Williams syndrome, that she had an intense preoccupation with a particular pop-singer – in this case, Bob Geldof. Further questioning of her parents confirmed that any man of a certain age with long hair or an Irish accent would be approached, asked if he was Geldof, have his hair stroked or requests made to sit on his knee. While the parents viewed this behavior as rather “cute,” the school (where there were a number of male teachers with longish hair) interpreted the behavior very differently. The working “hypotheses” – that her “sexualized” behavior was probably related to her particular preoccupation and that her disruptive behavior in class was mainly due to her constant questioning and inability to cope intellectually – were supported by observations at school where it became clear that educationally the placement was quite unsuitable. Her move to a unit for children with mild to moderate intellectual impairments led to a significant improvement in her classroom behaviors, and as staff members were warned beforehand of her particular preoccupation, any inappropriate responses to female members of staff were prevented from the outset.

Non-clinic-based Assessment

Successful intervention necessitates a clear understanding of the factors that may be causing or maintaining problem behaviors or interfering with learning. Although the above examples illustrate how informal observations conducted around the time of the formal assessment helped to inform both understanding and intervention, in many cases psychological assessment will require more detailed and systematic data collection in the home and/or school, or other settings.

Observational data can be collected in a number of ways, including time-sampling, latency recording, duration recording, event recording and ABC (Antecedent–Behavior–Consequence) analysis. There are also several formal systems available for observing children that enable the observer to monitor change over time and evaluate the effect of interventions on behavior (e.g., Behavioral Observation of Students in Schools [BOSS]; Shapiro, 1996; and the Classroom Interaction System [CIS]; Smith & Hardman, 2003; see chapter 19).

The need for non-clinic-based assessment is especially important when there is a discrepancy between the various accounts of behavior (e.g., disagreements between parents and teachers concerning the nature or severity of the presenting difficulties, or when the behavior observed in the clinic does not tally with other reports). For example, a child referred for learning or behavioral difficulties at school may, on testing, show no obvious intellectual impairment. If more detailed assessment also fails to identify any specific cognitive/learning impairments (i.e., in language, reading, memory, executive functioning or other skills), then further investigation will be needed to explore possible home or school-based factors (family disruption, parent-child relationship problems, bullying, or emotional or mental health problems) that are affecting progress.

Children with intellectual impairments, and especially those with autism, may behave very differently in different situations or with different people. One 11-year-old boy with autism and moderate intellectual impairment was described by his teachers as the “easiest pupil in the class”; his parents requested a referral because his behavior at home was impossible to manage. School and home visits indicated that the reports from both teachers and parents were essentially accurate and that his behavior differed markedly in the two settings. However, it was also noticed that at school the child often seemed very tense and he would become upset, sometimes destroying his work, if everything was not completed perfectly. It was apparent too, that at playtime he was very reluctant to go outside, disliked team games of any kind, avoided other children as much as possible, showed many stereotyped behaviors and was clearly a source of some amusement to other pupils. Two possible causes for the problems at home were proposed:

1. Pressure to perform well in school was leading to stress which was only apparent when he was in the familiar home setting;
2. Some form of covert bullying/teasing was occurring.

Personal accounts by individuals with autism (Sainsbury, 2000) indicate that playtimes, far from being pleasurable, can be more akin to “torture” – sometimes because of bullying but also because of the child’s total failure to understand the multitude of unwritten rules governing playground behavior. In this case, allowing the child to use the computer room during playtimes and team games significantly reduced his anxiety level at school (teachers completed a brief rating sheet at the end of each lesson to monitor this). Parental ratings of disruptive behavior, however, decreased only slightly. A very simple diary record indicated that the most difficult days for them occurred when he had English or design and technology for the final afternoon session. If the day finished with maths or computing he returned home much calmer. A reorganization of his timetable, so that he spent the last hour of each day working alone on maths or computing problems resulted in his arriving home much more relaxed. Although the situation at home remained difficult, his parents felt that they now had better understanding of, and hence better control over, his behavior.

Psychological assessments conducted outside the clinic may also produce unpredicted findings. For example, in group
settings (home, classroom or a residential unit) reports of difficulties often focus on one particular individual. However, systematic observations may indicate that the problem is not restricted to the referral case. For example, a teacher in a school for children with moderate intellectual impairment had asked for help with a particular student who was described as being constantly off-task and disrupting other pupils. Classroom assessments included counts of on-task behaviors using very simple time sampling techniques (child not sitting at desk at 15-minute intervals). These indicated that the child concerned was off-task no more than other pupils. However, when out of his desk he had a habit of dribbling and smearing saliva and it was this specific undesirable behavior that needed to be the focus of intervention. 

In families too, although one child may be the center of parental concerns, there may also be difficulties with regard to other siblings. A broad psychological assessment can be crucial in identifying these and in refocusing intervention on the wider family dynamics.

Observations made as part of the assessment process may suggest minor modifications that can help considerably. Thus, the disruption caused by one child who constantly arrived late for lessons was minimized by simply recommending that he be supplied with a desk by the door and that this desk had a drawer with basic equipment, such as paper and writing materials that he could use if he had lost (as was typical) his school bag.

Of course, psychological assessment may also reveal much more fundamental learning or behavioral problems and there may be inadequacies or inconsistencies in the ways these are dealt with at home or at school. In such cases, the initial assessment can be essential in establishing the basis for more systematic cognitive, behavioral or pharmacological interventions.

Assessing Behavioral Functions

The term “applied behavior analysis” has, in recent years, often been used synonymously with the intensive home-based programs for preschool children with autism promoted by Lovaas (1993, 1996; see chapters 46, 62 & 74). However, as reviews such as that by Baer, Wolf, and Risley (1968) indicated, the value of applied behavioral analysis in reducing behavioral problems or improving behavioral functioning has been recognized for decades. Early studies stressed the importance of the ABC model (i.e., identifying the antecedent events that appeared to trigger the behavior and the modification of the consequences resulting from the behavior). However, in real-life settings, establishing the true antecedents to a specific behavior may be very difficult. For example, a child may arrive at school in a disturbed state because of something that happened on the bus en route, an event the night before or even something that occurred days or weeks earlier. Thus, recent applications of behavioral analysis have tended to focus on the observable consequences of behavior. The functional analysis of behavior – identifying the functions of “challenging behaviors” especially for non-verbal, severely intellectually impaired individuals – has also had a major role in changing the way in which problem behaviors are interpreted and treated. Assessments of this kind, which are often conducted in experimental analog situations (see chapter 62), frequently reveal that so-called “maladaptive behaviors” may be extremely adaptive if an individual is unable to express his or her needs or feelings in any other way. Functional communication training (i.e., teaching alternative forms of communication by means of pictures/symbols/electronic devices, etc.) can then enable individuals to express their need for assistance, to obtain attention or desired objects, or to escape unwanted situations more effectively. Such strategies, as well as increasing communicative competence, frequently result in a decrease in disruptive, aggressive, stereotyped and self-injurious behaviors (for reviews see Durand & Merges, 2001; Hanley, Iwata, & McCord, 2003).

Although the majority of studies involving functional analysis have been conducted within experimental settings, it is possible to adapt this methodology to more naturalistic environments. Over the years, a variety of behavior checklists or brief observation scales have been developed to assist in the assessment of problem behaviors in children with developmental disorders (e.g., Communication Forms and Functions Scale [CFFS], Schuler, Peck, Willard et al., 1989; Motivation Assessment Scale [MAS], Durand & Crimmens, 1988; Shogren & Rojahn, 2004; Functional Analysis Checklist [FAC], Sturmey, 2001; Questions about Behavioral Function [QABF], Nicholson, Konstantinid & Furniss, 2006; Paclawskyj, Matson, Rush et al., 2001). While none of these are without problems, they can provide a useful framework for behavioral assessment, forming the basis of hypotheses about causation that can then be systematically tested. Part of the FAC, for example, focuses on an hourly breakdown of the individual’s typical daily schedule. Using this very simple observational format with a severely intellectually impaired child, referred for his very disruptive behaviors in a respite setting, clearly demonstrated that, for most of the day, he was left alone with very little adult interaction. It was when adults actively intervened (often inconsistently and unpredictably) that outbursts occurred. Introducing regular, brief, low-intensity interactions focused on activities that he seemed to enjoy, significantly reduced the severity and frequency of disruptive behaviors.

Assessing Intervention Effectiveness

Strategies used in psychological assessment may also be important in evaluating the effectiveness of other interventions to which the child is exposed. Certain therapies (e.g., special diets, vitamin supplements, sensory integration or facilitated communication) have attracted the attention of parents of children with developmental problems (particularly autism) because of wide publicity. Glowing testimonials on treatment websites, or DVD demonstrations of apparent “miracles” are highly seductive and it is easy to understand why parents seek out these “alternative” treatments. One such example is Facilitated Communication, in which a facilitator physically supports the client’s use of a key- or letter-board to indicate his or her
needs or thoughts. This technique was claimed to lead to “Communication Unbound” (Biklen, 1993). Despite evidence from over 50 studies indicating such claims are false (Simpson & Myles, 1995) and statements by the American Psychological Association (1994) and the American Academy of Pediatrics Committee on Children with Disabilities (1998) describing this as an ineffective and potentially dangerous form of treatment, its use by private therapists, and even in some schools, continues. Clinicians’ dismissal of such therapies as “useless” is unlikely to be readily accepted by desperate parents. However, by adopting a psychological approach to monitoring and assessment, parents may be helped to assess the effects on their own child more objectively. For example, the parents of a young boy with Down syndrome were convinced that his weekly sensory integration sessions (which claimed to restore defective neurological processing; for review see Smith, Mrusek, & Mozingo, 2005) were of great benefit. In contrast, his school believed that the sessions resulted in his behavior deteriorating on the days following therapy and conflicts had arisen when they had asked the family to discontinue therapy. Having agreed on a specific set of behaviors that should be monitored over time, the psychologist involved (who was unaware of the days therapy was conducted) called the parents and school every morning over a period of 4 weeks to rate these. An adaptation of the Personal Questionnaire Rapid Screening Test (PQRST; Chalkely & Mulhall, 1991) is useful in such circumstances as it is very difficult for raters to remember all their baseline ratings. Over the course of the month little evidence emerged to support the school’s view that the therapy resulted in a worsening of behavior; however, parental records showed no consistent improvement. The outcome was that the school ceased their complaints about treatment, leading to better relationships with the family; the family did not discontinue therapy but they became somewhat more skeptical about its effectiveness and reduced the number of sessions, thus allowing the child to take part in some extracurricular school activities such as horse riding.

In another case, the parents of a teenage boy with autism were battling with local social services about the quality of care he was receiving at home. The school was using Facilitated Communication and in these sessions he apparently demonstrated impressive scientific knowledge; his level of written English was also remarkable. The therapist claimed that his progress was being held back by his parents and that he should be removed to a residential placement. Formal psychological assessment was also important. For example, in recent years, structured and informal observations of children with Cornelia de Lange syndrome suggested that severe discomfort caused by gastrointestinal reflux (GER) might be the cause of syndrome-specific behaviors such as self-injury, nocturnal agitation and hyperactivity. Consequently, medical or surgical intervention for GER is now standard therapy, frequently leading to a significant decrease in behavioral problems (Luzzani, Macchini, & Valade et al., 2003). Although in many cases of severe self-injurious behavior (SIB) the cause may be much more difficult to determine, theory-driven psychological assessment has had an important role in both identifying possible causes and developing interventions based on these.

Much of the early work on SIB in individuals with severe intellectual impairments made use of functional analysis and controlled manipulation of experimental contingencies (Iwata, Dorsey, Slifer et al., 1982; Repp, Singh, & Karsh et al., 1991). However, such methods are expensive in time and resources. Moreover, although analog situations can be adapted to the home situation (Oliver, Demetriades, & Hall, 2002), they do not necessarily reflect real-life settings. A clinically more relevant approach to assessment is described by Moss, Oliver, & Aron et al. (2005). Based on their wide clinical experience of Cornelia de Lange syndrome, they conducted unstructured observations in the classroom of the specific types of SIB associated with this condition (skin picking, poking, hitting and finger biting) and the settings in which these occurred. Among the eight children observed, seven showed a clear relationship between SIB and setting, although the combination of factors involved varied from child to child (for the eighth child subsequent treatment for GER reduced SIB to near zero). Identifying the settings that contribute to an increase
or decrease in SIB is clearly crucial for successful intervention. In the case of children with Lesch–Nyhan syndrome (in which SIB occurs in nearly all children and is thought to be biologically based) direct observations, driven by psychological theory, indicated that environmental influences (notably levels of demand or attention) were also highly influential. In particular, the finding that SIB tended to increase during periods of low attention has significant implications for intervention.

A further important finding, again related to detailed psychological assessment of children with severe intellectual impairment and SIB, relates to the spontaneous use of self-restraint. Clinical observation, and a number of single case studies, described children using their own form of restraint (e.g., by restricting the movement of arms or hand to prevent self-harm). Subsequent research with larger samples suggested that self-restraint was greater in children who were not provided with protective devices (Oliver, Murphy, Hall et al., 2003). Based on these observations, shaping procedures have been successfully used to reduce dependence on protective devices and also gradually to decrease the degree of self-restraint (e.g., progressing from having the arm tucked tightly into the shirt sleeve to wearing a simple wrist-band; Oliver et al., 2003). For children with debilitating and sometimes life-threatening behaviors, the potential value of systematic psychological assessments such as these, conducted over time and with different disorders, is immense. The research program of Oliver and his team (Hall, Oliver, & Murphy, 2001; Moss et al., 2005; Oliver, Demetriades, & Hall, 2002) illustrates how single case reports, based on observations made in the context of psychological assessment, can lead to larger case series studies and subsequently to systematic comparative investigations of self-injury in different conditions.

Value of Single Case Research

Within the hierarchy of research-based evidence, single case studies are generally viewed as the weakest form of data. Nevertheless, within the behavioral field, single case studies have, over the years, led to an increasing number of randomized controlled trials. Psychologists were amongst the first to develop statistical techniques to assess the significance of individual change (Payne & Jones, 1957) and single case methodology continues to play an important part in psychological assessment (Crawford & Garthwaite, 2004). In turn, single case publications themselves derive from psychological assessment of particular patterns of behavior, or individual responses to treatment. In our own research for example, early clinical observations and single case reports of the effectiveness of picture-based forms of communication for non-speaking children with autism (Howlin & Rutter, 1987) led to an interest in the use of a specific picture-based program (Picture Exchange Communication System [PECS]; Bondy & Frost, 1994), investigation of its implementation in special schools (Magiati & Howlin, 2003) and ultimately to a large randomized controlled trial (Howlin, Gordon, Pasco et al., 2007). Similar stages – moving from successful outcomes with single clinical cases, through case series reports to efficacy and effectiveness studies – can also be traced within the fields of behavioral intervention (see chapter 62), cognitive therapy (see chapter 63) and parent training (see chapter 64).

Psychometric Assessment

Intelligence and IQ Tests – Historical Background

Since the emergence of “intelligence testing” in the late 19th century (Cattell, 1890; Galton, 1883) there has been much debate about what “intelligence” is and how to measure it. Some of this discussion has been compromised by inconsistent use of the terms “intelligence” and “intelligence quotient (IQ),” but there are also substantive arguments about psychological theory and empirical methodology (Horn & Blankson, 2005). One approach has been to side-step the sometimes acrimonious debate and simply define intelligence as “what intelligence tests measure” (Boring, 1929; Sparrow & Davis, 2000). However, there is strong empirical evidence that IQ tests do measure something meaningful about development, cognitive abilities and adaptive behavior. Thus, IQ scores show moderate (0.6) to high (0.8) stability over time (Bayley, 1949; Moffitt, Caspi, Harkness et al., 1993) although stability from infancy is lower, at least in clinical samples (Bowen, Gibson, Leslie et al., 1996; Charman, Taylor, Drew et al., 2003). IQ scores also correlate highly with real-life outcomes, such as academic achievements, employment and income (Gottfredson & Deary, 2004).

Following on from Galton and Cattell but deviating from their emphasis on sensory and motor assessments (which are now considered more relevant for the assessment of infants; Hadders-Algra, 2005), Binet used the term intelligence to refer to “the sum total of higher mental processes” (Binet & Simon, 1905/1916). Many of the features that characterize current IQ tests were developed in the first Binet–Simon Scale (1905/1916), including items ranked by difficulty, detailed administration protocols, and the concepts of age-graded norms and mental age. Around the same time, Spearman (1904) proposed his concept of a “g” or general factor, empirically derived from factor analysis. While the subsequent century-long debate about the existence and nature of “g” has failed to reach a consensus, most contemporary theories of intelligence admit the presence of a general factor, with recent indications that this may have an identifiable brain basis (Duncan, Seitz, Kolodny et al., 2000). This general factor has been characterized as “fluid reasoning ability” (Carroll, 1989; Cronbach, 1984), working memory capacity or mental complexity (Kyllonen, 1996).

Another important landmark in the history of intelligence testing was the focus on individual profile analysis, particularly with regard to verbal-performance differences or scatter (Rapaport, Gil, & Schafer, 1945/6; Wechsler, 1939). Following the development of factor analysis methodology (Cohen, 1959), Kaufman suggested a three-factor system for the Wechsler Intelligence Scale for Children–Revised (WISC-R; Wechsler, 1974): Verbal Comprehension, Perceptual Organization and Freedom from Distractibility. Although profile
analysis – interpretation of patterns of peaks and troughs across individual subtests – has its advocates, others have expressed caution about the poor reliability of differences scores (Anastasi & Urbina, 1997; McDermott, Fantuzzo, Glutting et al., 1992). Nevertheless, the current version of the Wechsler scales (WISC-IV; Wechsler, 2003) has developed this approach even further by replacing the Performance (PIQ) and Verbal (VIQ) summary scores with four factor-based index scores: Verbal Comprehension, Perceptual Reasoning, Working Memory and Processing Speed.

**Standardized Assessments**
Understanding of psychometric theory and the statistical methods used to derive standardized scores is essential for interpretation and analysis of scores derived from intelligence tests (for a cautionary note see Micceri, 1989). It is also necessary if psychologists are to be able to assess the implications of their use with particular clinical populations or individuals. Statistical methods, primarily factor analysis, have been used to derive global metrics of psychological constructs from individual test items. Many standardized tests have scaled scores with means of 100 and standard deviations of 15. Standard scores are then used to define average, below average or superior ability depending on how many standard deviations above or below the general population mean a child’s performance lies (for comprehensive reviews see Anastasi & Urbina, 1997; Sattler, 2001).

Findings from standardized tests then have to be related to the taxonomy for classification within educational and clinical systems that operate in any country. These may differ from ICD-10 and DSM-IV classification systems – sometimes creating a tension between medical-led clinical teams and education-led school services. Thus, within the UK education system, an IQ between 70 and 50/55 is described as “moderate learning difficulty,” whereas ICD-10/DSM-IV criteria define an IQ in this range as “mild mental retardation.” The terminology used to describe children with low IQ is also inconsistent. The North American term “mental retardation” is considered pejorative in Europe where the term “intellectual disability” is preferred, even though this does not appear in the ICD-10/DSM-IV classification system (see chapter 49). Furthermore, terms such as “learning difficulty,” “learning disability” and “intellectual disability” tend to be used interchangeably, and confusingly.

**What Makes a “Good Test”?**
In determining the applicability of any test, consideration should be given to the size, composition and diversity of the standardization sample in relation to the individual, group or setting for which it is to be used. Characteristics such as age, sex distribution, educational, social, economic and geographic backgrounds of the normative sample are all important. For example, individuals with low IQ are often omitted from school-based standardization samples (Simonoff, Pickles, Chadwick et al., 2006), leading to problems in their use with children with intellectual disabilities. When the test was normed is also crucial because there is likely to be an increase in scores in successive cohorts of children from any one country (the so-called “cohort effect”), generally due to a combination of improvements in diet and education (Flynn, 1987; Hertzog, 1994). Sometimes, as noted above, there can be justification for using an out-of-date test but the possible effect of this on the results must be taken into account. Clinical reports should state the nature of the normative sample when this differs from the testing situation (e.g., test was normed in a different country).

Other critical test parameters are reliability and validity. The different types of reliability that are most relevant are split-half and test–retest reliability – the latter is particularly important for indicating the minimum test–retest time period that is vulnerable to practice and other learning effects. Some tests provide parallel forms to enable such difficulties to be minimized. Construct validity is usually documented by comparing test scores from the normative sample to scores on another established IQ test or to a previous version of the same test. Data on cross-validation should be provided in the test manual.

The final “test of a good test” is the accessibility and relevance of the test items to the population on whom the test is to be used. Particular considerations (e.g., on timed items) apply for children with sensory or physical limitations such as those with cerebral palsy or sight or hearing impairments. Some tests of general intelligence, such as the Wechsler tests, rely heavily on understanding verbal instructions; others specifically eliminate the need for verbal comprehension (e.g., Leiter International Performance Scale–Revised, Roid & Miller, 1997; Snijders-Oomen Non-verbal Intelligence Scale, Snijders & Snijders-Oomen, 1976; see p. 307). These considerations make some UK practitioners favor the K-ABC and Leiter for testing individuals with autistic spectrum disorders (Tsatsanis, Dartnall, Cicchetti et al., 2003). However, it should be recognized that these are currently standardized only in the USA. Another consideration is how attractive and engaging the materials are, and more recent editions of many of the most widely used intelligence tests now use colorful and modern test stimuli.

**Psychometric Properties of the Most Widely Used Tests of Intelligence**
Most well-established tests have been standardized on large representative samples (mostly from the USA) ranging from 2200 6- to 16-year-olds for WISC-IV (Wechsler, 2003) to over 8000 children and adults (3–85 years plus) for the Stanford–Binet Test, 5th Edition (SB-5; Roid, 2003). Some measures, most notably the SB-5, have included substantial (>1200) subsamples of children with learning and behavior problems. Internal consistency, test–retest and split-half reliabilities for overall measures of “IQ” and for the main index or subscale scores on these tests are high (>0.80 to >0.90). Individual subtest reliabilities are lower. Many test manuals also report concurrent validity scores based on standardization subsamples completing two contemporaneous measures (see also Flanagan & Harrison, 2005). Cross-measure correlations of the most general indexes of “IQ” or “intelligence”
tend to be above 0.80. This indicates—at least at the level of relatively large standardization groups—that many of these measures are tapping similar constructs (perhaps even “g”!).

Tests of General Intelligence

Among the best established tests are the SB-5 (Roid, 2003) and the suite of Wechsler tests (Wechsler Preschool and Primary Scale of Intelligence, 3rd Edition (WPPSI-III; Wechsler, 2002); WISC-IV (Wechsler, 2003); Wechsler Adult Intelligence Scale, 3rd Edition (WAIS-III; Wechsler, 1997)). The SB-5 covers the whole age range from 2 years to older adulthood, while the three Wechsler tests provide overlapping scales for preschoolers, school-age children and adults (for comprehensive reviews see Roid & Pomplun, 2005; Zhu & Weiss, 2005). The Wechsler suite of tests probably remains the most widely used in professional practice internationally and has been translated into many languages.

Both the Wechsler and Stanford-Binet tests have been criticized as being based on an outmoded historical perspective of intelligence. However, recent revisions go some way to addressing this criticism. For example, the new four-factor structure of the ability indices derived in WISC-IV (Verbal Comprehension, Perceptual Reasoning, Working Memory and Processing Speed) relates well to constructs in more contemporary theories of intelligence such as fluid reasoning and processing speed (Georgas, Van de Vijver, Weiss et al., 2003). The most radical change to the Wechsler tests is the de-emphasis on the PIQ and VIQ scales with the recommendation that clinical reports emphasize the global intelligence Full Scale IQ and the four processing/ability index scores. These index scores are more closely tied to empirically based theories of intelligence and are of greater remedial value in identifying individual profiles of cognitive strength and weakness.

The most recent revision of the SB-5 (Roid, 2003) has also undergone significant change. Its five-factor structure (based on the five-factor hierarchical mode of Carroll, 1993) allows for each factor (Fluid Reasoning, Knowledge, Quantitative Reasoning, Visual–Spatial Processing and Working Memory) to be measured using separate verbal and non-verbal subtests. There are also attempts (Roid & Pomplun, 2005) to identify which factor scores discriminate best between clinical groups, including children with attention deficit/hyperactivity disorder (ADHD), average IQ autism and low IQ. However, while statistical procedures, such as discriminant function analysis, can indicate how well within a particular sample scores can “classify” cases, this does not translate into a clinically utilizable metric for any individual child. Indeed, the notion that a child who scores at a particular level on one factor or subscale, or one who has a particular size of discrepancy between a score on one factor or subscale versus another, is likely to have a particular neurodevelopmental condition is misleading and inappropriate.

Many other tests of general intelligence are also available: Cognitive Assessment System (CAS; Naglieri & Das, 1997); the US standardized Differential Ability Scales II (DAS-II; Elliott, 2006) and its UK equivalent the British Ability Scales II (BAS-II; Elliott, 1997); the Kaufman Assessment Battery for Children II (KABC-II; Kaufman & Kaufman, 2004); and the Woodcock–Johnson III Tests of Cognitive Abilities (WJ-III-COG; Woodcock, McGrew, & Mather, 2001). For comprehensive summaries see Flanagan and Harrison (2005), Kaufman and Kaufman (2001) and Sattler (2001). Each has different advantages and below we highlight some of the issues relevant to the practitioner when deciding which test to use.

The DAS/BAS tests are conceptually tied to particular abilities in the Cattell–Horn–Carroll (CHC) model of intelligence, although the summary scores most commonly used include a General Conceptual Ability (GCA) index—anakin to Wechsler Full Scale IQ (FSIQ) and cluster scores of Verbal and Nonverbal Ability. Three overlapping sets of subtests are available for children aged 2:6–17:11 years and within each subset there is a Special Non-verbal Composite of subtests that can be administered without verbal instructions. The WJ-III-COG provides a battery of 31 subtests that are also tied to the hierarchical CHC model. Scores can be reported for “narrow cognitive abilities” (lexical knowledge, phonetic coding, visual memory), “broad cognitive abilities” (comprehension knowledge [Gc], fluid reasoning [Gf]), “cognitive category clusters” (verbal ability, cognitive efficiency) and “general intellectual ability.”

Other tests are modeled on somewhat different theories of intelligence and are also more explicitly linked to strategies for remediation. The KABC-II (Kaufman & Kaufman, 2004) retains the theoretical emphasis of the original (KABC; Kaufman & Kaufman, 1983). The KABC-II is derived from Luria’s (1966) neuropsychological model of information processing (simultaneous versus sequential) as opposed to information content (verbal versus visuospatial); Luria-based constructs of learning ability and planning ability are also included. Aside from the extended age range (3:0–18:11 years) the most significant change to the KABC-II is the incorporation of new subtests that explicitly measure aspects of the CHC model: short-term memory (Gsm), fluid reasoning (Gf) and crystallized abilities (Gc). Two different composites can be calculated: the Mental Processing Index (MPI), related to Luria’s theory, and the Fluid-Crystallized Index (FCI) based on the CHC model. Kaufman, Kaufman, Kaufman-Singer et al. (2005) recommend that the CHC model be used as a starting point for assessment unless the child is bilingual, or has language comprehension problems or autism. Another valuable component of the Kaufman tests is the reduced reliance on verbal understanding/responding, so that non-verbal subtests can be both administered and responded to without speech.

The KABC-II is conceptually similar to the CAS (Naglieri & Das, 1997). This has been developed to model the Planning, Attention, Simultaneous and Successive (PASS) theory of intelligence—also heavily influenced by Luria’s work (Naglieri, 2005; Naglieri & Das, 2005). The CAS standardization sample included over 800 children with special needs (intellectual disability/mental retardation, learning disorders, ADHD) to allow for examination of subtest profiles across clinical populations. The CAS also emphasizes strategies for
remediation according to a child’s profile of strengths and weaknesses (Naglieri & Johnson, 2000).

There are a number of brief IQ assessments available, such as the Wechsler Abbreviated Scale of Intelligence (WASI; Wechsler, 1999) and the Kaufman Brief Intelligence Test, 2nd Edition (K-BIT-2; Kaufman & Kaufman, 2006), some of which do not need to be administered by fully qualified psychologists, and others that can be administered across whole school populations, such as the Cognitive Abilities Test, 3rd Edition (CAT3; Lohman, Thorndike, Hagen et al., 2001). Such measures can provide a useful indication of a child’s general functioning for research purposes and can be useful clinically when a child has previously undergone extensive testing and updated assessments are required to monitor progress. However, results can be misleading if wrongly applied in clinical settings. For example, achieving a normal IQ on a brief assessment does not rule out the presence of significant specific learning difficulties; a low score does not provide detailed information about the nature of the child’s difficulties.

**Test Selection and Administration for Special Populations**

While most well-established IQ scales have large standardization samples and good psychometric properties, caution is needed when using tests of more specific aspects of cognitive ability. These typically have smaller standardization samples, less robust validity/reliability data, and, as they are more recent, have not undergone the decades-long iterative revision processes that characterize the more widely used tests. Nevertheless, they are often very valuable for testing children with special needs.

**Testing Children with Language Impairments**

Among tests that have been specifically developed for children with hearing or language difficulties are the Leiter International Performance Scale–Revised (Leiter-R; Roid & Miller, 1997), the Snijders-Oomen Non-verbal Intelligence Scale (Snijders & Snijders-Ooman, 1976; Snijders, Telleghen, & Laros, 1989) and the Universal Non-verbal Intelligence Test (UNIT; Bracken & McCallum, 1997). All can be administered without spoken instructions, using demonstrations of correct responses. The UNIT comprises two subscales measuring memory and reasoning; the Leiter-R includes the two domains of ability tested by its predecessor – Reasoning and Visualization (Leiter-IPS; Leiter, 1952) – plus new domains of Ability, Attention and Memory. These tests are also useful for children from different language or cultural backgrounds. However, a full clinical assessment should include measures of language understanding and expression (in the child’s own language, if possible; if not, in the language in which he or she is being educated), because communicative function (note this is not the same as spoken language) is key to adaptive learning, behavior and development (see chapter 47).

**Testing Children with Low IQ**

Parents whose children have learning difficulties and the teachers who work with them will often report clearly observed strengths and weaknesses in their children’s skills, even if all these skills are relatively delayed for their age. Both parents and teachers are naturally keen to use children’s strengths to maximize their learning. However, when children have low IQs, it is not meaningful to use standardized psychometric tests to determine whether they have any specific difficulties (i.e., to use subtest profiles and index scores to identify individual strengths and weaknesses). This is because if a child has an IQ, for example, at the 2nd centile or lower, it is not possible to have a score on any other test that is reliably significantly lower.

Many clinicians use mental age equivalents to estimate children’s levels of functioning when they are below the basal level on standardized tests or subtests. While this can be useful for estimating the degree of a learning difficulty, discrepancies between age-equivalents should not be used as evidence of significant strengths and weaknesses. Skills in different areas do not always develop in a linear and comparable fashion, nor do they necessarily continue to develop throughout childhood. Ideally, comparisons between tests should only be made using evaluated statistical procedures.

**Assessment of Preschool Children**

Until the 1990s the use of intelligence tests with preschool children and toddlers was controversial, both because of unease about the appropriateness of such testing and concerns regarding the stability (and hence predictability) of performance at this age (Bagnato & Neisworth, 1994; Flanagan & Alfonso, 1995). However, in the past decade there has been considerable development of preschool tests. Several of the instruments reviewed above have extended the age range downwards to 2–3 years (e.g., SB-5; DAS/BAS; WJ-III-COG; WPPSI-III) and other tests specifically designed for preschoolers have been developed, such as the Bayley Scales of Infant Development (0–42 months; Bayley, 1993) and Mullen Scale of Early Learning (0–68 months; Mullen, 1995; for comprehensive reviews of preschool assessments see Lipkin & Allen, 2005; Isquith, Crawford, Espy et al., 2005). There is also good evidence that early test scores are generally reliable predictors of longer term functioning (Brooks-Gunn, McCarton, Casey et al., 1994; Lonigan, Burgess, & Anthony, 2000).

**Tests of Other Abilities**

Frequently, there is a need for more extensive testing (e.g., to examine language, visuospatial skills, executive functions, memory, attention and motor development). Eliciting relevant information from parents and school about the child’s development and general adaptive functioning can indicate when assessment in specific developmental domains is required (see chapter 22).

The administration of a comprehensive neuropsychological battery can provide an indication of underlying neurological conditions, when conducted within the context of a broader neuropsychiatric assessment service (e.g., when results are considered in conjunction with electroencephalogram [EEG] and/or magnetic resonance imaging [MRI] data). In the absence
CHAPTER 21

of such provision a broad picture of the child’s strengths and difficulties can be obtained by means of assessments across multiple inter-related domains. For example, if a child with behavioral difficulties is assessed as having average IQ, the assumption may be made that his or her behavior is a consequence of emotional disturbance, poor home circumstances, lack of discipline, etc. However, Mattison, Hooper, and Carlson (2006) used the NEPSY (Korkman, Kirk, & Kemp, 1997) to examine the neuropsychological profiles of primary school children with significant emotional and behavioral difficulties. They found that over half of the pupils scored at least two standard deviations below the mean on at least one domain, usually language or attention/executive functions. Scores were significantly related to academic achievement and teacher ratings of behavior and attention, and children’s aggressive and disruptive behavior could often be attributed to misunderstanding of language and poor impulse control. Similarly, Ripley and Yuill (2005) found that pupils who had been excluded from school had poorer expressive language and, in the case of the youngest children, poorer auditory working memory than controls. Expressive problems were also linked to high levels of emotional symptoms. Within clinical practice it is well-established that language and attention/executive impairments are highly associated with problem behavior and several studies have found that 30–50% of children referred to child and adolescent mental health services (CAMHS) have language, reading or other learning difficulties (Cohen, Davine, Horodezky et al., 1993; Humphrey, 2006; Javorsky, 1995; see chapters 47 & 48).

Assessment of Executive Functioning and Attention

Executive functioning difficulties are implicated in many different learning and neurodevelopmental disorders (e.g., autism and ADHD, Happé, Booth, Charlton et al., 2006, see chapters 34 & 46; dyslexia, Helland & Ashjornsøen, 2000, see chapter 48; Tourette syndrome and obsessive compulsive disorder (OCD), Watkins, Sahakian, Robertson et al., 2005, see chapters 43 & 44) and may be at the root of many children’s behavioral and emotional difficulties. The term “executive functions” refers to the set of skills required for higher order thinking (e.g., problem-solving, planning and the ability to react appropriately to complex multicomponent situations using previous learning). Attention and memory skills are also involved.

The importance of evaluating executive functions is particularly relevant when there is a significant discrepancy between a child’s intellectual ability and his or her adaptive functioning (Morgan, Singer-Harris, Bernstein et al., 2000) or when there are difficulties with self-help and self-organization. Instruments such as the Behavioral Assessment of Dysexecutive Syndrome for Children (BADS-C; Emslie, Wilson, Burden et al., 2003) can be helpful when used in conjunction with a structured parents and teacher rating scale (e.g., Adaptive Behavior Assessment System Second Edition [ABAS-II]; Harrison & Oakland, 2003) or the Vineland Adaptive Behavior Scale-II (Sparrow, Cicchetti, & Balla, 2006) for determining whether executive functioning difficulties are affecting daily functioning (Bolte & Poustka, 2002; Stein, Szumowski, Blondis et al., 1995). If this proves to be the case, independence training should be implemented; a more structured home environment is also likely to be beneficial.

Testing children’s executive functions and attention skills can pose significant problems because structured assessments do not necessarily reflect the child’s functioning in unstructured real-life situations. Moreover, formal assessments tend to test only subcomponents of executive skills: attention switching (e.g., Trails tasks); monitoring and responding to feedback (e.g., Wisconsin Card Sorting Test); planning multistep rule-based strategies (e.g., Tower of Hanoi). Although these tests have proved useful for adults they have proved less so for children whose executive skills are still developing and in whom the differentiation between executive domains is less clear-cut (Hughes, 2002; Wright, Waterman, Prescott et al., 2003).

Recent tests of executive function have been increasingly influenced by neurodevelopmental models (Karmiloff-Smith, 1998), and recognition of the need for more ecologically valid assessments. The BADS-C, for example (Emslie, Wilson, Burden et al., 2003), although adapted from an adult test, more closely reflects real-life problems and may provide a better indication of the child’s difficulties in everyday situations. It also provides norms for various groups of children according to age and IQ.

There is now a range of executive tests specifically for young children (3–12 years; NEPSY; Korkman, Kirk, & Kemp, 1997); others range from 8 to 80 years (Delis–Kaplan Executive Function System [D-KEFS]; Delis, Kaplan, & Kramer, 2001). Many assess a wide range of executive abilities such as working memory, planning, flexibility and inhibition (the ability to withhold an impulsive or learned response). The computerized Cambridge Neuropsychological Testing Automated Battery (CANTAB; Luciana, 2003) provides a number of measures of executive function, including planning, set-shifting and flexibility. The advantage of computerized measures is that they provide accurate and objective measures of children’s skills in specific areas. The disadvantage is that they cannot provide clinical evaluations of how children fail tests – information that is often essential for designing interventions.

There are also scales for assessing memory (e.g., Children’s Memory Scale [CMS]; Cohen, 1997); Wide Range Assessment of Learning and Memory, Second Edition (WRAML2; Sheslow & Adams, 1990); Working Memory Test Battery for Children (WMTB-C; Pickering & Gathercole, 2001). These tap skills such as immediate and delayed memory (verbal and visual), phonological loop, visuospatial sketchpad and executive memory. However, these measures tend to be based on relatively small standardization samples.

Assessments of attention include the Test of Everyday Attention in Children (TEA-Ch; Manly, Robertson, Anderson et al., 1998), which measures areas such as sustained attention, switching attention and inhibition. Computerized tests, such as the Conners’ Continuous Performance Test (CPT-II;
Conners, 2000), measure elements of attention including sustained attention, response speed and impulsivity.

Tests of specific skills such as memory, attention and executive function are most reliable when a child's intellectual ability is within the average range. However, referrers to neuropsychological assessment services often request more extensive testing for children with low IQs because they can observe specific strengths and weaknesses in their skills. For example, if the teacher of a child with a Full Scale IQ of 70 was reporting that the child appeared to have particular memory problems (e.g., could not remember what had been said to them or taught to them the day before), it might be tempting to assess the child's verbal memory. However, when IQ is around 70 (2nd centile) or below, interpretation of test score discrepancies is very difficult. If the child in question achieved a verbal memory score of 55 (0.1st centile), this would represent a statistically significant discrepancy between their achieved score and that predicted from their IQ. Nevertheless, in clinical terms, it would be unsafe to describe such children as having a specific verbal memory impairment, because they would be expected to score poorly on most tests because of their global intellectual impairment. However, within any group of pupils with mild intellectual disabilities, there will be those who stand out as being more hyperactive, less attentive or with poorer working memory and, while such observations are valid and important for informing intervention and management, conducting extensive neuropsychological assessments is not a reliable way of eliciting such information.

**Achievement Tests**

Both general and specific learning difficulties will affect academic progress and it is often a failure to progress academically that first brings intellectual difficulties to the attention of parents and teachers. In educational practice, school-based achievement test results are useful for identifying children who are falling behind but within the clinical setting they are no substitute for dedicated psychological assessment. Furthermore, in most countries, they focus only on circumscribed aspects of learning. Within education, a range of measures, such as the Neale reading tests (Neale, 1997), is used to monitor reading skills. However, to determine whether a child has specific literacy difficulties, it is necessary to use tests that provide standard scores and have been normed in conjunction with IQ measures. Such tests include the Wechsler Individual Achievement Test, 2nd Edition (WIAT-II; Wechsler, 2001), Woodcock–Johnson III Achievement Tests (WJ-III; Woodcock, McGrew, & Mather, 2001) and the Wide Range Achievement Test (WRAT-III; Wilkinson & Roberston, 2006).

**Practical Issues**

One question for the practicing psychologist in a CAMHS setting is which children to recommend for psychological assessment if there is not capacity to see all the children. A combination of factors such as a family history of learning difficulties, or observations from school staff detailing when children show most problem behavior (e.g., when the verbal demands are high; when there is least structure), can act as indicators for further neuropsychological assessment (Humphrey, 2006).

Another issue is how far to extend any clinical assessment, given that further assessment with one child limits the resources available to others (Yates & Taub, 2003). A pragmatic rule-of-thumb is to continue assessment until a reasonable answer to identifying likely contributing causes to an individual child’s learning or behavioral problems has been reached. The current working hypothesis can then be put “on hold” until the planned intervention has had time to take effect. If intervention is successful there may be no grounds for additional assessment; if intervention fails then the hypothesis formulation-testing-iterative process should continue.

**Unstandardized Assessments**

The importance of non-clinic assessments for both understanding and remediating children’s problems was discussed in detail earlier in this chapter. Observation of the child’s skills in a variety of unstructured settings can also be crucial in identifying the specific nature of a child’s learning difficulties and for implementing appropriate remedial strategies. This may involve examining how the child approaches normal, everyday activities and school learning tasks in order to determine how he or she learns and responds to mediation. Here the focus is on identifying what works for that child, rather than simply assessing what is going wrong. Although such observations may lack scientific rigor, they should, nevertheless, be informed by a scientific approach and be as objective and systematic as possible. The advantage lies in the high validity of such observations and their direct relevance to any individual child.

Dynamic assessment, based largely on Vygotsky’s theory (1978) and Feuerstein, Rand, Hoffman et al. (1980) Instrumental Enrichment Program of Cognitive Modifiability, represents an alternative approach to traditional cognitive assessments and is based on the concept that intelligence is constantly influenced by ongoing activity. In dynamic assessment, the psychologist attempts to assess the child’s learning potential or the modifiability of his or her learning style. This involves a process of testing, intervening and retesting, and includes analysis of qualitative changes in the child’s responses, a record of the mediated learning experiences, measures of test score gains and ratings of modifiability and learning strategies. A similar approach, designed to provide a link between the assessment and intervention processes, is the Response to Instruction model (Fuchs & Fuchs, 1998). Its specific aim is to provide early intervention and avoid discrimination against minority students (Fuchs, Mock, Morgan et al., 2003; Vaughn & Fuchs, 2003). Advocates argue that “learning tests” provide a fairer and more valid assessment than static intelligence tests (Fabio, 2005; Guthrie & Stein, 1996) and that they provide effective interventions (Tzuriel, 2000). However, this approach has remained rather
CHAPTER 21

marginalized (Kozulin, 2005), perhaps because it mainly relies on individual practitioners developing specific interventions for individual children, with the consequent problems of interpreting results.

**Intervention**

There have been few controlled studies examining the efficacy of interventions for either global or specific learning difficulties (D’Amato, Crepeau-Hobson, Leesa et al., 2005) and recommendations for classroom interventions are normally made on an ad hoc basis according to the experience and ingenuity of individual psychologists and teachers. The support any individual child receives is also likely to depend more on available resources than on any evidence base (Rothlisberg, D’Amato, & Palencia, 2003; Sattler & D’Amato, 2002).

In the UK, educational psychologists increasingly use a “consultation model” in their direct work with schools (Caplan, 1970; Wagner, 2000). The consultation model aims to improve the quality of children’s education and care by supporting organizational change to assist all children (Alkon, Ramler, & MacLennan, 2003) rather than trying to address the specific problems or needs of individual pupils (Collins, Mascia, Kendall et al., 2003).

The use of the consultation model is intended to maximize the impact of psychologists’ interventions by gaining the cooperation and commitment of everyone involved with the child and by moving away from looking for within-child factors to find solutions to problems. If feedback from the psychologist is provided simply via a written report or presented as a fait accompli, staff at all levels, from classroom assistant to headteacher, may disagree with the recommendations or feel powerless to carry them out, and may well resent the interference and imposition of the “expert,” whom they may not even have met face-to-face. Psychologists need to gain the cooperation of school staff because they rarely carry out the interventions themselves but rather make recommendations to those managing the children on a daily basis. The consultation model seeks to ensure that staff and parents working with the child have a personal commitment to making interventions work and are able to develop problem-solving skills that will prepare them for future difficulties (Caplan, 1995; Sandoval, 2003). While consultation as a model of service delivery has been embraced by educational psychology services in the UK, and is also being introduced in the USA, there do not appear to be any published studies providing evidence of its efficacy in terms of its benefits for children or schools.

**Intervention Case Studies**

The following hypothetical brief case studies illustrate the benefits of combining observational data with assessment information. In each example the same observed behavior is discussed so that the importance of interpreting test data to identify the cause of behavioral and learning difficulties can be highlighted.

**Case description**

Lucy is an 8-year-old girl. Observed behavior in class: Lucy was distractible; daydreamed; misunderstood the teacher’s instructions; lost her possessions; was always in the wrong place; maths and literacy skills were very weak. Her teacher believed she had poor attention and that her behavior was attention-seeking as, when an adult worked with her, she was able to perform much better. Initial observations, using timesampling, indicated that Lucy was off-task 70% of the time. An age-matched peer was only off-task 22% of the time in the same lesson.

The following tests were included in the test battery:

- Wechsler Intelligence Scale for Children UK, 4th Edition (WISC-IV-UK)
- Children’s Memory Scale (CMS)
- Working Memory Test Battery for Children (WMTB-C)
- Delis-Kaplan Executive Function System (D-KEFS)
- Behavioral Assessment of the Dysexecutive Syndrome for Children (BADS-C)

Scores are given as standard (mean: 100, average range 85–115) or scaled scores (mean: 10, average range 7–13).

**Assessment results: Example 1**

Lucy obtained a full-scale IQ of 95 (WISC-IV UK), but a Working Memory Index of 62. Further assessment indicated significant verbal working memory impairment (WMTB, Phonological Loop, Standard Score: 75, Central Executive: 62). Teacher reports supported clinic observations that she found it hard to retain and manipulate verbal or auditory information in her head. She confused instructions; could not sequence and hold on to ideas that she had generated herself; could not use number sequences for mental arithmetic; could not remember her ideas for writing or how to spell the words and found it hard to filter out classroom noise when the teacher was speaking.

Interventions were needed to provide external support for her weak working memory. The main aim was to reduce the amount of verbal information she had to retain by providing her with visual reminders. For example, she should use number lines and tables during maths; she should be provided with lists of instructions that she can tick off as she works; and she should plan out her stories, perhaps graphically, before attempting to write. She should sit at the front of the class to reduce distractions.

**Assessment results: Example 2**

Assessments show that Sophie had average intellectual ability (Full Scale IQ: 90) but very poor executive skills (e.g., D-KEFS Colour-Word Interference, scaled score: 3. Tower, scaled score: 3. BADS-C, standard score: 55). She found it hard to plan her work although she could follow individually given instructions well; she did nothing when given open-ended tasks; could not organize herself unless following a repetitive and learned routine; could not hold instructions in her head or generate an understanding of what the instructions meant in practical terms and did not know when to apply rules.
Interventions needed to focus on providing a model or framework within which Sophie could operate. At the beginning of every task she should be shown each step that she will need to take; she should be shown the endpoint of what she is trying to achieve and she should be taken through the steps needed to achieve this goal. By following this process and achieving success on several occasions, she should be able to learn how to apply the same series of steps to similar situations (i.e., she will develop a template to use in the future). When faced with changes to the task, she will need support to adapt her learned system. She should be provided with a visual timetable of the day’s events and the things she needs for each session so that she can begin to learn to organize herself and see the sequence of events ahead of her.

Assessment results: Example 3
Assessment showed that Alice had a mild intellectual disability (Full Scale IQ: 63). She found it hard to learn from being told about things; she could not concentrate on the teacher’s narrative, and processed language too slowly to keep up with the class. Her learning capacity was limited. She seemed to learn new information at the expense of previously learned material. She struggled with literacy and numeracy.

Interventions were needed to target Alice’s learning style and slow pace of learning. She would need to learn through practical experience rather than verbal description. She would find it easiest to learn concepts that could be practically demonstrated rather than abstract concepts. Aiding her understanding should improve her concentration. She might benefit from a precision teaching approach to literacy (e.g., only teaching her a few words at a time initially rather than attempting to teach her “how to read”). Precision teaching and direct instruction would allow teachers to evaluate her rate of learning and prevent new learning “knocking out” previously learned information (Solity, Deavers, Kerfoot et al., 1999). Numeracy should be taught through the use of concrete materials; standard notation of maths should be introduced gradually when basic skills are consolidated.

These examples are used to illustrate the potential dangers of an inadequately implemented hypothesis-testing model. For example, if Lucy were observed in class to have a poor attention span, the hypothesis might be that she had a primary attention deficit. If, upon administration of an attention test, she achieved low scores, the psychologist might conclude that Lucy had a specific attention difficulty. However, that conclusion could only be reached if Lucy were found to have a significant discrepancy between her IQ and attention scores and if other contributing factors such as language difficulties, hearing impairments and trauma had been excluded.

Practical Considerations
Psychometric assessment relies on the child’s performance on a series of tasks conducted in the testing environment. Thus, it is essential to create an environment that allows the child to perform as well as he or she is able. An appropriate environment should be relatively free of distractions (conducting psychometric assessments in a clinic room with a sink or large open box of toys is rarely a good idea) but suitably child friendly and age appropriate. In order for the psychologist to engage optimally with the child, some “warm-up” activities (e.g., conversation, drawing, toy play) are also important. Moreover, such activities allow the clinician to determine the child’s social interaction and communication style and to identify favored activities – these can be useful as “rewards” for remaining on task. However, warm-up or reward activities should not be extensive else they risk that the transition from “play” to a more structured, possibly more difficult, activity might be unsuccessful. The clinician will have to make decisions on the approach to any individual child on the basis of parental or teacher report and clinical judgment. All of these considerations can be important in maximizing the child’s motivation and engagement and also to help interpret why the child might be failing on items that would seem to be well within his or her competence. Ideally, children should be tested in the absence of their parents but younger children may refuse to be separated. In such circumstances several cautions are necessary. While the parents’ presence can put the child at ease it can also lead to “clingy” behavior in children who are particularly shy or nervous, or avoidant behavior when children are finding the test difficult. Parents should be positioned so that they can see what the child is being asked to do and how they are responding but not so close that they are tempted to interfere or so that the child becomes overly aware of parents’ monitoring of his or her performance.

As stressed earlier in this chapter, school- or home-based assessments are often necessary to supplement the information obtained at the clinic. School visits should include observations during structured classroom activities and at break or meal times. Observation of the child working in the classroom and his or her response to adult direction can also provide information relevant to hypothesis generation and testing. Psychological assessment in the home is relevant to assessing children’s behavior or relationships as these may differ considerably in different settings. However, formal assessment of cognitive abilities in the home is not usually recommended, not least because of all the distractions present in most family homes.

What to Report and How
As a consequence of their psychometric assessment, most psychologists will produce a report for fellow professionals, parents and schools. The purpose of this is to inform all those involved with the child on a regular basis about how his or her learning problems may be affecting behavior at home and/or school, the extent to which these difficulties are remediable, and the external support or additional teaching needed to maximize progress and minimize the longer term impact of these difficulties.

Although it is important that reports are written in such a way as to be accessible to all readers, whether professionals or parents, the use of vague terms, such as “below average”
CHAPTER 21

or “low ability,” without reference to the statistical data upon which such judgments are based, should be avoided. Ideally, when reporting test results, the circumstances of testing and any limitations of the test should be made explicit.

Interpretation of scores is dependent on:
1. The clinical information available that affects the ecological validity of scores;
2. The statistical normative data that will affect content and the construct validity and reliability of scores.

Therefore, when interpreting standardized scores it is important to look at different aspects of the normative data of the particular psychometric test being used. For example, even when two reliable index scores on the same psychometric measure are statistically significantly different from each other, it is very important to check the frequency of such differences within the normative data set. For example, if a child attains a Verbal Comprehension Index on the WISC-IV within the average range and a Working Memory Index within the low range, this discrepancy might be statistically significant at the 0.05 level but examination of the frequency data shows that such a discrepancy would be expected in 25% of the population and this information will affect the interpretation of the relevance of this score.

Following the assessment (after time spent scoring and rechecking scores; e.g., by checking mental addition both backwards and forwards) the practitioner should give verbal feedback to the parent(s). This should include a general description of what the test is measuring, how the child performed and what his or her behavior was like during the session. Clinicians should check with parents (particularly when they have been present) whether the child performed as expected. Discrepancy in performance in different situations is useful not only for developing hypotheses about the child’s abilities and behavior, but also for assessing parental expectations and understanding of their child’s abilities. At the end of the feedback parents should always be given a chance to ask questions. Psychologists need to be aware that concepts such as IQ, and the limitations of IQ testing, are often misunderstood. Discussion between clinician and parent(s) is helpful to establish mutual understanding about the assessment findings and to help them assimilate this information.

For children of an appropriate age and maturity, it is good practice to provide them with feedback. This is useful for eliciting their views concerning any difficulties at school and gauging their own awareness of “difference” from their class peers in terms of learning or behavior. It is important to be clear to parents and teachers that problems with learning and behavior and emotional difficulties can often co-occur and the outcomes and conclusions of a “whole child” assessment should address each of these features – even when the referral is for a “cognitive assessment” only.

In their reports, psychologists should make their hypotheses about the child’s difficulties explicit. This will enable other agencies working with the child, such as speech and language therapists, psychiatrists and pediatricians, to understand the formulation and add to the psychologist’s gathering of evidence, as well as aiding interagency collaboration. Reports should be sufficiently detailed to enable school staff to construct a precise measurable Individual Education Plan (IEP) that not only sets targets but includes specific teaching strategies to achieve those targets. Reports should also give teachers some idea of the rate of progress that should be anticipated so that methods can be usefully evaluated.

Conclusions

In this chapter we have stressed the important role of the psychologist as “science practitioner.” Cognitive assessment can be a vital part of the assessment process, and requires a rigorous and methodological approach to testing together with detailed understanding of psychological and statistical theory. Consequently, practitioners need continually to update their knowledge base as new developments arise, such as the advent of computerized testing (Berger, 2006) or new findings from emergent fields such as developmental cognitive neuroscience (Munakata, Casey, & Diamond, 2004). However, psychometric assessment is neither the psychologist’s only, nor indeed primary, role. Thus, we have attempted to illustrate the crucial importance that far broader, wide ranging and theory-driven assessment plays in formulating hypotheses about a child’s difficulties, systematically testing these hypotheses and, most importantly, in designing effective interventions.

PSYCHOLOGICAL ASSESSMENT IN THE CLINICAL CONTEXT

 CHAPTER 21

This chapter describes the contribution of physical examination and subsequent investigations to the detection and assessment of any organic physical disorder in children presenting with mental health symptoms to the child and adolescent mental health services (CAMHS). Chapters 12, 24 and 30 outline brain disorders and the etiological risks that they pose for psychiatric disorders. Chapters 57 and 70 describe the impact of physical illness on psychosocial function.

The purpose of any medical assessment, including physical examination and laboratory or other tests, is to identify causative, associated or exacerbating medical problems.

**Causation** may be difficult to establish; but, for example, in a child with intellectual disability, identifying the etiology informs prognosis and recurrence risk counseling, and may guide subsequent therapeutic and educational intervention. For many families the need to “leave no stone unturned” can block coping mechanisms until finding the cause is addressed.

**Associated** medical conditions include hypothyroidism in children with Down syndrome, and conductive deafness in children with chromosome 22q11 deletions, and can strongly influence the presentation and management of developmental and psychiatric disorders.

**Exacerbating** medical disorders include, for example, unrecognized sensorineural deafness in an adolescent with autism, and severe iron deficiency in children with hyperactivity and learning difficulties. They are seldom causal, but if unrecognized and untreated they serve to worsen cognitive and behavioral problems in vulnerable groups of children.

The guiding principle for history-taking, physical examination and subsequent investigations is that treatable conditions need to be identified and a high priority given to any condition with genetic implications for the child or other family members. The impact of false negative and false positive tests, the discomfort associated with some examinations and investigations, and economic constraints, mean that clinicians need to know when to accept that a given child has been adequately examined and investigated. In this chapter we outline a systematic approach for using the relevant evidence to decide what makes particular aspects of history, examination and investigation worthwhile for a particular child.

Even though this chapter primarily focuses on what is reasonable to expect of the mental health professional, there are huge differences in training, seniority and experience that will affect an individual’s threshold to refer to another specialist colleague, or examine and investigate personally. These factors, as well as national and international variations in the availability of specialist services and investigations, mean that the interpretation and application of didactic protocols can be difficult, despite their superficial attractiveness (Palfrey & Frazer, 2000).

**Screening Programs**

Most screening tests in pediatrics were designed to identify children at increased risk for certain disorders. It is expected that the natural history of the disorder is known, and that an intervention is available that can change its course.

The screening programs adopted vary internationally. Neonatal screening is rapidly growing, particularly with technologies such as tandem mass spectrometry, which allows the detection of a wide range of inborn errors of metabolism near birth. Phenylketonuria and thyroid function are particular examples of well-established neonatal screens in many western countries (National Screening Committee, 2006a,b). In the UK there has been a trend in recent years to decrease preschool screening programs and place an increasing reliance on parental concerns being brought to the appropriate professional group. In the preschool years this is usually a health visitor, and at school age either school nursing or teaching staff. Barlow, Stewart-Brown, & Fletcher (1998) conducted a critical appraisal of school-entry examination literature; disappointingly, no study provided either follow-up of children after referral to estimate the positive predictive value or yield of the screening, or follow-up of the whole cohort to identify false negative cases. The conclusion was that “Data on the effectiveness and efficiency of both the routine and selective school medical examination in accurately identifying children with new or ongoing health problems are not available at the present time” and challenged the ethics of such a program.

Unfortunately, and even in situations where routine screening has taken place, the assumption cannot be that a specific problem has been excluded. The advent of universal neonatal hearing screening does not rule out the need for subsequent hearing tests, particularly if there is parental or school...
concern. Late-onset sensorineural losses and middle-ear conductive problems can be acquired subsequent to birth. Any undiagnosed hearing loss can have devastating effects on a child’s daytime performance, sociability and behavior. Even newborn testing for congenital hypothyroidism can miss hypothalamic hypothyroidism and primary hypothyroidism.

Faced with this variable and changing picture we suggest in the first instance that the clinician in the mental health clinic enquire about and document which routine screening tests have and have not been carried out. A negative screen may reduce the likelihood of a disorder, but this must always be outweighed by any clinical, parental or school concerns, which should trigger appropriate referral and investigations.

What is Worthwhile in History and Examination?

The approach to deciding if an activity is worthwhile applies as much to history-taking as to performing an examination or medical investigations. In all three situations the clinician needs a degree of specific local background knowledge, applicable to the population of children referred to the clinic. The concepts of availability, affordability and precision apply equally to physical examination as to medical investigations.

In a busy clinic room, time is the main commodity, and aspects of history and physical investigation need to be worthwhile. Hampton, Harrison, Mitchell et al. (1975) compared medical diagnosis after reading the referral letter, after taking a history and after physical examination. With history and the referral letter, the diagnosis was reached in 66 out of 80 cases. Clinical examination contributed and resulted in another seven diagnoses and laboratory investigations to another seven. Of more relevance to the specific population of children with psychiatric disorders and their comorbidities is the work of Dooley, Gordon, Wood et al. (2003), who prospectively assessed the impact of each component of the pediatric neurological consultation in 500 consecutive referrals to a tertiary care pediatric neurology clinic. Specifically, they found that examination and investigations were not influential for children with headaches, Tourette syndrome, developmental delay or attention deficit/hyperactivity disorder (ADHD). In children with developmental delay, examination did not alter their subsequent decision about investigation. For the majority of children, even in a specialized clinic with relatively high pre-test probabilities of neurological disorder, history influenced management in over 90% of cases, and examination in less than 6%.

Sackett, Haynes, Tugwell et al. (1991) have clarified the process of deciding what is worthwhile. The concept of pretest probability requires the clinician to know or estimate the likelihood of the particular disorder being considered. Here populations differ and a child presenting to their GP with a headache for the first time has a lower “pre-test probability” of an underlying brain tumor than a child presenting to a regional pediatric neurology clinic with the same symptoms.

Clinical history also affects pre-test probability of a certain diagnosis. For example, 0.4–3% of children with autism are found to also have tuberous sclerosis (Smalley, Smith, & Tanguay, 1991). When epilepsy and intellectual disability are additionally present the likelihood of also having tuberous sclerosis rises to 8–14% (Riikonen & Simell, 1990). In a cohort of children with autism the baseline chance of any child having fragile X syndrome is around 1.6%. However, a thorough physical examination that identifies key physical markers increases the likelihood of fragile X to 45% (Brown, Jenkins, Neri et al., 1991). For the interested reader, Sackett et al. (1991) propose a convenient nomogram using Bayes’ theorem that generates post-test probabilities if one knows the likelihood ratio of a given examination or test finding (Dooley, Gordon, Wood et al., 2003). Results of using such a system have been published for the investigation of children with learning difficulties and potential fragile X syndrome (Hartley, Salt, Dorling et al., 2002), and for children with motor delay and potential Duchenne muscular dystrophy (Dorling & Salt, 2001). In both examples it is clear which clinical findings would generate post-test probabilities that might take the clinician over a diagnosis or treatment threshold (Table 22.1).

Clinical experience, alongside the available evidence above, thus supports the need for any health professional to remain focused on the critical process of taking a good clinical history for organic disorders, before becoming distracted by lengthy examination protocols and a wide choice of modern investigations. The risks of missing a particular diagnosis are also likely to weigh heavily with clinicians in their decision-making.

The sections that follow on history and examination are by no means comprehensive, but focus on what is worthwhile.

History-Taking

Family History

We assume that a full family history for psychiatric, neurological, medical or learning difficulties and details of consanguinity is accepted as standard. We argue that a full “organic” history is worthwhile for any child presenting to CAMHS. Even when the history has been taken by a previous health care professional, it is not unusual for the family to have subsequently identified a further affected member, or remembered a significant prior illness. Furthermore, if time is short, the history is likely to be the most worthwhile area to spend time on, with examination and investigations taking much less time.

Pregnancy

An enquiry about pregnancy is expected by parents and is also worthwhile. The full range of teratogens, including tobacco, alcohol and most anticonvulsants, needs systematic enquiry, as does any history of rashes and fever during pregnancy, which may indicate exposure to a congenital viral infection.

Previous neonatal deaths or even acute life-threatening episodes in a sibling can be the most important pointer towards
an inborn error of metabolism. These rare conditions can present as unexplained learning and behavioral difficulties and are autosomal recessive with a recurrence risk of 25%.

Asking about previous spontaneous abortions may sometimes be uncomfortable for the clinician to ask, or parents to answer, but needs including in all histories. The important group is those couples who have had two or more spontaneous abortions; as many as 1 in 20 of these parents will carry a chromosome translocation or inversion. This may be associated with further viable children with unbalanced chromosomal disorders (Gardner & Sutherland, 1996).

Birth and Neonatal History
Parents are frequently concerned that any difficulty at birth is the cause of subsequent behavior or developmental problems, and therefore it is important to establish the gestational age at birth, the birth weight and whether the baby was “small for dates” (i.e., less than 10th centile at birth). Birth details need to include the type of delivery, state of the baby at birth and subsequent neonatal course. Although a history of traumatic birth may be of significance, it can also be a marker of pre-existing fetal difficulties, or be explained by recall bias. Persistent Apgar scores below 5, any symptoms of neonatal encephalopathy (e.g., fits), early imaging evidence, general metabolic disturbance, requirement for breathing support and the period for which that was needed would all be relevant in considering a difficult birth as a risk factor for subsequent developmental problems (see chapter 12).

Early Developmental History (Up to 5 Years)
We encourage the routine taking of a developmental history, alongside a behavioral history. Once again we are not in favor of the universal use of didactic developmental questionnaires. We prefer a flexible and responsive style of history-taking which uses broad probes that can quickly be refined to pursue any specific hypothesis that emerges. In this way the developmental history can be as quick as 10 minutes, to 1 hour in complex cases.

Dates of milestones are often hard for parents to recall. The advent of near universal parent-held records in the UK has proved invaluable and, where applicable, parents should be encouraged to bring these to the first assessment.

With the possible exception of remembering when a child first walked, dates of milestones need linking to key points in the family’s life such as births, deaths, house moves, etc. Parents who have significant depression in the child’s early life frequently find accurate recall much more difficult. Relative ages of acquisition of milestones can be easier for parents to remember, but while comparison with peers or siblings may be useful, it can also be misleading. The clinician needs to remember gender differences when comparing milestones in young children, and the huge normal range for most milestones.

Even when everything seems normal, “milestone moments” are a useful basis for discussing concerns. As a minimum we would propose the mental health professional gains an overview of the child’s development and behavior during the first year of life, the expected changes in communication competence in the second year, and development and behavior during preschool placements, primary and secondary school and the transitions between them. Table 22.2 gives a simplified description of the skills expected at varying ages up to 5 years.

The age of onset of symptoms is crucial for a number of conditions, but establishing whether the pattern of development followed a normal trajectory is more difficult. Careful questioning is required to assess whether there is a loss of skills, or onset of new and different behaviors. It can be difficult to distinguish persistent continuing loss of skills from the plateauing that happens so often in children with a severe intellectual disability. The gains and plateaus of normal development

CHAPTER 22

are often much more exaggerated in these developmentally delayed children.

Timing and trajectory are crucial for a number of conditions. It would appear that, for a number of prenatally acquired disorders, the brain is still capable of sustaining a certain amount of developmental progress before higher order functions fail. Thus, deaf children may babble normally in the first 6 months of life but then, lacking the usual language input, fail to develop further oral language skills. Some children with autism can progress well early in the first year but then show more apparent difficulties when demands on their social interaction and understanding increase. In children with Rett syndrome, early developmental skills can often appear in normal order (although usually delayed) before the process slows and there is emergence of extrapyramidal features and loss of useful hand function. In many neurological, genetic or metabolic disorders the advent of early seizures marks the beginning of developmental plateauing or decline. Seizure onset in the first 2 years is a marker of risk for developmental delay and autistic features.

Systematic Enquiry

The clinician will be aware that the separation of history and examination is necessary for the written page, but does not occur in reality. Observations of a child’s general appearance, height and weight, signs of ill health and behavior are taking place before and during any period of history-taking, and may reasonably direct specific avenues of questioning.

We suggest starting with a probe into recent and past medical health with attention to hospitalizations, chronic diseases, hospital admissions and time off school with illness. General questions about physical and mental energy and enthusiasm for in-school and out-of-school activities are important, as is a discussion about whether these have recently changed.

Enquiries about appetite, weight gain or loss are important and naturally accompany the measurement and plotting of a child’s height and weight centiles. Systematic enquiry is then made into concerns about motor competences, gait, hand and general co-ordination skills, sleep problems, gastrointestinal symptoms, headache, seizures, aches and pains generally, unspecified illnesses and weaknesses and any known medical problem. Fits, fainty, headaches and other neurological symptoms are dealt with in specific sections that follow below.

Common disorders of childhood (e.g., asthma) should lead to an enquiry into medications that the child takes, both prescribed and over-the-counter.

Some symptoms are seen more commonly in particular disorders than in the general population, including thirst and excessive drinking in children with autism (who do not have diabetes), and constipation in many children with learning difficulties. Enquire about achievement of bowel and bladder control day and night, any day or night loss of control and history of stool withholding or opening in the nappy only (common in the autism spectrum disorders; see chapter 56). For gastrointestinal symptoms, a description of appetite, abdominal pain, vomiting, constipation and diarrhea is important, as is a discussion of the severity, frequency, timing, and exacerbating and relieving factors.

Primary sleep disorders are common in the general pediatric population and can exacerbate any emotional or behavioral symptoms (see chapter 54). Sleep disorders secondary to mood disorders are also common, and therefore this remains an important area of enquiry. Sleep difficulties can be broadly divided into problems with falling asleep, staying asleep or excessive daytime sleepiness. Insomnia, obstructive sleep apnea, restless leg syndrome and narcolepsy all impact on daytime behaviors, cognition and quality of life (Kotagal & Pianosi, 2006).

Perhaps the most difficult yet important part of history-taking is the presentation of child abuse, including factitious illness. Child abuse has protean manifestations, and without an awareness that it is common, and is often hidden for years, the diagnosis may be missed. Well-described presentations include withdrawal and depression, seizures, allergies and psychiatric symptoms. Often in the case of factitious illness the presentation of the illness or disease course does not make sense, and treatment is invariably ineffective or associated with the development of more symptoms.

We emphasize that for both these areas meticulous documentation of the history, which caregiver was being interviewed, and explanations and timings for all events is essential. It is often small but repeated inconsistencies in these cases that trigger suspicions that can prompt fuller multiagency investigations (see chapter 28).

Behavioral Phenotypes

The recognition that many genetic disorders present with both dysmorphic signs and well-characterized behavioral patterns can often guide the choice of investigations and speed diagnosis. Suspicions of a particular behavioral phenotype may begin during history-taking and then be strengthened by observations of the child (Table 22.3). The level of intellectual function of the child or young person (an essential component of the diagnostic framework), combined with specific neuropsychiatric diagnosis, will direct the clinician towards particular investigations. As in so many areas of medicine, knowledge of what phenotypes exist is the essential precondition for their recognition. Only if the Smith–Magenis syndrome phenotype is part of a clinician’s diagnostic vocabulary will the self-injuring and sleepless autism spectrum child be quickly and appropriately investigated. Similarly, the disinhibited talkative child with a heart murmur presenting to an ADHD clinic may be recognized as having Williams syndrome, even if the facial dysmorphic features are subtle and would have been missed.

Examination

Although we include details of the neurological examination, we do not propose that all children presenting to mental health services need a full physical and neurological examination.
Table 22.3 Selected syndromes associated with self-injurious/challenging behavior and intellectual disability. (All are rare apart from 22q deletion (1 in 2000) and prevalence data, which are uncertain in most cases, have been omitted – this list comprises the “more common” top 10). Physical, behavioral and genetic information has been kept to a minimum to act as an aide-memoire without replacing any of the larger pre-existing texts and electronic databases. CHAPTER 22

This would not be supported by the available evidence, particularly in children with no intellectual impairment presenting with common emotional and behavioral problems. Much of the time a detailed examination will have been carried out previously and, unlike the history, we do not feel this always needs repeating. There are obviously certain aspects of the history, behavior or psychiatric diagnosis that may trigger specific examinations or investigations, and these are addressed separately.

General
The main purpose of physical examination in the absence of any specific organic symptoms is to look for evidence of physical abuse and neglect or a specific medical diagnosis. The general inspection is usually closely followed by a skin inspection looking for bruises and birthmarks. In older children the examination needs also to identify any signs of drug use including needle tracks, abscesses or hyperpigmentation on the arms. In those children with any degree of intellectual disability or intellectual disability, a systematic look for more dysmorphic features, including an inspection of the genitalia, may be required.

The height and weight should be plotted on appropriate centile charts. It is usually the trajectory that matters more than any one absolute measurement. Here again the parent-held record, where available, may contain earlier measurements for comparison. Changing trends and markedly discrepant weights for heights may be relevant for disorders such as Marfan syndrome, anorexia, the obesity of Prader–Willi and the adverse effects of some medications. Obesity in childhood is increasingly common and itself has major health implications. It could be a contraindication to some medications (e.g., risperidone). For some conditions, specialized growth charts are available (e.g., for children with Down syndrome) and are more informative.

There are no studies considering the impact of routine cardiovascular examination for children with mental health problems. Significant cardiac problems usually present early in life. In the absence of cardiac symptoms there is little justification for a full examination of pulses, heart sounds and blood pressure. Innocent murmurs are common in children, particularly in potentially stressful environments. In general, innocent murmurs will be asymptomatic, soft, early systolic and change with position. Pathological murmurs are more likely to be loud, symptomatic and continuous. If in any doubt a referral to a cardiologist is appropriate.

Certain medications should be monitored with regular recording of blood pressure and pulse rate from the baseline measurement. In such situations, blood pressure testing is important but the examiner needs to remember to use a cuff that covers two-thirds distance elbow to shoulder, and then interpret blood pressure with reference to age-appropriate normative values. An electrocardiogram (ECG) is indicated before starting some medications (e.g., tricyclics) but not as a routine.

Symptoms of abdominal pain or constipation should prompt abdominal examination. A distended abdomen with palpable stools suggests a degree of constipation that is capable of causing significant pain and changes in mood and can be treated. The routine examination of vision and hearing in the child mental health setting is unlikely to be worthwhile, and has considerable potential to yield harmful false positive and false negative results (Hall & Elliman, 2006). We would be guided by parental concerns for visual problems and remember that a family history of eye disorders is often the best indicator that ophthalmological examination is required. Although there continues to be some debate, the early identification of a squint remains important (Table 22.6).

The additive impairment for any child with mental health problems of an unrecognized conductive or sensorineural hearing loss has already been discussed. The difficulty is that without the right expertise, equipment and environment there is little value in attempting hearing screening and we therefore encourage a very low threshold for referral to pediatric audiology services.

In the group of children who have problems communicating their symptoms, and where reasons for particular behaviors or changes in behavior are being sought (often those with intellectual disability and autism), a thorough physical examination becomes very important. Physical problems as straightforward as a tooth abscess, constipation or ear infections can all present with complex changes in behavior (often increased self-injury) in children with intellectual disability. Examination may have to be undertaken under sedation in a hospital in order to be certain that a physical pain does not underlie behaviors or to ensure that behaviors such as self-injury have not resulted in damage. Examples from the authors’ personal experience include gastroesophageal reflux and chronic constipation as causes of challenging behavior and retinal detachment resulting from self-injury: all requiring sedated investigation in older teenagers with severe intellectual disability, autism and challenging behavior.

Dysmorphology
Much has been written about the recognition of facial dysmorphology. The advent of sophisticated electronic dysmorphology databases, while helpful, in no way replaces the opinion of experienced clinical geneticists. For many non-geneticists, the clinical history, examination and behavioral phenotype should precede and strongly influence the likelihood of attributing significance to facial features.

As in all aspects of examination, height, weight and head circumference are an important place to start. In genetic terms, these may act as pointers to many underlying conditions such as Sotos syndrome (large head, tall and often outbursts of challenging behaviors), XXX, XXY and XYY syndromes (tall, accompanying behavior and language problems) and Turner syndrome (XO) (girls with small stature and sometimes autism spectrum; see chapter 24).

The study of what is worthwhile remains the focus of our discussion, and congenital minor malformations (e.g., a pre-auricular skin tag, short fifth finger, sacral dimple, webbing of skin between toes) are a good example. Single minor
malformations are not a marker for occult major malformations. However, one-quarter of infants with three or more minor malformations will have a major malformation (Leppig, Werler, Cann et al., 1987). Of these, around 15% will involve the CNS. Finding one major malformation (e.g., history of repaired cleft palate) in an adolescent presenting with psychosis should lead to the search for another major malformation such as congenital heart disease and a request for testing for abnormality in chromosome 22q11.

The surface skin features of tuberous sclerosis and neurofibromatosis are important, but again clues in the history will indicate the need for assessment. A child with developmental delay, autism and seizures should have a thorough examination including use of a Wood’s light to highlight the “ash-leaf” depigmented areas. Parents (and child) will usually remember whether this has been performed and, unless it was a long time ago, it should not need repeating within a mental health clinic. If there has been no such prior examination, the decision of individual child mental health professionals whether to examine themselves or refer will depend on their confidence and experience and facilities available. The possibility of falsely reassuring or falsely worrying a family exists with physical signs, just as with investigations.

Genital physical examination in the mental health setting can be important for conditions such as Prader–Willi syndrome and fragile X, both of which can present with behaviors that may present for the first time to child mental health services (see chapter 24). However, there is no evidence to support doing this routinely without good suspicion, and in fragile X syndrome this is of little help in the prepubertal child.

Table 22.4 summarizes some features of syndromes in children presenting to mental health services. We would suggest all such examinations should take place at the end of a general process of observation and gradual physical examination, and end with the vest and pants off. During this time, in addition to parents’ or carers’ verbal consent, we would wish to have the child’s assent and to respect their autonomy and privacy at all times.

**Neurological examination**

Despite the ordered precision suggested by proforma, the value of opportunistic observation cannot be overemphasized. The examination starts when the child walks towards the consulting room, climbs the stairs, manipulates the toys, gets up and down from the floor and sits in and out of chairs and talks – listen for speech abnormalities that may indicate neurological problems such as dysarthria. For a very young child, the physical examination is usually a confirmation of what has already been observed. Many movement disorders are diagnosed by the time the child has risen from a chair, walked across the room, turned round and walked back. Standing on tip-toes, hopping and walking heel-toe and on the outer edge.
Severe behavior disturbance, sleep problems

### Table 22.5

Measurement of head circumference, which has already been discussed in the context of genetic disorders, is also an important part of the neurological examination. It needs to be accurately measured (best of three if possible) and then accurately plotted on an appropriate centile chart. It often reduces anxiety for the child if the parents’ head circumferences are measured first, and this is anyway a necessary step. The most common cause of large and small heads is simply familial, and thus a comparison of midparental head centiles should precede interpretation of any single measurement. It is important to remember that even acceleration in head growth with genotype crossing in the early years can still be familial and not to remember that any examination of a child’s gait includes an observation of how naturally the arms swing. A subtle hemiplegic cerebral palsy may well only be apparent on hopping, or observation of less spontaneous movements, or of flexed posturing of the arm on the affected side. Although some children do toe-walk normally (and often as a familial trait), it is more often seen in autism and can also be a sign of increased tone, or associated with contractures. A wide-based gait can again be simple immaturity, but raises suspicions about hypotonia or cerebellar problems. Children with neuromuscular problems such as Duchenne muscular dystrophy may present with learning or language difficulties before their motor signs become obvious. They should be observed rising from a chair and getting up from lying on the floor for signs of proximal muscle weakness. Look at the spine if there is any concern about asymmetry of movement or posture, a tuft of hair and pes cavus suggesting a hidden spinal lesion. Look for wasting in muscle groups (e.g., the calf in peroneal muscular atrophy).

Obvious dysmorphic features of the face have been discussed above. Mobility and strength may not be obviously affected in congenital hemiplegia but are in bilateral cerebral palsy. Limited movement plus dribbling, oromotor impairment and no speech may signal upper motor signs (e.g., perisylvian syndromes such as Worster–Drought syndrome; Clark, Carr, Reilly et al., 2000).

Neurological Motor Examination – A Rough Guide

Assessing Stance and Gait
Ask the child to stand still with eyes open then shut.
• Unsteadiness with eyes closed may indicate a sensory loss–posterior column (positive Romberg sign), peripheral neuropathy or vestibular problem (falls to one side consistently). Watch the child walk away from you, turn and walk towards you.
• An ataxic gait is broad-based, unsteadiness is worse on “heel–toe” tightrope walk.
• Hemiparetic gait is with shoulder adducted, elbow flexed, forearm pronated and fingers flexed or fisted, foot plantar flexed, leg internally rotated and knee extended. If subtle, you may need to “stress” the system by asking the child to hop on each leg in turn.
• In a diplegic gait the legs scissor and may be crouched.
• A high-stepping slapping gait is typical of peripheral neuropathy.

Ask the child to walk on their heels (difficult if foot extensor or calf muscles are short or spastic), on toes and on the outside of incured feet (Fog test).
• These walking tests assess associated movements (e.g., arm flexion, curling of both hands and fingers) which are normal up to 9 years. This is principally a test of neurological maturity, but marked asymmetry is abnormal.
Ask child to get up from floor as an easy test of proximal muscle power.
• Gower’s test for weakness is positive if child has to climb up his or her own legs. This is abnormal and seen in muscle disease (e.g., Duchenne muscular dystrophy).

Tests for Cerebellar Function
Ask the child to reach with either hand to touch your finger and then return to touch their nose. Move your target finger to “stress” the system and ensure the need for the child to stretch a little.
• Past pointing and poor co-ordination may indicate cerebellar abnormality.

General observations
• Fasciculations (quivering under the skin) can signal neuromuscular disease.
• Tics are involuntary contractions in single or groups of muscles, repetitive and stereotyped.
• Myoclonus is a brief jerk in a muscle.
• Dystonia is a contraction, longer than myoclonus, resulting in spasm.
• Athetosis is spasms of writhing character, chorea is sinuous movements affecting multiple, usually distal joints.
• Hemiballismus – violent flinging movements of half the body.
• Static or intention tremors – these can signal cerebellar origin but also can be familial or due to medication.

Tone, Power and Reflexes
At the end of the above you may wish more formally to test tone, power and peripheral reflexes. If in doubt, refer.

Child Abuse Including Factitious Illness

Childhood abuse and childhood sexual abuse can present with a wide range of symptoms and signs, most of which are not, on their own, pathognomonic of abuse (see chapters 28 & 29). Psychiatric presentations can be subtle and varied including child regression, dementia-like symptoms and conversion behaviors. It is the combination, context and corroboration of information from multiprofessional opinion that usually result in successful identification and prevention of further abuse (Larcher, 2004). Specialist training is usually required as even the more obvious physical signs, including bruise types, bites and burns, can be missed unless some specific training has taken place (increasingly commonly mandatory for health care professionals). A search for more subtle signs, genital examinations and invasive procedures should take place on as few occasions as possible, preferably by an experienced team which will often include forensic expertise, police and social service support (Kellogg et al., 2005).

Münchausen syndrome by proxy (or factitious illness) forms an important and increasingly commonly recognized part of the spectrum of child abuse. Many children who are victims of factitious illness have long-term morbidity resulting from the attacks themselves or complications from the medical procedures that ensue. Virtually all have serious psychological sequelae from this form of abuse. It is said that parents who act as perpetrators in these cases often seem particularly close with the medical staff, eliciting their sympathies, and seem very eager to pursue invasive and in-patient testing for their child. Given that so much of the morbidity resulting from this condition occurs in hospitals and at the hands of the treating pediatrician or mental health professional, it is essential to consider the possibility of factitious illness in the differential diagnosis as early as possible.

Standard toxicology studies are often inadequate for detecting poisons that perpetrators give; examples include tricyclic antidepressant abuse in cases of CNS depression, and warfarin in apparent coagulopathies (Galvin, Newton, & Vandeven, 2005). It is worth measuring blood levels if a child is on medications (e.g., antiepileptics or antidepressants) as toxic levels may be causing the presenting symptoms.

Given that these children are very likely to have received care from multiple hospitals and doctors, records from all professionals need to be meticulously kept and shared if required. As in all subgroups of child abuse, the use of a multidisciplinary team (including pediatricians, social workers, the child protection team and often the police) is essential for these cases (Working Party of the RCPCH, 2002).

Investigations

Unfortunately, the attraction of newer technologies often overtakes the need for a robust evaluation of a test in a representative and controlled large-scale study. Few investigations have undergone any analysis of sensitivity or specificity in truly representative clinical populations and control groups. As

with history and examination, the same standard of requiring a test to be available, affordable, accurate and precise exists. Knowledge of pre-test probabilities and likelihood ratios will help determine the potential for any particular investigation to affect management.

The potential to discover a treatable condition or one that will inform future family reproductive decisions remains the most important reason to pursue testing. Other potential benefits and drawbacks of testing are summarized in Table 22.7.

Harm From Testing
Anyone who has been faced with children with developmental delay will acknowledge that for some parents the need to know is great, and therefore any investigation that may “tell us something” has to be a good thing; but if it tells us the wrong thing then it is clearly not a good thing. False positives and false negatives occur all the time, and the more investigations carried out per child, the more chance of unearthing a “borderline” result that simply worries parents and causes the child to be subject to more unnecessary tests. False positive genetic tests for fragile X when cytogenetic techniques were used affected extended families, who may have been subjected to needless screening (Gringras & Barnicoat, 1998). Furthermore, the process of blood tests, electroencephalogram (EEG) and scans can be aversive for some children (and parents).

Numbers Needed to Test
In evidence-based medicine we have found the concept of “number needed to test” in order to find one positive result that will affect management, helpful in this regard. The calculation is not too difficult but crucially depends on the prevalence of the condition in the population being tested. In some countries, if HIV testing were advocated for every child presenting with unexplained neuropsychiatric symptoms, the number needed to test would be high; in others low enough to make routine testing worthwhile. Examples exist even on a national level where in certain locations screening for lead is important and should be part of every guideline, while in other areas it would be an expensive investigation that would yield too few positive results.

Economics
It is clear that no health system will be able to sustain an approach of carrying out every test available on every child with intellectual disability or neuropsychiatric problems, regardless of cost or impact on the child. It is increasingly clear that economic considerations will affect thresholds for investigations, between countries, regions and even individual units.

Current Testing Schema
When evidence-based methods are employed, the results tend to support fewer rather than more investigations. To improve yield, investigations need to be tailored to individual populations. It is likely that a stepwise approach is effective but this needs further evaluation. If it is certain that cerebral imaging (computed tomography [CT] or magnetic resonance imaging [MRI]) will need to take place, then we would suggest performing them first as they may give enough diagnostic clarity to avoid the need for subsequent tests.

Cerebral Imaging
The decision of what cerebral imaging and when is far from easy. While, for example, MRI scans give a higher yield than CT scans, the debate is still open on whether they are worthwhile. In one study, 224 MRI scans were carried out in children with developmental delay and other problems (Bouhadiba, Dacher, Monroc et al., 2000). A retrospective analysis of clinical findings and diagnostic yield found abnormalities in 109 cases, but none that resulted in any patient care modification. In some cases it was even unclear whether they represented normal variants or true abnormalities.

Cerebral or cerebellar dysgenesis is usually the most common diagnostic category in these children, and while we do not know what causes this, it implies a prenatal event which
should then usefully limit further laboratory investigations for acquired or metabolic causes (Shevell, Majnemer, Rosenbaum et al., 2001). In rarer cases, MRI studies can show a characteristic signature for metabolic, neurocutaneous and degenerative disorders and can even give enough information to direct subsequent genetic testing.

Attractive new technologies are constantly evolving, with functional and diffusion tensor imaging techniques currently exciting the research world. Despite their promise, they still lack any of the robust validation work in representative populations that we would suggest is prerequisite to considering their routine clinical use (see chapter 11).

Genetic Investigations

Genetic investigations continue at an astonishing pace. Many useful reviews have been written to summarize the role of genetic investigations for children with developmental delays (Pollowski, 2003). High-resolution chromosome banding still remains important for many children with intellectual disability. Specific molecular genetic tests – fMRI studies for fragile X syndrome, MECP2 for Rett syndrome and fluorescent in-situ hybridisation (FISH) 22q11.2 studies for velocardiofacial syndrome – can confirm specific diagnoses with known natural histories and heritabilities.

Although limited by cost and time, subtelomere fluorescent in situ hybridisation (FISH) is receiving increasing support as a routine investigation in children with intellectual disability. Some studies report such chromosome subtelomere rearrangements occurring with a frequency of 7–10% in children with mild to moderate intellectual disability, and approximately 50% of cases are familial (Dawson, Putnam, Schultz et al., 2002). Positive results from this investigation are eight times more likely than fragile X in some intellectually disabled populations.

Uniparental disomy – in which both copies of a chromosome pair or region are inherited from only one parent – is well known in the context of chromosome 15 in Angelman and Prader–Willi syndromes, and is now recognized to affect many more chromosomes with resultant physical and neurological problems. Newer and cheaper methods for genetic investigations include multiplex ligation-dependent probe amplification (MLPA). They suggest that genetic investigations will increasingly contribute towards the investigation and understanding of these children (see chapter 24).

Metabolic Investigations

The range of metabolic conditions that can be relatively easily detected, even at birth, has dramatically increased. However, there is still debate about the yield of such testing.

The most important principle in later detection of metabolic disorders is that there are clues in the history that greatly alter the pre-test probability of detecting a metabolic disorder. Key pointers in the clinical history include consanguinity, failure to thrive and episodic decompensations (often during minor illnesses). Examination findings may include coarse facial features or hepatosplenomegaly. Although the yield of metabolic testing across population studies is lower than that of MRI scans and genetic testing, the debate is not quite that simple. Metabolic screening if positive is more likely to offer a treatment possibility or recurrence information than most other investigations, and may therefore be more worthwhile (Papavasiliou, Bazigou, Paraskewoulakos et al., 2000).

The authors recommend watching this area with interest, but would not recommend metabolic testing for children presenting to CAMHS unless strongly indicated by any of the above clinical clues.

Electroencephalography

The EEG examination is most commonly used as an adjunct to the diagnosis and management of epilepsy. An EEG should be carried out to support a diagnosis of epilepsy and is usually recommended after the second epileptic seizure and in certain circumstances after the first (see chapter 17). An EEG is unhelpful and not indicated if the clinical presentation suggests a non-epileptic event, and an EEG should never be used in isolation to make a diagnosis of epilepsy. Where a standard EEG has not contributed to the diagnosis or classification of the epilepsy, a sleep EEG (under sleep-deprived conditions, which enhance EEG abnormality, or sleep induced with melatonin) or video or ambulatory EEG may be used. Epileptiform activity (spike, spike–wave complexes and ictal discharges) on the EEG with coincident clinical symptomatology is the hallmark of epilepsy. Identical epileptiform activity known as interictal epileptiform discharges (IEDs), which are not associated with obvious clinical phenomena, also occur. In some studies they have been associated with altered performance on a variety of cognitive and memory tasks carried out during awake EEGs. However, their significance remains uncertain. A review of IEDs suggested that “although they can have an additional and independent effect, this is mild” (Aldenkamp & Arends, 2004).

The finding of abnormality in the EEG in otherwise normal people who have never had an epileptic seizure is common. In one study of 60 healthy student volunteers screened for neurological disorder, only 6.7% did not show any transient “abnormality” in a whole night’s sleep recording of the EEG. Abnormalities were mainly sharp but also spike-like activity (Beun, van Emde Boas, & Dekker, 1998).

Many previous uses of EEG, such as the diagnosis of brain tumors, have been superseded by both CT and MRI neuro-imaging. However, there are rarer examples of an EEG study helping in non-seizure-related diagnoses. These include children presenting with the characteristic physical and behavioral phenotype of Angelman syndrome, who often have characteristic EEG changes that may precede seizures and support the diagnosis. The investigation of developmental regression can be supported by identifying the distinctive patterns of periodic discharges in subacute sclerosing panencephalitis and Creutzfeldt–Jakob disease. The EEG can aid diagnosis in both infective (herpes simplex) and non-infective (Hashimoto) causes of encephalitis, and a diffuse slowing pattern is a hallmark of some metabolic encephalopathies and can be used to track progress. Finally, the EEG is often employed...
in presentations with coma, but interpretation is complex with marked variations dependent on cause.

Specific Clinical Scenarios

The Child with Developmental Delay

In the relatively uncommon scenario in which a detailed history and thorough examination have yielded no clues, there is a debated “minimum” raft of investigations for a child with moderate to severe delay. The outcome of this debate is the fact that even similarly trained UK pediatricians, when confronted with exactly the same hypothetical case scenario of a child with developmental delay, varied widely in the type (26 different investigations) and the number of investigations in combination they would perform (0–15) (Gringras, 1998).

Developmental Delay without Motor Signs

One larger study separated children with developmental delay into subtypes with global delay, motor delay, developmental language delay and autistic spectrum disorders (Majnemer & Shevell, 1995). The etiological yield varied across these delay subtypes: 55% for global developmental delay, 59.1% for motor delay, 4.2% for developmental language disorders and 2% for autistic spectrum disorders. Thus, the subtype of delay is important, and the yield is lowest in those children with “pure” language disorders or autism.

On most lists therefore, the investigations would appear as in Table 22.8, but even these are open to debate, as is the order we have suggested performing them.

Developmental Delay with Motor Signs

The reader is referred to the neurological examination section (see p. 327). The likelihood of an underlying cause in this group of children is much higher, and thus examination is worthwhile. In most cases, an early referral will be appropriate if the child is not already known to pediatric neurology services. There are both treatment and important genetic implications for diagnoses such as Duchenne muscular dystrophy. Simpletics need differentiating from choreoathetoid movements but for diagnoses such as Duchenne muscular dystrophy. Wilson disease and Friedreich ataxia are extremely rare, even in pediatric neurology clinics. Huntington chorea is also rare, but the child can often present with behavioral issues, long before motor problems are identified.

The Child with Delayed/Impaired Speech and Language

Delayed speech and language development is common and usually part of normal developmental variation, or associated with intellectual disability, in which case investigation follows the developmental delay protocol above but with a low threshold for requesting chromosome analysis to look for sex chromosome abnormalities. Hearing assessment is obviously crucial to exclude deafness, but thereafter cases are often divided into those with severe receptive language impairment and those with speech and articulation impairments. The former may benefit from a sleep EEG to exclude Landau-Kleffner syndrome if the clinician is confident of any regression beyond the first 10-word stage and there is marked fluctuation of language skills. However, in the case where a child has not reached a 10-word stage and presents with an autistic phenotype an EEG is not informative.

For the group with speech and articulation impairment, the presence of symptoms and signs of oromotor involvement such as dribbling, chewing problems or palatal insufficiency is important. Abnormalities on neurological examination may suggest Worster-Drought syndrome and prompt an MRI brain scan looking for perisylvian abnormalities (Clark et al., 2000). Palatal abnormalities should lead to consideration of genetic causes such as 22q deletion. Medical investigations are unlikely to be helpful in the absence of the above signs or symptoms.

The Child with a Possible Seizure

The prevalence of epilepsy in the UK is 0.5% in children, with 1 in 2000 children developing epilepsy each year. The National Child Development Study (Ross, Peckham, West et al., 1980) found that 0.7% of all children had at least one episode of altered consciousness in their lifetime, and nearly 40% of those children had other paroxysmal episodes. The differential diagnosis of a first seizure is wide. The important factor to remember about epilepsy is that in studies of either adults or children, 10–40% are wrongly diagnosed with epilepsy. Recently, the National Centre for Clinical Excellence (NICE) in the UK produced recommendations for practice (NICE, 2004). The main recommendation is that confirmation of a diagnosis of epilepsy should be made in children by a pediatrician with specialist training and expertise in epilepsy who can undertake further investigations. In addition to the importance of an extremely good description, by somebody who has seen an episode, the increased availability of home videos has been very helpful. Together these will often allow accurate diagnostic classification and diagnosis of the type of epilepsy syndrome. For most psychiatrists the appropriate course of action would be to refer to the pediatrician rather than undertaking further investigation themselves.

The mental health professional may, however, find themselves in the position of management of young people with epilepsy taking antiepileptic drugs (AEDs) who may or may not have additional learning and neuropsychiatric problems. The clinician should bear in mind the need for someone to

review the requirement for and dose of AEDs (which may exacerbate or reduce behaviors), a protocol for emergency treatment in the community for those prone to prolonged or repeated seizures, the possible interaction with oral contraceptives in girls and the risks of particular medications in pregnancy (see chapter 30).

Neuroimaging with MRI is recommended to identify structural abnormalities causing epilepsy, especially in those under 2 years, where there is any suggestion of focal epilepsy, or in those where epilepsy persists despite medication treatment.

Differently sited focal epileptic activity of continuous spike–waves during sleep (CSWS) may be related to varying neuropsychological deficits in a spectrum of childhood encephalopathies with or without overt seizures (e.g., language regression syndromes such as Landau–Kleffner syndrome), cognitive regression with occipital discharges and benign Rolandic epilepsy (a common benign epilepsy with centrotemporal spikes). Support for a causative role of the epileptic discharges in causing the language regression is suggested by the start of language recovery when the sleep abnormalities disappear (Robinson, Baird, Robinson et al., 2001; Wilson, Djukic, Shinnar et al., 2003). Knowledge of the possibility of such epileptic phenomena will alert the clinician to a story of fluctuating cognitive and behavioral manifestations and prompt referral to the pediatric neurologist or pediatric epilepsy specialist.

**The Child with Regression**

Parents will occasionally report a loss of skills and this always needs taking very seriously. The difficulty often arises in deciding what may be developmental plateauing in a child whose peers have started to accelerate in one or another domain. Altered function is a feature of many other ordinary life experiences including change of school and family domestic upheaval. History and examination, including type of developmental neuropsychiatric diagnosis and whether the regression is progressive or has plateaued, help guide further investigation. There should be a low threshold for onward referral, particularly if the regression is accompanied by epilepsy or abnormal neurological findings.

Causes of regression are often grouped either by age of presentation or pattern of clinical features. Children with white matter disease are more likely to present with focal neurological deficits, spasticity and blindness, whereas those with gray matter disease initially present with seizures, personality change and dementia. If the peripheral nervous system is also involved, mitochondrial and lysosomal disorders are more likely. The presence of other organ involvement again suggests mitochondrial and lysosomal, and also peroxisomal disorders.

Detailed description of the causes and investigations for regression are the remit of pediatric neurology textbooks. We have chosen just a few salient examples to illustrate the range of causes and subtle differences in presentation.

In many countries human immunodeficiency virus (HIV) infections are becoming an important cause of regression, with neurological and neuropsychiatric manifestations usually present in the first 3 years of life (see chapter 58). These include loss of developmental milestones, loss of cognitive abilities and progressive, often symmetrical, motor deficits with ataxia and eventual spasticity. This presentation can be subtle or delayed, particularly if children are on retroviral medications.

Parents of a proportion (15–30% in varying series) of children with autism report language regression in the second year of life (loss of use of words after 5+ words are established for 3 months; Tuchman & Rapin, 1997). This feature of autism remains a puzzle and has been the subject of investigation without finding any positive results that have effectively influenced treatment. Landau–Kleffner syndrome has been discussed, but it is very rare and most children presenting with language regression under the age of 36 months will have autism (McVicar, Ballaban-Gil, Rapin et al., 2005). In issuing its guidelines, the report of the quality standards committee of the American Neurology Association states that “the relationship between regression early or late in autism and epileptiform discharges or electrical status in slow wave sleep (ESES) remains unclear” (Filipek, Accardo, Ashwal et al., 2000). Our view on the present evidence is that an EEG should be carried out as part of the investigation of clinically suspected epilepsy, not routinely in regression in autism (Baird, Robinson, Boyd et al., 2006). Regression in autism after the age of 36 months is less common, and if there is a 2-year period of normal development it is termed childhood disintegrative disorder (CDD). As the regression frequently involves not only social and communicative and language regression, but also bowel and bladder and cognitive function, investigations are frequently undertaken; but if the diagnosis of CDD is correct and the phenotype that of autism, the yield of investigation is frustratingly low.

A study group focusing on the very rare progressive intellectual and neurological degenerative (PIND) diseases was established to collate data in the UK from May 1997 to October 2005. During the surveillance, over 90 different neurodegenerative conditions were determined. Subacute symptom onset is common and psychiatric presentations— including dysphoria, withdrawal anxiety, insomnia and loss of interest—are not unusual, particularly for degenerative neurological diseases such as the rarer variant Creutzfeldt–Jakob degenerative neurological disease. Children with those conditions will invariably develop signs of neurological dysfunction evident on thorough clinical examination. For example, there may be signs of spastic paraparesis in adrenoleukodystrophy, visual loss in neuronal ceroid lipofuscinosis or extrapyramidal features in Wilson disease. Some diagnostic features, although specific, may be subtle. San Filippo is an example of a condition in which regression can occur with or without autistic symptoms but where signs may be missed. The 10 most commonly reported PIND diagnoses are listed with some basic clinical features in Table 22.9.

**The Child with ADHD**

Routine investigations are not recommended as part of the diagnosis. There have been inconsistent findings in the tests of thyroid function, lead levels, EEG and imaging, and
consequently none are routinely recommended (see chapter 34). A recent review of the value of chromosome tests in ADHD confirms that without other clinical concerns, such as intellectual disability, these should not be routinely performed (Stephen & Kindley, 2006). It is most important to enquire about sleep problems, as interference with sleep can cause symptoms indistinguishable from those of ADHD. Baseline physical examination should focus on height, weight, pulse and blood pressure.

The Child with Autism
The importance of history, checking that hearing and vision have been tested at some stage recently, and more detailed examination has already been discussed. The overall yield in medical investigations is very low when applied routinely (Battaglia & Carey, 2006). We would suggest only fMRI (for fragile X syndrome) and karyotype, and even this is likely to have a low yield unless there are other clinical indications, including intellectual disability. The yield of testing for MECP2, the Rett gene, when assessing children with abnormalities suggestive of the broader phenotype, including learning difficulties and regression, remains to be determined. There is no justification for EEG routinely in autism but the clinician needs to be alert to fluctuant symptoms and regression with suspicion of epilepsy, and should use the EEG only as a clinical tool that contributes to the evaluation of epilepsy. Neuroimaging is worthwhile only when there are specific neurological signs, a focus found on EEG (sometimes) or the triad of severe intellectual disability, autism and epilepsy. There is no evidence to justify routine hair analysis, celiac testing, fungal or immunological tests, lumbar puncture, micronutrients or vitamin measurements, or urinary peptide determination (Battaglia & Carey, 2006).

The Child with Tourette Syndrome
The challenge in most children with tic disorders is to be sure of the diagnosis (see chapter 44). Once again a good clinical history is fundamental to reaching a confident diagnosis. True tics are often accompanied by an urge to carry them out, can be resisted by the child for a while, but then burst out, usually with a feeling of relief. The phenomenon of tic suppression often means that a short clinic visit can pass with no tics seen in all but the most severe of cases. The era of video cameras and even video phones has helped diagnosis greatly. With careful history and observation, there is usually no confusion between tics and other movement disorders such as chorea or dystonia.

The diagnosis of uncomplicated Tourette syndrome should not trigger any further investigations in most situations. Only if there are very atypical symptoms, which go beyond the common fluctuating picture often seen in Tourette syndrome, such as a progressively worsening picture or localizing neurological signs, would we consider referring for a neurological opinion and an appropriate battery of neurological investigations.

The discovery of a streptococcal autoimmune association in certain cases of tic disorder, Tourette syndrome and obsessive-compulsive disorder promised a whole new battery of useful
investigations and treatment options for these disorders. However, rates of streptococcal infections in the general population are high, as are the presence of antibodies to the streptococcus. Some detailed antibody studies have challenged the hypothesis that this population differs from controls in any immunological manner (Singer, Hong, Yoon et al., 2005). This means that we are cautious in recommending the investigation of a child with tics, Tourette or obsessive-compulsive disorder with a view to treating “the PANDAS,” as neither antibiotics, steroids or plasmapheresis have good evidence to support their use, and the latter two carry potential for side-effects (King, 2006).

The Child with Anorexia Nervosa
There are no epidemiological studies that justify investigating these children differently from those with other mental health disorders. However, there are case reports of occasional hypothalamic germin-cell tumors presenting with classic symptoms of anorexia, but these are very uncommon, and we suspect that neurological examination would usually have been revealing (Chipkevitch, 1994). However, this may influence an individual’s threshold for neuroimaging, particularly when faced with a severe, early and atypical presentation.

The value of neuroimaging to monitor the degree of cerebral atrophy is debatable and usually forms part of non-evidence-based protocols. Otherwise, medical work-up depends on the degree of starvation and length of illness, covering the whole spectrum of tests: metabolic, hormonal and bone density.

The Child with Psychosis
Neurobiological studies during the early course of psychoses have shown brain structural alterations that are present early in the illness and may predate symptom onset. Some changes, notably those in frontal and temporal lobes, can progress during the early phases of the illness (Keshavan, Berger, Zipursky et al., 2005). The importance of these findings, however, is less clear. They do not yet alter treatment or prevention options, or inform prognosis accurately.

We are aware that neuroimaging is often “routine” but like many investigations discussed in this chapter, the evidence is lacking and we would question how worthwhile this investigation is. More common basic investigations include urine toxicology screen, thyroid function tests, liver function tests, full blood count and erythrocyte sedimentation rate. Endocrine abnormalities may present with a range of neuropsychiatric symptoms in adolescence. Tests for thyroid and parathyroid function are recommended.

The Child with Fatigue, Chronic Fatigue Syndrome
The Royal College of Pediatrics and Child Health (RCPCH, 2004) has produced evidence-based guidelines for the management of Chronic Fatigue Syndrome/myalgic encephalopathy (CFS/ME). This emphasizes there is no distinct marker for CFS/ME. There are diagnostic criteria, and there is a differential diagnosis of profound fatigue (see chapter 70). A

family history specifically for CFS/ME should be taken; and tests to exclude known physical causes are listed in Table 22.10.

The Child with Abdominal Pain
Recurrent abdominal pain occurs in up to 10–15% of schoolchildren with wide impact on school attendance. Anxiety, mild depression and low self-esteem are common associations. Questioning needs to exclude those with bleeding and use of drugs such as anti-inflammatory agents. In those with bowel symptoms the type of symptom dictates the investigation; for example, frequent diarrhea may lead to stool examination (e.g., for Giardia). In the absence of constipation or diarrhea, recurrent abdominal pain for at least 12 not necessarily consecutive weeks in 12 months, presenting in the mental health clinic with psychiatric symptoms, should prompt consideration of a search for Helicobacter pylori (Nakayama, Horuichi, Kumagai et al., 2006).

The Child with Headaches
Children with headaches present commonly to both pediatric and child mental health services. Chronic headaches are often comorbid with anxiety and depressive disorders and associated with somatization and school problems. Tension-type headache and migraine are the two most common types of headache in children and adolescents. However, classification systems have difficulty in separating tension-type headaches from migraine without aura in children. Although the smaller genetic effect on tension-type headache than on migraine suggests that the two disorders are distinct, many believe that tension-type headache and migraine represent the same pathophysiological spectrum. Novel clinical approaches to identifying the different types of headache have included the use of drawing by the children. These headache drawings were shown to be a simple inexpensive aid in the diagnosis of headache type, with a very high sensitivity, specificity and predictive value for migraine (drawings that contained an artistic feature consistent with migraine, e.g., pounding pain, nausea/vomiting, desire to lie down, periorbital pain,
photophobia, visual scotoma) versus non-migraine headaches (Stafstrom, Rostasy, & Minster, 2002).

Headaches are diagnosed clinically rather than by any specific testing (Lewis, Ashwal, Dahl et al., 2002). Parents are often concerned about the possibility of underlying brain pathology, but most can be reassured on the basis of history and examination. On history-taking the high-risk group are those headaches that have been present less than 6 months and have one other predictor from a list that includes sleep disturbing headaches, vomiting, abnormal neurological examination, seizures and a total absence of any family history of headaches or migraines. In those children where a treatable intracranial lesion was found to be responsible for the headache, the neurological examination was abnormal either because of papilledema, eye movement abnormalities or motor or gait dysfunction (Lewis & Dorbad, 2000).

The routine use of any diagnostic studies for headaches, including neuroimaging, is therefore not indicated when the clinical history is without associated risk factors and the child’s examination is normal.

In a review of the presenting features of 200 cases of brain tumors in children, the most common symptom was headache. However, new onset visual, educational and behavioral symptoms (notably lethargy) were also prominent; additional symptoms were present at some stage; and 88% had neurological signs on examination (Wilne, Ferris, Nathwani et al., 2006).

Conclusions

Organic physical disorders may cause, exacerbate or be associated with mental health symptoms in any child presenting to CAMHS. Many of these conditions may be treatable, and many may give important prognostic and recurrence risk information. Children with an intellectual disability and seizures need particular consideration, as the phenomenon of “overshadowing” can lead to both overlooked psychiatric diagnoses and missed physical and genetic diagnoses. The harm from false positive and false negative diagnoses, as well as economic and ethical testing considerations, should guide our choice of investigations at all times. We know that the evidence appraised in this chapter will rapidly become out of date but hope that we have provided a framework for the busy clinician to appraise any newer evidence and apply it to their own practice. The general principles of knowing when to stop investigating and reassure, and when to refer, will remain valid.

Influences on Psychopathology
Genetic research and knowledge across medicine and science are advancing very rapidly. This process is being facilitated both by enormous advances in technology and a progressive integration of genetics with other areas of research. Despite its seeming complexity, the goal of psychiatric genetics research is essentially that of delineating the causal processes that lead to disease or disorder. The two main approaches and types of study design used in psychiatric genetics generate different kinds of results. First, there are studies that essentially focus on the degree of resemblance among relatives for a given disorder or characteristic. The study of individuals who differ in their degree of genetic relatedness (using family, twin and adoption designs) allows influences regarding the strength of genetic contributions to the liability for disorder to be inferred. Such research is now moving well beyond assessments of heritability in order to tackle important questions on causal mechanisms.

The second type of genetic design focuses at the molecular level on specific genes identified through laboratory methods. The most dramatic successes to date have been with single gene disorders (autosomal dominant, autosomal recessive or sex-linked disorders; see chapter 24) such as Huntington disease and cystic fibrosis, in which there is a direct connection between one gene or gene anomaly and a disorder. These conditions are important but rare. This success has been a major driving force for the next challenge of identifying genetic risk factors for complex disorders such as cardiovascular disease and psychiatric disorders, which represent the major global burdens of disease. In these conditions, multiple genes and environmental risk factors co-act and interact in a probabilistic rather than deterministic fashion. In recent years there have been some notable successes in identifying risk genes for these types of common, complex disorders notably Alzheimer disease, asthma, macular degeneration, schizophrenia and attention deficit/hyperactivity disorder (ADHD). However, identifying susceptibility genes is only the start. What is especially exciting about this field for clinicians working in child psychiatry services is the increasing focus on potential causal chain mechanisms that lead from genetic risk to disorder, with emerging evidence for a dynamic interplay between genes and environment (Kendler & Prescott, 2006; Rutter, 2006).

Enthusiasm about the importance and potential impact of genetics is sometimes tempered by caution or suspicion because of the previous history of the appalling misuse of genetics for political ends. There are also, quite rightly, a number of ethical issues that need careful consideration (Nuffield Council on Bioethics, 1998). However, much of the concerns over potential misuse have stemmed from misconceptions about how nature and nurture operate. In this chapter, we set out to address the key issues in genetics that are of relevance to psychopathology. We also include brief descriptions of the methods used and what is known about the science of genetics. We hope to impart to clinicians an appreciation of what genetics research can and cannot tell us and to enable them to interpret new findings in this field. Specific genetic findings are covered in the relevant chapters for each disorder.

What is a Gene and How Does it Work?

The Gene at a Molecular Level

A gene is a unit of inheritance that is made up of a stretch of DNA, more specifically a sequence of molecules called nucleotides. There are four of these nucleotides: guanine (G), cytosine (C), adenine (A) and thymine (T). The inheritance “code” encrypted in genes essentially lies in the sequence of these nucleotides. The human genome, as well as containing genes, mainly consists of non-coding sequences of nucleotides. The physical locations of these are referred to as loci. This sequence in genes and non-coding regions varies across individuals in the population but not as much as one would think. In fact, around 99% of the DNA sequence is common to all humans. However, for clinical research purposes, it is the variation that we are interested in (see p. 344). This individual variation provides genetic markers (variants or polymorphisms) across the genome, which are used to identify disease susceptibility loci. Although most of the sequence in the human genome appears to be non-coding, there is increasing interest in these non-coding regions. Recent evidence suggests that these regions are not simply redundant “junk” DNA as previously thought, but significantly contribute to human variation in different ways (e.g., by regulating and modifying the pathway from gene to protein). In other words, genes that do not code for proteins may influence the effects of those
that do through their influence on gene transcription and gene expression (Castillo-Davis, 2005). The traditional notion that there is one gene for each protein effect is misleading in so far as multiple inherited DNA elements are involved in the processes leading to gene expression.

Genes and non-coding sequences of DNA lie on chromosomes, which have a short arm (known as p), a long arm (q) and a centromere (c) in the middle (Fig. 23.1). Each chromosome is one of a pair and humans possess 46 chromosomes, of which 22 pairs are known as autosomes and 1 pair consist of the sex chromosomes (XX for females, XY for males; see chapter 24). The autosomes are numbered 1–22. To describe the physical location of a locus on a chromosome, the number of the chromosome is followed by the arm on which the gene is situated and then a number to indicate where on the arm the gene/marker is located. For example, the gene coding for the enzyme catecholamine-O-methyltransferase (COMT), involved in the breakdown of the neurotransmitters dopamine, noradrenaline and adrenaline, is located on chromosome 22q11.

Alternative forms of a gene (or non-coding) variant are known as alleles. As each chromosome is one of a pair (excepting sex chromosomes in males, who have one X and one Y chromosome), an individual possesses two alleles for a given gene (Fig. 23.1). The description of these two alleles is known as a genotype. Thus, at locus A, if there are two alleles called 1 and 2, an individual with two copies of allele 1 is said to have a genotype of 1,1.

Genes code for proteins; thus, the term gene “for” a particular disorder is misleading. The processes and pathways leading from gene to protein to brain function and structure and then to phenotype are complex. Within each gene, there are also coding and non-coding sequences known as exons and introns, respectively. The coding encrypted in the gene DNA sequence is first “read” and copied into messenger RNA (transcription). Then, sections of sequence are taken out (spliced) and the mRNA code is “read” and this message brings together the sequence of amino acids specified by the code (translation). These amino acids, of which there are a variety, are the building blocks of proteins. The genetic code is encrypted in such a way that a sequence of three nucleotides (e.g., CAG) codes for a specific type of amino acid (e.g., valine; Fig. 23.2). This provides a basic description of how a gene codes for a protein. It is now being realized that the process is far more complex than this (see p. 342). We provide some illustrations of this complexity and new research will undoubtedly continue to change current thinking.

How is knowledge about gene expression currently being applied in psychiatry and child psychiatry? Examining mRNA expression in vitro or in animal brains is used to test whether specific gene variants of interest (e.g., those that have been found to be associated with schizophrenia) are functional; that is, whether or not the variation results in changes to proteins. This provides one initial clue that the variant might be a causal risk factor. For example, a variant in the gene encoding the serotonin transporter (an enzyme involved in the reuptake of serotonin in the synaptic cleft) was found to have an effect on expression of this protein, thereby potentially affecting serotonin levels in the brain. A particular form of this variant has been suggested to be associated with an increased risk of depression when the individual is also exposed to life events (Caspi, McClay, Moffitt et al., 2002).

There is also increasing research focusing on investigating gene expression patterns in different regions in the brain (in human postmortem brains where the individual has a specific psychiatric disorder, in animal models of psychiatric disorder
or in animals where the focus is on examining normal traits). Here the aims are to examine how already identified gene variants might exert risk effects on disorders and identify some of the biological processes involved in the disorder to provide clues about which genes to examine in humans affected by psychiatric disorder and provide some insight into whether an associated gene is actually involved in the pathogenesis of the disorder.

Gene activity/expression is a complex process (Fig. 23.3), regulated by inherited genetic factors and mechanisms, non-inherited genetic mechanisms (epigenetics), endogenous biological factors such as hormones (e.g., stress hormones and sex hormones) and environmental factors operating externally to the individual organism (e.g., toxins, psychosocial stress).

Inherited Genetic Factors Affecting Gene Expression
Gene activity and thus protein manufacture is known to be regulated by non-coding regions of the genome. Some of these regulatory regions have been found near the gene in question; these are known as cis modulators (e.g., promoter regions that are sequences found at the beginning of a gene; Fig. 23.2); and also, more surprisingly, in regions that are not near the gene being regulated, known as trans modulators. The switching on and off and regulation of genes are not only crucial in development, but occur throughout the lifespan and provide an important means by which organisms adapt to changing environmental circumstances and so evolve. One well-known example is the gene coding for the enzyme involved in the breakdown of lactose. In many ethnic groups this gene (and thus the enzyme activity it regulates) is commonly switched off after childhood (when milk is no longer the main source of nutrition), resulting in poor tolerance to milk in adulthood. There is increasing interest in the possibility that such regulatory regions have an important role in psychiatric disorders. This is because many susceptibility gene variants do not appear to encode protein changes, whereas regulatory regions do affect protein function.

Parent-of-Origin Effects
An interesting example of non-inherited genetic influences on gene activity is the process of imprinting (see chapter 24). Here, gene expression depends on which parent the gene is inherited from, whereby one of two inherited alleles (maternal or paternal) is silenced. It is thought that imprinted genes are important in the “battle of the sexes” whereby, in evolutionary terms, paternal genes “compete” with those inherited from mother. This “battle” refers to the evolutionary advantage for a male to increase prenatal nutritional resources for his own offspring, whereas for the mother there are advantages in sharing out resources amongst all her offspring, regardless of their paternal origins. For example, imprinted genes appear to contribute to fetal and postnatal growth, with genes of paternal origin tending to increase nutritional resources being taken from the mother and genes of maternal origin reducing the demand for maternal resources. These parent-of-origin effects have been found to contribute to disorders such as Prader–Willi syndrome. However, there is increasing evidence that such influences may also be relevant in psychiatric and other complex disorders and contribute to gender differences in behavior (for examples see chapter 24).
Environmental Influences on Gene Expression

Environmental influences interplay with genetic risk factors (Fig. 23.3) at an observable phenotypic level (see p. 343) and also have an important effect on gene activity at a cellular level. Animal studies demonstrate that exposure to early specific environmental conditions influences health and characteristics in animals through non-inherited effects on gene activity. For example, maternal caregiving behavior early in life, notably high levels of licking and grooming of rat pups, has an effect on brain glucocorticoid receptor expression and sensitivity to stress in the offspring (Meaney & Szyf, 2005). This effect is observable even when non-genetically related pups are fostered to low-licking mothers and appears to be a type of early “programming effect” that is mediated by structural modifications of DNA. Surprisingly, these non-inherited effects may persist over two generations. Biological mechanisms explaining this process (e.g., DNA methylation and histone acetylation which contribute to this “epigenetic marking” early in life) are now being discovered and in animals appear to be potentially reversible (Weaver, Champagne, Brown et al., 2005). This exciting and developing area of research highlights how the processes by which inherited and non-inherited genetic and environmental factors exert risk effects on health, behavior and psychopathology are complex and intimately intertwined.

**Phenotypic Pathway from Gene to Child Psychiatric Disorder**

Biological pathways and mechanisms are essential areas of research in terms of understanding the pathogenesis of disorders. For clinicians there is additional interest in the complex phenotypic pathways that lead from genes/cellular processes to psychiatric disorder. Endophenotypes have been described as measurable characteristics thought to lie along the pathway from gene to psychiatric disorder but that are closer to the gene and that are thought to have a simpler relationship with a given gene (Cannon, 2005; Gottesman & Gould, 2003). For a trait to meet the criteria as a potential endophenotype for a given disorder, it must be genetically influenced itself and associated with the disorder. It should also be familial and genetically related to the disorder in question with the endophenotype linked to the gene of interest. Finally, the endophenotype should not result from the disorder itself.

More recently, there has been a stronger interest in intermediate phenotypes (Meyer-Lindenberg & Weinberger, 2006). These differ crucially from endophenotypes with respect to the lack of any assumption that they are necessarily closely connected to gene action. Rather, they are similar with respect to the assumption that they have a key role in the causal biological processes leading to disorder. Thus, in the study of the progression from HIV to AIDS there are laboratory findings that index the stage reached in the process. This is an example of an intermediate phenotype that is not an endophenotype. Such intermediate phenotypes are most useful in investigating the effects of drug action without the need to wait for the final endpoint. There are equivalent intervening changes in carcinogenic and in allergic diseases. It may be presumed that the same is likely to apply in the field of psychopathology. The snag is the lack of any adequate understanding of the underlying neural processes in most instances. So far, the key intermediate phenotypes and putative endophenotypes of interest in psychiatry have been neuroimaging features, cognitive and emotional processing and psychophysiological measures.

For example, there is now a very large area of research that has shown that a variant in the gene coding for the enzyme COMT, which is responsible for breakdown of dopamine in the prefrontal cortex (PFC), is linked to an individual’s performance on tasks assessing prefrontal cognition (Tunbridge, Harrison, & Weinberger, 2006). This gene variant is functional. That is, it affects the activity of the COMT enzyme whereby one form of the variant (the val allele) results in higher activity of the enzyme and thus greater clearance of dopamine in the PFC. The other form (the met allele) is associated with lower enzyme activity. It is the higher activity val allele that has been found to be linked to lower levels of dopamine in the prefrontal cortex and associated with cognitive function. The findings to date suggest that the COMT val/met variant influences PFC function but there is no compelling evidence yet that this represents a risk pathway for psychiatric disorders such as schizophrenia.

Another example is provided by a study that suggested that a functional variant in the serotonin transporter gene variant may be linked to amygdala reactivity to environmental stimuli (Hariri, Drabant, Munoz et al., 2005; Hariri, Drabant, & Weinberger, 2006). The importance of this finding concerns the identification of a possible biological pathway and the evidence that this operates in individuals without psychopathology.

There are different schools of thought with regard to the importance of endophenotypes. Some suggest that identifying susceptibility genes for them may be easier than for psychiatric disorders themselves but, thus far, the evidence is lacking as assessed by the standard of replicated findings. An alternative view is that the focus on endophenotypes becomes more important after specific genes that influence psychiatric disorder are identified. The next question is how does that gene variant exert its risk effects? Does the gene influence psychiatric disorder through effects on brain structure or specific alterations in function such as those mediated through effects on neurotransmitters, specific cognitive mechanisms or temperamental attributes? The key point is that the value of genetic findings is crucially dependent on determination of the biological pathways involved (Meyer-Lindenberg & Weinberger, 2006). The issue of whether or not any index of that pathway is closer to the gene action is an interesting specific question but it fails to recognize that the delineation of biological pathways is as relevant to environmental risk mechanisms as genetic ones. Accordingly, our preference is for the broader concept of intermediate phenotypes rather than the narrower genetic concept of endophenotypes.
Gene–Environment Interplay at the Clinical/Phenotypical Level

There is increasing evidence that genes do not just exert risk effects by influencing specific traits, but can work indirectly by increasing an individual’s vulnerability to environmental adversity (gene–environment interaction) and also have indirect risk effects by being involved in bringing about environmental adversity (gene–environment correlation).

Gene–Environment Interaction

Environmental factors not only influence gene activity at a cellular level but have also been found to modify the effects of inherited genetic liability for psychiatric and medical disorders at an observable phenotypic level (Fig. 23.3). It is well recognized by researchers and clinicians that individuals vary in their response when exposed to an environmental risk factor. The term gene–environment interaction ($G \times E$) is now widely used to describe the phenomenon whereby even where there is genetic susceptibility, an individual does not necessarily show disorder until exposed to an environmental risk factor (Rutter, Moffitt, & Caspi, 2006). This is important for researchers to appreciate, as some genes will not appear to be risk genes unless the individual is also exposed to a risk environment. Thus, $G \times E$ may account for non-replication of findings in different genetic studies. It is also a clinically relevant issue that is of potential importance to prevention and treatment approaches, because it suggests that changes in environmental factors can prevent the manifestation of genetic dispositional factors.

Investigation of $G \times E$ has been undertaken using twin and adoption strategies, and more recently in molecular genetic studies. The first group of studies allows for testing whether the association of a specific environmental risk factor with psychopathology varies depending on genetic risk for a disorder which is inferred by virtue of having a biologically affected relative with that disorder. Molecular genetic studies provide the opportunity of testing for $G \times E$ in a different way; specifically by testing whether the risk effect of a specific environmental factor varies depending on possession of an allelic variant of one specific gene. For example, in a study based on the Dunedin cohort, a variant in a gene coding for the enzyme monoamine oxidase A (MAOA), involved in the breakdown of dopamine, noradrenaline, adrenaline and serotonin (see chapter 16), was significantly associated with adult antisocial behavior but only when there had been exposure to childhood maltreatment (Caspi et al., 2002). This finding of interaction between the MAOA gene and family adversity has been replicated in other samples (Kim-Cohen, Caspi, Taylor et al., 2006), is supported by animal study findings, and imaging work supports plausible biological mechanisms linking this MAOA gene variant to aggression (Meyer-Lindenberg, Buckholtz, Kolachana et al., 2006). In the same Dunedin sample, a serotonin transporter gene variant was found to be associated with depression but only where there had been exposure to life events (Caspi et al., 2002). This finding has again been replicated by several groups although there are also non-replications (Kendler, Kuhn, Vittum et al., 2005; Zammit & Owen, 2006). The findings are supported by animal and imaging studies. Clearly, given the potential pitfalls of multiple statistical testing that can increase the rate of false positives (and there are hundreds of thousands of gene variants that could be tested with many different environmental factors), testing for $G \times E$ needs to be empirically driven and findings have to be replicated. That is, the specific hypotheses need to be scientifically plausible, the environmental risk factor should ideally be causal or at least a proximal risk factor (see chapter 25), the gene variant should be functional (have an effect on proteins) and there should ideally be some information about potential biological plausibility (Moffitt, Caspi, & Rutter, 2005; Rutter, Moffitt, & Caspi, 2006). A clinically important example of $G \times E$ is individual genetic variation in the clinical response to medication. This variation between individuals can arise because of genetic differences in pharmacokinetics (Sadee & Dai, 2005; see also chapter 16); for example, variation in genes affecting the activity of metabolizing enzymes in the liver. It can also arise because of genetic variation in drug targets in the brain (pharmacodynamics); for example, neurotransmitter receptor binding. One example is the suggestion that a variant in the dopamine D3 receptor may be associated with susceptibility to medication-related tardive dyskinesia in schizophrenia (Malhotra, Murphy, & Kennedy, 2004). This area of pharma-cogenetics research is becoming of increasing interest across medicine because it holds the potential for individually tailoring treatments and better predicting response and side-effects (see chapter 16). However, at present findings remain preliminary and treatment response is likely to be influenced by many different genes as well as environmental risk factors.

Gene–Environment Correlation

This phenomenon is characterized by the co-occurrence of genetic and environmental risk factors that arises because the presence and degree of severity of an environmental risk factor is related to the individual’s genetic make-up. This concept of genes and environmental risk factors going hand in hand will be familiar to clinicians and epidemiologists; given that other risk factors tend to cluster, adversities are often multiple. There are three potential sources of gene–environment correlation (Plomin, 1994).

First, children not only inherit genes from their parents, but are also exposed to environments created by these parents. When the parental genes that provide risk also shape parental behavior that influences the rearing environment, there is a passive gene–environment correlation. An example of this would be the association between parental mental disorder and family discord (Rutter, 1989). The parental genes are thereby contributing to the likelihood that the child will be exposed to risky environments. Second, children at increased genetic risk may seek out risky environments as a result of their own genetically influenced behavior. A possible example of such an active gene–environment correlation would be the case of a child with ADHD whose impulsive risk-taking behavior involves him...
or her in maladaptive peer groups. Finally, individuals’ own genetically influenced behavior will evoke responses from other people; for example, when a child with genetic susceptibility for antisocial behavior evokes hostile responses from others. This is known as evocative gene–environment correlation. The influence of individuals on their environments has long been recognized in developmental psychology (Bell, 1968). The study of gene–environment correlations takes this concept a step further in highlighting the role of genes in this causal process.

Again, this issue is of relevance to both clinicians and researchers. First, there needs to be an appreciation that genetic and environmental risks are not mutually exclusive. Even where there is a strong family history of disorder, there may be additional risk effects from environmental factors that go hand in hand with genetic risk factors in these families and that can be modified. Second, for researchers, there needs to be an awareness that the associations between specific environmental risk factors (e.g., family conflict and antisocial behavior) can arise because of genes influencing both the risk factor and outcome (“genetic mediation”). Ideally, one needs to test whether there are risk effects of the environmental factor that are independent of genetic risk (“environmental mediation”; see p. 351) (Rutter, 2007).

There is evidence to suggest that gene–environment correlation is especially important in child psychiatry for antisocial behavior (Ge, 1996; O’Connor, 1998) and depression (Rice, Harold, & Thapar, 2003; Silberg, Pickles, Rutter et al., 1999). For example, two adoption studies have shown that biologically unrelated adoptive parents of children at high genetic risk of antisocial behavior show greater negative parenting practices than adoptive parents of children at low genetic risk as indexed by disorder in the biological parents (Ge, 1996; O’Connor, 1998). The adverse parenting appeared to be provoked by the children’s behavior but nevertheless still carried risk effects on the behavior, independent of the direct genetic influences.

How Genes are Inherited and Transmitted from one Generation to the Next

In this section, we consider how genes are passed onto the next generation. Mendel, an Augustinian monk, first deduced the existence of a unit of inheritance and the rules governing transmission of this unit (now known as a gene) from generation to generation. He inferred all this from a famous set of experiments on peas. This deduction was reached long before DNA and genes were discovered. Mendel’s Laws are now well-established (McGuffin, Owen, & Gottesman, 2002). One law is that during gamete formation, maternal and paternal allele pairs separate and one of each is transmitted to the offspring. Another important law is that where two characteristics are influenced by two different genes (when there is simple single-gene inheritance), the two genes will be transmitted independently in the next generation. For example, if one “parent” has red flowers and smooth peas, the offspring’s flower color and smoothness of its peas will be independent of each other. This is because during fertilization and meiosis, the genetic sequence from both the mother and father is shuffled (in the way that a sequence of playing cards will be changed by shuffling) by the process of recombination, whereby a chromosome crosses over with its partner chromosome at many different recombination points. It is sufficient to know that the process of recombination means that there is, on average, a 50 : 50 chance of genetic sequences being inherited together, unless they are physically located close to each other on a chromosome when there will be a departure from this Mendelian rule. The departure from this rule whereby two genetic loci tend to be co-inherited is known as “linkage disequilibrium” and is used in mapping human disease and traits.

Single-gene disorders, such as tuberous sclerosis, which can be associated with autism (see chapters 24 & 46), are sometimes known as Mendelian disorders because the transmission from generation to generation can be clearly seen to follow Mendel’s Laws. Genes that increase susceptibility for complex disorders such as psychiatric disorders also follow Mendel’s Laws. However, here multiple gene risk effects operate, not only in an additive fashion, but also through gene–gene interaction (epistasis) and gene–environment interplay (see p. 343). Detecting gene–gene interaction is becoming an area of research interest. Like $G \times E$, it can explain why some risk gene variants may not behave as risk factors for disorder unless they are accompanied by other specific risk gene variants. The genetic background is thus important and may account for why risk effect sizes of susceptibility genes that influence complex diseases have been found to be relatively small and why findings vary in different studies, although there are other explanations for non-replication.

In summary, the inheritance patterns of most common disorders and traits, including psychiatric disorders, are not straightforward, which explains why many affected individuals (e.g., with autism or diabetes) may, but do not necessarily, have a known affected relative. These disorders are known as complex, polygenic (influenced by many genes) or multifactorial (influenced by different risk factors) disorders.

Molecular Genetic Research Methods

In this section we provide sufficient information for non-specialist researchers and clinicians to interpret genetic study findings and to be aware of the strengths and weaknesses of different designs.

The process of identifying genes that influence disorder or traits involves testing for links between variation in individuals’ DNA and the trait or disorder in question (phenotype). The first generation of useful markers were restriction fragment length polymorphisms (RFLPs) where DNA variation consisted of different length markers after digestion of the DNA
by an enzyme. The second generation consisted of microsatellite markers that were made up of repeated DNA sequences (e.g., (CA)_n), which are still used. The most recent group of markers are single nucleotide polymorphisms (SNPs). These are variations in single nucleotides that occur commonly. These are extremely useful markers as they are relatively cheap and more accurate to genotype, provide denser coverage of the genome and are associated with greater statistical power when testing for risk gene variants across the genome. There is now the technology for high throughput genotyping, and more recently genotyping using DNA “chips” that allow for rapid genotyping of large numbers of SNPs for large samples of people. Increasingly, this type of work is being undertaken commercially at lower and lower prices as the process is being increasingly automated. The selection of markers whereby most common genetic variation is selected is an important task, so that all possible markers do not have to be genotyped. A public database of more than 1 million SNPs (HapMap; Altshuler & Clark, 2005) and information about the patterns of linkage disequilibrium between these markers that can guide selection of “tagging SNPs” for genetic studies is now available. Most recently, another type of common variation in the genome has been recognized. This is structural variation in the genome that includes copy number variants (CNVs). These CNVs have been found to capture variation in gene expression and are likely to be important in contributing to complex diseases (Stranger, Forrest, Dunning et al., 2007) such as autism (Autism Consortium Group, 2007).

Some research groups also use a type of laboratory screening approach that is easy and cheap to undertake. DNA pooling involves evaluating the “pooled” frequencies of multiple genetic marker alleles in two groups, cases and controls, rather than individually genotyping each marker. Markers that appear more commonly in cases can then be examined in a second stage by more costly individual genotyping. Such methods have been used in molecular genetic studies of IQ for example. The two main types of methods used to identify susceptibility genes are linkage and association approaches. Linkage studies involve testing whether specific genetic markers or sets of markers are co-inherited with disorder in affected families. Association studies are traditional epidemiological type designs based on testing whether the frequency of a specific marker, or sets of markers, is higher in those affected compared with a control group. In the past there have been concerns about the possibility of false positive findings (population stratification) from association studies, essentially because of inadequate matching of controls so that they differ genetically from cases for reasons other than the disorder (e.g., ethnicity differences). To circumvent this potential problem, many researchers have adopted the approach whereby parental DNA is collected, and the alleles that are not transmitted to the affected offspring are used as the controls in statistical analysis. These methods are known as family-based rather than case-control association methods and include the Transmission Disequilibrium Test (TDT) and Haplotype Relative Risk method (HRR). For later onsets disease, where collecting parental DNA is not feasible, another approach is to test for population stratification in the laboratory by examining whether random gene variants not thought to be involved in disease, differ in cases and controls.

Throughout this chapter, the risk gene variant has been considered in terms of one particular allelic risk factor. Linkage and association studies have also focused on sets of markers and for some conditions (e.g., Crohn disease) the risk variant appears to be a specific grouping of alleles across a set of different markers within the gene. This set of alleles is known as a haplotype. In psychiatry, there has been some suggestion that a haplotype derived from several markers in the COMT gene is functional (Bray, Buckland, Williams et al., 2003) and is associated with schizophrenia (Schiffman, Bronstein, Sternfeld et al., 2002).

One of the major difficulties in psychiatry is that the biological mechanisms involved in the development of psychiatric disorders are unclear and there is currently a lack of understanding of their pathophysiology. This situation contrasts with some other complex disorders such as diabetes, where it is known that a lack of insulin results in raised blood glucose levels that in turn lead to adverse consequences. It is for this reason that hypothesis-free molecular genetic strategies, which involve no assumptions about the underlying biology of psychiatric disorders and where the whole genome is systematically searched for risk variants, are attractive in psychiatry.

Linkage Studies
In whole-genome linkage studies, the goal is to identify susceptibility gene variants through positional strategies; that is, by locating specific regions in the genome that harbor disease susceptibility genes. These studies are based on samples of families consisting of multiply affected relatives. Linkage studies that involve knowing the pattern of inheritance of the disorder and that are statistically parametric in nature have been successful in identifying susceptibility genes for single-gene disorders such as Huntington chorea and tuberous sclerosis. For complex disorders, including psychiatric disorders where inheritance is not straightforward, non-parametric linkage methods are used. The most commonly used approach is to select affected sibling pairs (ASPs), where at least two siblings in a family have the disorder in question. On average, for any given marker (remembering that each individual has a pair of chromosomes), 1 in 4 full biological siblings will inherit the same pair of alleles from their parents (one from mother, one from father, identical by descent), 1 in 4 will share zero alleles and half will share one alleles. If the marker lies close to the disease susceptibility locus (when there is significant linkage), ASPs will share more of the linked marker alleles than expected. This departure from expectation occurs because the marker is in linkage disequilibrium with the disease susceptibility locus (i.e., recombination between the two loci on the chromosome is lower than expected). In whole-genome linkage studies, markers across the genome are selected, genotyped and each one is tested for linkage with the disorder. As this
involves multiple testing, the currently accepted genome-wide significance level is stringent (Lander & Kruglyak, 1995). For example, in an ASP linkage study of ADHD, one region on chromosome 16p13 achieved genome-wide significance and a number of other regions reached the threshold for suggestive linkage (Smalley, Kustanovich, Minassian et al., 2002). However, specific susceptibility genes within any of these regions have yet to be identified (see chapter 34).

This ASP linkage approach has until recently been the strategy of choice for molecular genetic studies of complex disorders, including schizophrenia, bipolar disorder and autism, as well as medical conditions such as diabetes, asthma, rheumatoid arthritis and Crohn disease. Another linkage strategy that has been less commonly used in psychiatry because the samples are more difficult to collect, is based on collections of smaller numbers of multiplex families in which there are usually several generations of multiply affected family members. This strategy is also more challenging where the manifestation of disorder is developmentally influenced; for example, ADHD or reading disability may be difficult to diagnose retrospectively in the grandparent generation.

Linkage studies provide an initial “broad-brush” approach to identifying susceptibility genes in that they can identify regions of the genome that may harbor these genes (significant regions of linkage may include very many genes). They are better at picking up genes of larger effect but are not able to pick up genes of small effect. There has been some impatience with linkage studies and criticisms made about the usefulness of this approach as results were not as quickly forthcoming as initially thought. With the benefit of hindsight, it is clear that early forecasts of how quickly susceptibility genes for complex disorders would be identified were unrealistically optimistic. Now, with larger samples, linkage studies are beginning to yield results. For example, linkage studies have led to replicated findings of susceptibility gene variants for schizophrenia (see chapter 45), Crohn disease and asthma.

Whole-Genome Association Studies

Until now, the most cost-effective and pragmatic approach has been to first undertake linkage studies to identify chromosomal regions of interest and then to carry out more detailed mapping with multiple markers in these regions to identify the susceptibility gene. A useful analogy here is to think of linkage studies as the equivalent of screening in epidemiology, where sensitivity in picking up the true cases may be a problem, and subsequent association studies as the detailed interviews on the selected group. For epidemiological studies, if detailed interviews could be undertaken easily and cost-effectively in large numbers, one would want to interview the whole sample. For molecular genetic studies, it is now becoming cost-effective to test thousands and thousands of markers across the genome (search for susceptibility loci in detail across the genome with high levels of sensitivity) and such studies are now yielding replicated findings. These studies, which are also hypothesis-free, are known as whole-genome association studies (WGA).

There is some excitement about this approach as it now provides a feasible systematic method of searching the whole genome for susceptibility genes of small effect size (Carlson, Eberle, Kruglyak et al., 2004) and because several WGA studies of complex disorders, including bipolar disorder, published in 2007, have resulted in the identification of susceptibility loci (Wellcome Trust Case Control Consortium, 2007). Given the issues of multiple testing and the risks of false positives, very large samples sizes are likely to be needed to avoid the statistical problem of a large number of false positive findings whereby apparent susceptibility loci are found to be associated simply by chance. It is not certain exactly how large samples need to be. Theoretically, several thousand cases are desirable. However, one whole-genome association study of only 96 cases of macular degeneration and 50 controls (Klein, Zeiss, Chew et al., 2005) resulted in identification of a susceptibility gene and this finding has been replicated. Large-scale sample collections are a challenge in psychiatry where establishing the phenotype is expensive and labor-intensive. At the time of this chapter going to press however, WGA studies seem to be one important way forward.

Molecular Genetic Strategies that Involve Testing Specific Hypotheses

These studies involve selecting specific genes that are thought a priori to be involved in the disease process and then examining variants within these selected “candidate” genes. These candidate genes can be either functional and/or positional. Positional candidate gene studies involve selecting genes according to evidence on position (i.e., in genomic regions of significant linkage or association, see p. 345). This type of positional candidate gene fine mapping association study following replicated linkage findings has resulted in identifying a susceptibility locus KIAA0319 for reading disability (Cope, Harold, Hill et al., 2005).

Another positional strategy involves following up clues about the potential position of a susceptibility gene provided by individual families who present with a disorder and have a specific region of a chromosome disrupted. For example, a study of a family with a translocation involving a region on chromosome 1 and schizophrenia and bipolar disorder led to the identification of a susceptibility gene DISC1 for schizophrenia (Millar, Pickard, Mackie et al., 2005; Owen, Craddock, & O’Donovan, 2005). Another well-known example is the description of a Dutch family where multiple members showed seriously aggressive behavior and learning disability accompanied by a mutation in the MAOA gene (Brunner, Nelen, van Zandvoort et al., 1993). A variant in the MAOA gene, in the presence of environmental adversity has since been linked to antisocial behavior (Casp et al., 2002).

Functional, rather than positional, candidate gene studies are considered by many as problematic. This is because here genes are selected on the basis of an assumption that they are involved in the pathophysiology of disease and one of the aims of genetic studies is to elucidate novel biological pathways. This type of method has been partially successful in diabetes
where variants in the insulin gene have been found to be associated with the disorder. However, the situation is different for psychiatric disorders where the pathophysiology is unknown. Nevertheless, despite these criticisms, functional candidate gene association studies have been successful for some disorders, notably ADHD (see chapter 34).

Clues for selecting functional candidate genes can come from a variety of research studies. These include studies of animals that show behaviors of relevance to psychiatry (e.g., hyperactivity), postmortem human and animal gene expression studies (these can shed light on which biological systems are involved in a disorder; see p. 340), psychopharmacology, and imaging research. Animal studies that have guided candidate gene work have included instances in which specific genes are artificially disrupted (e.g., knockout mice or irradiated mutants) and where the animal then shows a phenotype of interest. An example relevant to child psychiatry is the dopamine transporter knockout mouse that shows marked hyperactivity and where there is some evidence from metaanalysis that a variant in the dopamine transporter gene is associated with ADHD (Farøe, Perlis, Doyle et al., 2005).

Another example whereby genetics research was guided by animal studies is the finding of association between variants in the SNAP25 (synaptosomal associated protein) gene, which is involved in vesicular uptake of neurotransmitters and ADHD. This clue came from findings that the coloboma mutant mouse, which has a deletion on a segment of chromosome including the SNAP25 gene, shows marked motor hyperactivity (Thapar, O'Donovan, & Owen, 2003b).

Other clues about which genes may be involved may come from studies of behavioral phenotypes in humans who have a single gene disorder (see chapter 24). However, many would argue that the difficulty here is that the pathway to disorder in these individuals may be different, and also many of these single-gene disorders are accompanied by learning disability (lower IQ). Thus, it is not always straightforward to establish whether the apparent increased rates of a specific psychopathology (e.g., autism) arise specifically from disruption to the gene rather than from being related to lower IQ.

Once a gene variant has been found to be robustly associated with a disorder, given the potential for false positive findings, the next step required is that the finding should be independently replicated in other samples. This has been difficult in many instances and has led to criticism of psychiatric genetics. However, it must be remembered that large samples are needed to replicate findings (Goring, Terwilliger, & Blangero, 2001) and that false negative results can also be a problem. Moreover, for complex disorders, risk gene variants will interact with other gene variants and environmental factors, and it is likely that there will be phenotypic heterogeneity (e.g., because of differences in sample ascertainment). If these background factors vary in different samples, replication becomes problematic. Despite these challenges and the issues of phenotype definition, genetic findings in child and adult psychiatry are now being replicated and indeed significant evidence of association is now beginning to be yielded by meta-analyses, which some consider an overly stringent requirement.

Once association has been robustly demonstrated, as in all epidemiology, the next stage involves testing whether the risk factor is causal by investigating the mechanisms by which it exerts its risk effects. In genetics, this process needs to be undertaken at a biological and phenotypic level.

Once a genetic marker/haplotype has been found to be robustly associated with a disorder, it is crucial to identify whether or not it is functional. The areas of research on gene expression profiling (transcriptomics) and proteomics that involve examining gene products are becoming increasingly important (see p. 340). However, in child psychiatry, a problem is that brain tissue to undertake such studies is usually not readily available. The next stage involves investigating the physiological mechanisms that lead to disorder, in which it is crucial for genetics research to be fully integrated with other areas of neuroscience, such as imaging. It is also becoming increasingly apparent that once it is established that a gene variant is associated with a disorder, these next stages of biological and phenotypic research are also challenging and not straightforward tasks. Animal studies provide a means of examining gene function and investigating the link between genes, biological pathways and behaviors and cognition that could increasingly inform human genetics research.

Defining the Phenotype for Genetic Studies

Diagnosis
Success in identifying susceptibility genes for complex disorders is dependent on how well the phenotype is defined. That is not always straightforward in psychiatry (an exception is Alzheimer disease), where phenotypes are defined on the basis of reported symptoms rather than on the basis of measurable pathology or physiological measures (e.g., diagnostic intestinal biopsy for Crohn disease, high blood glucose levels for diabetes). However, the use of research diagnostic interviews (see chapter 19) has meant that diagnoses can be made at least with high levels of reliability. Also, there is increasing evidence of biological and clinical validity for some disorders (see chapter 2). However, there is considerable variation in the clinical presentation of psychiatric disorders, as there is across the whole of medicine. This has led to some interest as to whether this observable variation indexes underlying etiological heterogeneity and whether inclusion of such clinical/phenotypic information can help refine the search for susceptibility genes. The evidence to date suggests that such phenotypic considerations may be useful and important. For example, linkage evidence for asthma was found to be stronger when the clinical covariate of bronchial hyper-responsiveness was included (van Eerdewegh, Little, Dupuis et al., 2002). Linkage to a chromosomal region for schizophrenia was refined by including depression as a covariate (Hamshere, Williams, Norton et al., 2005). One study of autism found that by including a factor representing the clinical phenotype of “insistence of sameness”
CHAPTER 23

Genetic linkage findings were strengthened and refined (Shao, Cuccaro, Hauser et al., 2003). It remains to be seen whether that can be replicated. There is also increasing evidence to suggest that consideration of the overlap of psychiatric disorders is important. For example, variants in two genes, NRG1 and DISC1, appear to influence a phenotype that is a mixture of schizophrenia and bipolar affective disorder (Craddock, O’Donovan, & Owen, 2006).

Modifying Factors
Gene variants may also influence the different phenotypic manifestation of disorder (e.g., antisocial behavior in ADHD, depression in schizophrenia) as those that contribute to its origins. In some instances, the same gene variants may influence phenotypic presentation, severity and course of a disorder. In other instances, different modifying genes may be important for these clinical aspects. For example, there is consistent evidence now that the COMT val/val genotype influences antisocial behavior in ADHD but not ADHD itself (Casp, Langley, Milne et al., 2008; Thapar, Langley, Fowler et al., 2005a; see chapter 34).

Trait Measures and Quantitative Trait Loci Studies
Traditionally, genetic studies have focused on clinical disorder, defined categorically. However, there is a strong opinion among some that it may be preferable to focus on identifying susceptibility genes for quantitative traits related to disorder (e.g., ADHD symptom scores rather than ADHD, or schizotypy rather than schizophrenia). Genes of small effect influencing continuously distributed trait measures are known as quantitative trait loci (QTL). QTL linkage and association studies have long been used successfully in plant and animal genetics, including investigating behavioral traits such as anxiety (Abiola, Angel, Avner et al., 2003). Furthermore, mapping QTLs that influence gene expression in animals and linking these to specific behaviors and characteristics is well advanced such that databases of this information are now available (Web QT: www.genednetwork.org).

The mapping of QTLs for continuously distributed measures has also been utilized in general medicine. Examples include blood pressure and cholesterol levels, which are continuously distributed trait measures that behave as risk dimensions in that they are associated with increased risk of ischemic heart disease in a continuous fashion. Another example is body mass index (BMI) because of its importance in terms of obesity. QTL studies of these risk dimensions, some of which are intermediate phenotypes, has been an important adjunct to focusing on molecular genetic studies of categorically defined clinical disorder (Abiola, Angel, Avner et al., 2003; Carlson, Eberle, Kruglyak et al., 2004).

Many child psychiatric disorders can also be easily conceptualized in dimensional terms or risk dimensions identified (e.g., depression or ADHD symptom scores or personality traits such as neuroticism). It has been argued that searching for QTLs for these types of continuously distributed trait measures is a more powerful strategy, both statistically and conceptually.

In reality, that depends on a number of different issues. First, there needs to be consideration of the ease of phenotyping. For QTL linkage studies, extremely large sample sizes are needed although statistical power can then be increased by selection strategies; for example, by selecting high and low scorers (this approach has been used for IQ and ADHD studies) or highly concordant and discordant sibling pairs (this approach has been used for mapping studies of neuroticism; Fullerton, Cubin, Tiwari et al., 2003). Where phenotyping is expensive (e.g., interviews are needed) this becomes a problem. Second, the issue of whether or not it is better to use categorical or dimensional conceptualizations of child psychopathology has received much attention and outside the realm of genetics is a topic of much discussion (Pickles & Angold, 2003; Rutter 2003; see chapters 2 & 4). However, the likelihood is that neither approach is right or wrong. What is of key importance is the nature of the relationship between the risk factor (here the gene variant) and phenotype. For example, a risk factor may influence an underlying risk dimension (e.g., a personality attribute for disorder) but not the disorder (e.g., depression). It may influence both. It may influence the disorder only and not the risk dimension given that there are numerous different risk pathways into psychiatric disorder. This will clearly not be known before the risk factor or gene variant is identified. Ideally, both approaches should be considered as they each have their strengths (Thapar, Langley, O’Donovan et al., 2006). However, to date, the replicated molecular genetic evidence in child and adult psychiatry has been most consistent for traditional clinical diagnoses (e.g., ADHD, schizophrenia, depression) and the evidence has been much weaker for QTL studies of trait measures. Of course, this may be because there has been less QTL research. For example, there have been a few QTL studies of hyperactivity symptom scores in the general population but, so far, association findings with susceptibility gene variants that have been associated with and replicated for clinical ADHD have been weaker (Mill, Xu, Ronald et al., 2005). On the other hand, the replicated imaging findings in relation to genetic variants do point to dimensional effects that extend across the general population. Overall, it is important to evaluate evidence as it emerges and remain open to different approaches.

Quasi-experimental Studies of Genetic Effects
In themselves, findings on susceptibility genes provide only a starting point for investigating causal processes. The potential of genetics lies in the leads it provides for other biological studies, but that potential will be realized only if such studies are integrated with genetics. In that connection, laboratory studies of gene functions will be crucial and, often, these will need to involve animal models of one kind or another. In addition, more clinically oriented quasi-experimental studies (e.g., where subjects undergo imaging after exposure to an experimental stressor) can be highly informative. Thus, structural and functional brain-imaging studies have been used to examine the differences in neural function in relation to psychological challenges associated with different genetic allelic
and over 50 for autism. Familial clustering of a condition can be around 2–4 for childhood depression, around 5 for ADHD and other psychiatric disorders. For example, the familial risk in terms of odds ratios is usually expressed as a relative risk or odds ratio and derived estimate will also depend on the estimated degree of familial clustering varies for different disorders. For example, the familial risk in terms of odds ratios is around 2–4 for childhood depression, around 5 for ADHD and over 50 for autism. Familial clustering of a condition can arise because of relatives sharing genes. For example, first-degree relatives (such as mother–child or full biological siblings) share on average 50% of their segregating genes and environmental factors can impact on all family members in a way that increases their similarity for a given trait or disorder. This type of environmental factors have an important role in antisocial behavior. Finally, a particularly interesting variety of adoption study is the cross-fostering design where the rate of a disorder in children at high genetic risk who are adopted in low environmental risk families is compared with that among children who are at high genetic risk who are adopted in low environmental risk families is compared with that among children who are at low genetic risk in high environmental risk and children at high genetic risk in high environmental risk. Such studies have also shown that high genetic risk and psychosocial adversity interact in substantially increasing the risk of antisocial behavior (see chapter 35) and in influencing IQ in children.

Adoption Studies
Adoption studies examine similarity for a given disorder between individuals and their biologically related relatives compared with their adoptive relatives (Rutter, Silberg, O’Connor et al., 1999a,b). Where a condition is genetically influenced, we would expect greater similarity with biological relatives, whereas an important shared environment contribution would lead to resemblance to biologically unrelated adoptive relatives. Adoption studies are also a useful method for examining gene–environment interaction and gene–environment correlation.

There are three main types of adoption design. First there are studies examining the adopted-away offspring of parents with a disorder. Such early studies found that adopted-away offspring of parents with schizophrenia also showed increases rates of schizophrenia. Second, there are studies that focus on examining the biological and adoptive relatives of affected adoptees. Such studies have found that genetic influences have an important role in antisocial behavior. Finally, a particularly interesting variety of adoption study is the cross-fostering design where the rate of a disorder in children at high genetic risk who are adopted in low environmental risk families is compared with that among children who are at low genetic risk/high environmental risk and children at high genetic risk/high environmental risk. Such studies have also shown that high genetic risk and psychosocial adversity interact in substantially increasing the risk of antisocial behavior (see chapter 35) and in influencing IQ in children.

Twin Studies
Twinning occurs on average in 1 in 80 births. Twin studies provide a natural experiment to disentangle genes and shared environmental effects. The premise of the twin study design is that monozygotic (MZ) twins are genetically identical (for some caveats see p. 350) and share 100% of their genes. Dizygotic (DZ) twins, like other full biological siblings, share on average 50% of their segregating genes. For genetically influenced traits or disorders, we thus would expect to see significantly greater MZ twin similarity (expressed as a correlation coefficient, rMZ) or concordance than DZ twin similarity (rDZ) or concordance. There are a number of
assumptions made in twin studies and these will be discussed in further detail.

Twin methods involve statistically inferring genetic and environmental contributions from the patterns of twin resemblance for a given trait or disorder in the population being studied. The phenotypic variance in the population is decomposed into variance explained by additive genetic factors and environmental influences of the shared and non-shared type. The proportion of additive genetic variance is known as heritability. Heritability estimates are thus simply a measure of variation. If there is no genetic variation (if there is a trait that is influenced by a single gene that everyone carries) that trait would show zero heritability. Like all measures of variance, heritability estimates are specific to the population being studied and do not provide an index of whether or not that trait is susceptible to change by intervention. A well-known example is height, which has a heritability of about 90%. Most of the individual differences in height are attributable to genetic factors. Nevertheless, it is well acknowledged that in wealthier countries the average adult height has steadily risen and that is partly attributable to better nutrition and not to a sudden change in the gene pool (Roche, 1979). MZ and DZ twin similarity can be expressed in proportions of variance as follows, where r refers to the observed twin correlation and estimates of $h^2 =$ heritability, $c^2 =$ shared or common environmental variance and $e^2 =$ non-shared environmental variance can be calculated: $r_{MZ} = h^2 + c^2; r_{DZ} = 0.5 h^2 + c^2; 1 - r_{MZ} = e^2$.

It can be seen that non-shared environmental variance ($e^2$) refers to non-inherited influences that make MZ twins dissimilar. This includes environmental influences which impact differentially on MZ twins in terms of a given phenotype, measurement error and random effects, which will appear as non-inherited differences.

Virtually all published twin studies estimate $h^2$, $c^2$ and $e^2$ as well as other parameters if additional data are available (e.g., parent data or specific measures of environment) using structural equation modeling techniques (see chapter 9). A hypothesized model of etiology is drawn up and this is represented by a path diagram. For computer programs such as Mx, observed data are provided and starting values for estimated parameters (e.g., $h^2$) are suggested by the researcher. The program iterates with different parameter estimates until the optimum statistical fit between the estimated model and the observed data is reached (e.g., maximizing a likelihood function). An estimate of how well the hypothesized model fits is derived as well as estimates of the parameters of interest. The most basic twin model will allow for estimation of $h^2$, $c^2$ and $e^2$, although now the focus in twin research is on answering specific questions (e.g., on comorbidity or gene–environment interplay and addressing developmental issues; see p. 352), rather than simply providing heritability estimates.

Although twin studies provide much useful research evidence on child psychopathology, there are a number of assumptions and drawbacks that need to be borne in mind when interpreting findings.

**Equal Environment Assumption**

The twin study design is based on the assumption that MZ and DZ twin pairs share environment (including prenatal environment; e.g., fetal nutrition) to the same extent in so far as the environment influences the trait being studied. The issue is not whether, in general, MZ twin pairs share environments to a greater extent than DZ twin pairs. It is obvious that they will because of active gene–environment correlations. However, the assumption is violated only if the genetically influenced environment influences phenotypic differences. Thus, it is well known that MZ twins are more likely than DZ twins to be dressed alike, but no-one supposes that this is likely to influence susceptibility for any psychiatric disorder.

Violations of the equal environment assumptions (EEAs) have been tested in several different ways. First, it has been examined by using a questionnaire measure of environmental sharing (e.g., assessing whether twins share friends) and by measuring the amount of twin contact. The findings have shown that MZ pairs do share more similar environments than DZ pairs but this is unrelated to twin similarity for psychopathology or behavior. Others have addressed the issue by investigating twins who are mistaken about their zygosity. These studies have generally found that it is true zygosity rather than the perception of zygosity that seems to be important (Goodman & Stevenson, 1991). The most robust method of testing the EEA is to determine whether environmental differences within MZ pairs are systematically associated with phenotypic differences within those pairs (Rutter, 2006). The findings show that they are with respect to antisocial behavior and depression but, so far as is known, there is no violation of the EEA with respect to twin studies of schizophrenia, autism, IQ and personality traits. This indicates that it makes no sense to consider the EEA as something that applies generally; rather, it has to be considered in relation to particular phenotypes. The increased environmental sharing in MZ pairs arises because of greater MZ twin similarity in genetically influenced behavior or traits. This does not negate the meaning of twin studies. Rather, it means that there needs to be an awareness that gene–environment correlations may contribute to the heritability estimate for some disorders. It should be added that, with respect to intrauterine influences, there is some tendency for MZ twins to differ more than DZ twins (because of the transfusion syndrome in some of the former), but it is doubtful whether this has much effect on heritabilities, other than perhaps on IQ.

**Placental Heterogeneity Within MZ Pairs**

Although MZ twins come from the same fertilized egg, the process by which twinning occurs is complex. Non-inherited genetic changes may have an important role and there may be other changes (e.g., imprinting effects; see p. 341) such that MZ twins are not truly genetically identical. Moreover, some MZ twin pairs share the same placental chorion (monochorionic) whereas others do not (dichorionic). There is some evidence to suggest that this may be important in that monochorionic MZ twins may be more similar in IQ than
dichorionic MZ twins (Jacobs, Van Gestel, Derom et al., 2001). This highlights that prenatal environmental influences that are unequally shared may sometimes be important.

Comparability of Twins to Singletons
Another potential concern is whether twins are representative of the general population. Twin births are higher risk prenatally and perinatally, they are of lower birth weight, some MZ twins show fetal-fetal transfusion syndrome (where one twin receives most of the blood supply) and being one of a twinship is an unusual experience. There is also evidence to suggest that mothers of twins show increased rates of depression in the early years. However, apart from somewhat increased rates of speech and language delay that appear to be environmental in origin (Thorpe, Rutter, & Greenwood, 2003), there is no consistent evidence that rates of psychopathology are different in twins.

Another potential source of difference among twins is that increasingly multiple births are arising as a result of fertility treatment. There is some recent concern that some in vitro fertilization (IVF) procedures may result in an increased rate of certain medical and developmental conditions (Gosden, Trasler, Lucifero et al., 2003). Families of IVF children may also differ from other families although as yet there is no evidence to suggest that twins conceived by IVF differ in rates of psychopathology (Tully, Moffitt, & Caspi, 2003) or in twin similarity compared with other twins (Goody, Rice, Boivin et al., 2005).

Blended Families Design
A recent innovation has been the use of a blended families design (Reiss, Hetherington, & Plomin, 2000) in which, in addition to twins, use is made of step-siblings, half-siblings and full biological siblings who vary in their genetic relationship but share some of their rearing environment. At first sight this seems an attractive design given the frequency of divorce and remarriage (D'Onofrio, Turkheimer, Eaves et al., 2003; Silberg & Eaves, 2004). In brief, the effects of the rearing environment provided by the biological mother can be compared with the comparable environment provided by the MZ twin mother who did not rear her nephew/niece. Three features of the design require conceptual and analytic attention. First, the possibility of assortative mating needs to be considered and taken into account. This is because, although the offspring have the same genetic relationship with their aunt who is an MZ cotwin of their mother, they differ with respect to their other parent/uncle. Second, it is unlikely that the children of the twins will be comparable in age, and may differ in gender; both will need to be taken into account. Finally, there is the assumption that the phenotype in parent and offspring has the same meaning. This can be problematic for disorders in which the phenotypic manifestations change with development (e.g., ADHD) and the heritability varies with age (as with depression and antisocial behavior). To a substantial extent, these issues can be dealt with through appropriate analyses but the rich potential of the COT design has still to be put to the test in a range of studies.

Second, provided that the putative environmental risk factor can be measured in a child-specific fashion (Purcell & Koenen, 2005), it is possible to use multivariate analyses to compare genetic and environmental mediation by treating the environment as a phenotype and employing across-twins and across-trait analyses in MZ and DZ pairs.

In this way, Pike & Plomin (1996) showed that family negativity had a true environmentally mediated effect on child psychopathology, even though some of the effect was genetically mediated. Other studies have shown the same for life events (Kendler, Kessler, Walters et al., 1995; Rice, Harold, & Thapar, 2003), and physical maltreatment (Jaffee, Caspi, Moffitt et al., 2004).

Third, environmental mediation can be studied by examining effects within MZ twin pairs (Pike, Reiss, Hetherington et al., 1996). Thus, Caspi, Moffitt, Morgan et al. (2004) examined the effects of maternal negative expressed emotion on antisocial behavior. The study involved two key design features that were crucial in testing causal effects in a rigorous fashion, beyond just excluding genetic mediation. To begin with, within-individual change over a 2-year time span was assessed, and this was combined with the use of different informants for the maternal expressed emotion and the child psychopathology. Both these design features are equally necessary in all the genetic designs to test environmental risk mediation, but they have only sometimes been employed. One query with
CHAPTER 23

respect to this design is what it was that led the mother to respond so differently to the two MZ twins. This does not affect the conclusiveness on environmental mediation but it could possibly affect the generalization of the finding to other samples.

There is also a fourth design that has sometimes been employed – the extended twin family design (Kendler, Neale, Prescott et al., 1996; Meyer, Rutter, Silberg et al., 2000). This uses the measures of the phenotype in parents and children, and the association of the former with the putative environmental risk factor to test for environmental risk mediation. Its use has shown the environmental impact of early parental loss on alcoholism and of family maladaptation on antisocial behavior. However, it is a problematic design with respect to the assumptions involved and the difficulty in putting these to the test. As a result it has not been much used.

Twin and Adoptee Designs to Test for Gene–Environment Interaction

It is usually claimed that adoptee studies are superior to twin studies for the study of $G \times E$ because they provide a better separation of $G \times E$. Indeed, the rationale is based on the separateness of genetic risk and environmental risk. Undoubtedly, this means that there is a “cleaner” testing of $G \times E$, but the downside is that, by design, it will be unusual for genetic risk and environmental risk to apply to the same individuals. That is, under natural circumstances, genetic and environmental risk would not be separated in this “experimental manner,” individuals would be exposed to both sets of risk. This means that the $G \times E$ effect on population variance will always be underestimated in adoption studies. Nevertheless, the findings have pointed to significant $G \times E$ with respect to antisocial behavior (Rutter, 2006; Rutter, Moffitt, & Caspi, 2006; van Os, Pedersen, & Mortensen, 2004); specifically, increased rates of antisocial behavior in the offspring of antisocial biological relatives who are also exposed to social adversity in the adoptive family compared to offspring who are at low genetic risk of antisocial behavior and those at high genetic risk but who are exposed to a positive adoptive environment.

Twin studies have been used in two different ways to study $G \times E$. First, as shown by Kendler et al. (1995), genetic risk can be inferred from the concordance (degree of similarity) findings for a given disorder among MZ and DZ twins. High genetic risk was inferred when MZ twins were already concordant for a past episode of psychopathology (e.g., depression) and low genetic risk when they were discordant (one twin had an episode of depression, the other remained unaffected), DZ pairs being intermediate. They showed that the risk of a new episode of major affective disorder was highest in the presence of high inferred genetic risk and when exposed to life events – pointing to $G \times E$. Jaffe, Caspi, Moffitt et al. (2004, 2005) showed the same with respect to maltreatment and antisocial behavior.

The second approach, exemplified by Silberg, Rutter, Neale et al. (2001), is to determine whether heritability is greater in the presence of environmental risk. This implies $G \times E$ because the $G \times E$ term is incorporated in the measure of heritability. Their findings suggested $G \times E$ with respect to life events and depression/anxiety.

It will be appreciated that the main limitation of twin and adoptee studies to test for $G \times E$ is that the effect has to be inferred and deals only with the generality of a genetic effect, rather than one that applies to specific identified gene variants. As such, twin and adoptee studies provide an invaluable filter for the situations in which true $G \times E$ is likely to apply, but the proper testing has to be undertaken through molecular genetic studies.

Variations in Heritability by Social Context

Psychiatric geneticists have always emphasized that heritability is a population and not an individual characteristic and that it is bound to vary according to environmental circumstances. Studies by Rowe, Jacobson, & Van den Oord (1999) and by Turkheimer, Haley, Waldron et al. (2003) aroused considerable interest in terms of their finding that heritability for IQ was much lower in the presence of environmental adversity. Unfortunately, the findings of other studies have been contradictory (Rutter, Moffitt, & Caspi, 2006; Rutter, 2006) and, although it would be extremely valuable to determine why heritability varies by social circumstance, there are several competing explanations with contrasting predictions and the findings so far are inconclusive.

Comorbidity

Psychiatric disorders commonly co-occur and symptoms covary. It remains unknown why this is the case, although there are a number of plausible mechanisms (Caron & Rutter, 1991; see also chapter 2). Twin studies provide one means of examining this issue, specifically by investigating whether a shared set of risk factors (genetic and environmental) contribute to the overlap of two or more phenotypes (e.g., both genetic and individual environmental factors contributing to the overlap of novelty seeking personality traits and cannabis use; Kendler & Prescott, 2006).

Alternatively, twin analyses can be undertaken to test whether a “risk index” mediates risk for another clinical outcome (e.g., social anxiety in females leading to alcoholism; Kendler & Prescott, 2006). Multivariate genetic analysis can be used to test this. Such studies have found that childhood anxiety and depression (Thapar & Rice, 2006) and that ADHD and conduct disorder symptoms (Silberg, Rutter, Meyer et al., 1996) share a common genetic etiology. This means that the comorbidity does not reflect the causal effect of one disorder on another, but rather the fact that shared risk factors (in this case genetic) apply to both. It might be thought that genetic studies will always lead to this conclusion but that is not so. Thus, in adults, analyses have shown that anxiety disorder may have a causal effect on substance abuse (through a form of self-medication) whereas the similar association in the case of depression does not – the supposed comorbidity arising only through shared genetic risk factors (Kendler & Prescott, 2006).
Developmental Questions

More recently, longitudinal twin studies have been used to examine questions about the contribution of etiological factors to the developmental continuity, change and phenotypic progression of child psychopathology. Such studies have been consistent in showing that genetic influences appear to become more important for depression symptoms in adolescence than in childhood. There is also evidence that this increased heritability over time may be partly explained by increased active and evocative gene–environment correlation through an increase in dependent life events in adolescence (Rice, Harold, & Thapar, 2003).

Most studies have also found that genetic factors have a major contribution to continuity in disorder and symptoms over time, but that non-shared environmental factors are most important in accounting for change. This appears to be the case for ADHD. For some disorders, notably adolescent depression and ADHD, additional genetic influences can be detected at later time points, suggesting that new age-specific genetic influences (that will include gene–environment correlation and G × E effects) may contribute to developmental change in the level of symptoms. Finally, change in phenotype over time has also been examined. For example, clinical and epidemiological studies have shown that childhood anxiety often precedes adolescent depression. Twin study findings additionally suggest that childhood anxiety is a precursor to depression and show that this is mainly because of shared genetic factors contributing to anxiety earlier in time and to depression at a later time (Rice, van den Bree, & Thapar, 2004). The relationship between earlier anxiety and later depression in adolescence also appears to arise through gene–environment interaction and gene–environment correlation with life events (Eaves, Silberg, & Erkanli, 2003).

Gender Effects

Many psychiatric disorders in childhood show gender differences in prevalence (Rutter, Caspi, & Moffitt, 2003). Neurodevelopmental disorders such as autism, ADHD and childhood onset schizophrenia show a male excess (see chapter 3). Depression affects more females but this gender difference only appears in early adolescence. The explanations for these observed sex differences remain elusive (Rutter, Caspi, & Moffitt, 2003) although biological, genetic and social factors are all likely to have a role. Twin studies allow for testing whether the contribution of genetic and environmental influences to a specific form of psychopathology differs across genders. Such designs have been used to test whether the magnitude of genetic and environmental contribution varies for males and females and to investigate whether there is significant evidence of gender-specific genetic influences. Although male–female differences in the rates of many disorders are well established, such studies have in general failed to show significant gender differences in genetic etiology although this may be because of low statistical power. However, there has been increasing interest in searching for molecular genetic mechanisms such as imprinting effects and for X-linked susceptibility genes (see chapter 24) that might account for gender differences in the rates of psychopathology.

Phenotype Definition

One of the key problems in psychiatry concerns the definition of diagnostic categories and delineation of their boundaries. Although obviously this cannot, and should not, be determined only by genetic findings, such findings can be helpful. For example, both the twin and family findings on autism clearly indicate that the genetic liability extends well beyond the traditional diagnostic category of a severely handicapping disorder (Le Couteur, Bailey, Goode et al., 1996; Rutter, 2005). Similarly, the findings on schizophrenia indicate that the diagnostic concept needs to be extended to include schizotypal personality disorder but, equally, it does not include many other forms of psychopathology that are sometimes associated with schizophrenia (Kendler, Masterson, Ungaro et al., 1984).

Twin studies have been used to examine the extent to which genetic influences extend to variations in the general population, and the extent to which the magnitude of these influences is the same as those that affect extreme diagnostic categories. The basic method of analysis involves a type of regression analysis commonly known as the DeFries and Fulker method after the authors who first published it (DeFries & Fulker, 1988). The findings have shown that ADHD and dyslexia appear to lie on continua, with high scores being as highly heritable as scores within the normal range, although the power to detect differences at the extreme end using this method is low. In contrast, high adolescent depression symptom scores, at least when self-rated, tend to be predominantly influenced by shared environmental factors, whereas the rest of the continuum is more highly heritable (Eley, 1997; Rende, Plomin, Reiss et al., 1993; Rice, Harold, & Thapar, 2002). This suggests etiological discontinuity for adolescent-reported depression symptoms.

The other phenotypic issue that has been examined using twin study designs is informant (e.g., parent and teacher) agreement and disagreement (for discussion of informant issues see chapter 20). These methods have also been used to test ways of integrating information from different informants informed by different patterns of genetic and environmental contribution. Here, the twin strategy used is the same as that outlined for examining comorbidity. The aim is to examine the extent to which covariation between raters is a result of shared genetic and environmental risk factors. The findings of such studies have suggested that while parents and teachers rate a construct of ADHD that is influenced by a common set of genetic factors, there are also informant-specific genetic and environmental contributions. Twin studies have also been used to examine rater biases. For example, there is evidence that mothers, but not teachers, may contrast twins when rating ADHD symptom scores (see chapter 34), with a tendency to increase twin differences. This results in near zero or negative DZ twin correlations, which are biologically implausible.
CHAPTER 23

Potential Clinical Implications

Genetics research is of enormous scientific relevance but what is the current and likely future clinical relevance in child psychiatry? The answer does not lie in any supposed deterministic influence of genes. As Kendler (1995, 2005) has noted, the effects of all known susceptibility genes in psychiatry are quite low (with odds ratios in the region of 1.4). As a result, it is seriously misleading to refer to genes “for” schizophrenia, autism or indeed any other form of mental disorder. Accordingly, there is a very limited scope for genetic testing in the case of complex multifactorial disorders; this applies to almost all forms of psychiatric disorder. On the other hand, genes are involved in one way or another in the causal processes leading to all forms of disorder and it is imperative that clinicians understand how these operate (Kendler, 2005).

Supposed Dichotomy Between Genetic and Environmental Disorders

Traditionally, many clinicians and researchers have sought to make a main subdivision between disorders that are mainly genetic and those that are mainly environmental. A key message from genetics is that this dichotomy is largely false. Gene–environment correlations and interactions mean that, even with strongly environmental disorders such as post-traumatic stress disorder (PTSD), individuals vary greatly in their response to stress and adversity, and that this variation is genetically influenced in part. However, it is not just a question of individual differences in “constitutional” susceptibility to environmental hazards, it is also a matter of genetically influenced differences in exposure to such hazards. Clinicians, like researchers, need to pay attention to the origins of risk factors and to differential susceptibility to them. Moreover, it may be misleading to view the genetic influences as applying just to vulnerability. Thus, it has been suggested (Boyce & Jemerin, 1990) that evolutionary considerations mean that they may concern responsivity, with such responsivity working in both positive and negative directions.

Primacy of the Environment or Genetic Determinism

In the past, many clinicians assumed the primacy of the environment in contributing to child psychopathology and sometimes this view led to blaming parents for their children’s problems (see chapter 1). This style of blame was unacceptable on many different grounds – ethical and clinical, as well as scientific. However, genetic research (along with other research strategies) has been helpful in showing that parental behavior may be influenced by psychopathology and in indicating that this is subject to genetic and environmental influences and the interplay between them (Kendler & Prescott, 2006; Rutter, Moffitt, & Caspi, 2006). Far from implying genetic determinism, the findings point to the need to understand the complex mixture of influences on individual behavior. As we have sought to emphasize here, exactly the same applies with respect to children’s behavior. The additional message from findings on gene–environment correlations is that just as child-rearing experiences influence children’s behavior, so also children’s behavior influences how parents respond to them. Both genetic and environmental research are at one in pointing to the evidence that bidirectional influences are the rule rather than the exception.

Conceptualization of Disorders, Diagnostic Boundaries and Subtypes

Some genetic enthusiasts expect that genetic findings will form the basis of new classificatory systems for psychiatric disorders. We disagree. The disagreement is primarily because most classificatory schemes that concern multifactorial disorders are best based on pathophysiology rather than any single basic causal factor (because there is not one). Nevertheless, it is likely that genetic advances will indirectly influence and support both diagnosis and classification because they will (through associated biological studies) lead to a better understanding of pathophysiology and because they will be informative on the commonalities and differences among different disorders (Kendler, 2006). Already it is clear that genetic findings have forced a broadening of the concept of both autism and schizophrenia and have shown the importance of considering dimensional risk and phenotypic features (with respect, for example, to ADHD, antisocial behavior and depression).

Prediction

Families with a family history of disorder (e.g., schizophrenia or depression) may well wish to know what the risk of disorder is for offspring or siblings. At present, clinicians are reliant on global risk scores derived from family studies (e.g., informing the family that the child is four times more likely than the average child to show the condition in question). Unfortunately, such information – which deals with population risks – is of very limited value for individual prediction. Identified susceptibility genes will help personalize risks but it is important to appreciate that the risks will still be probabilistic, rather than deterministic, because the actual outcome will depend on the presence of other (as yet to be identified) susceptibility genes, contributory genetic background factors and exposure to relevant environmental hazards. Genetic counseling in the case of multifactorial disorder is a much more uncertain enterprise than in the case of wholly genetic Mendelian disorders (see chapter 73).

Nevertheless, genetic findings on G × E can be helpful in personalizing the nature of risks. For example, where there is a familial risk of schizophrenia, the use of cannabis may be more risky. Moreover, there is now evidence to indicate that those carrying a specific COMT gene variant are more likely to be unusually sensitive to the adverse effects of cannabis smoking on psychotic symptoms (Caspi, Moffitt, Cannon et al., 2005). These findings suggest that there are increased risks of using cannabis in this specific group.
For obvious reasons, the comparable genetic influences on susceptibility to child maltreatment and to life stressors do not have such a straightforward preventive implication. It would not be very helpful to recommend that children should avoid being physically abused and should avoid life stressors! Nevertheless, in the longer term there is a clinical implication. Once we understand why and how genetic factors influence susceptibility to risk environments, there will be implications for prevention and interventions. Also, pharmacogenetic findings may, in time, be helpful in indicating which individuals are likely to be responsive to particular medications and which have an unusually high risk of side-effects. The research findings, so far, do not provide such guidance (other than at a rather rudimentary level) but it is likely that they will be more helpful in the future.

Finally, genetic findings may be helpful in identifying individuals for whom interventions may be especially needed. Traditionally, it has often been assumed that these individuals will be those with disorders that are least influenced by genetic factors. The findings on G × E and rGE suggest that often the reverse may be the reality. The need for environmental interventions may be greatest in those who are genetically most vulnerable. Once more, the findings are not yet at a point at which they have a direct implication for action but they do challenge the traditional assumptions.

Nature of Environmental Interventions
Potentially, an understanding of genetic mechanisms should lead to important guidelines on what sort of environmental intervention is likely to be effective. The most striking example is provided by the Mendelian disorder of phenylketonuria. It is a real sense a wholly genetic disorder because the resulting metabolic defect (leading to profound intellectual disability) is entirely brought about by the genetic anomaly. However, because the clinical effects are brought about by the body’s inability to deal with the normal dietary component of phenylalanine, the effective treatment is provided by a radical change in diet. In an equally real sense, the resulting handicap is entirely environmentally determined (albeit entirely dependent on the presence of the genetic anomaly). We have no idea whether there will be any other equivalent in the field of multifactorial psychiatric disorders. Nevertheless, genetic knowledge indicates that we should not necessarily assume that the pathophysiological mechanisms will necessarily involve neurotransmitters. We may ask, for example, why it is that a disorder such as autism is so remarkably unresponsive to the medications used so far. The answer may lie in our having used the wrong drugs but, equally, it might be because the underlying pathophysiological mechanisms involve the immune system rather than neurotransmitters. That is, genetics can point the way to novel treatment targets for the development of specific pharmacological agents. The basic point is that we need to be aware that the brain is part of the body and of broader bodily systems and the underlying causal processes could involve these rather than (or in addition to) brain systems.

Conclusions
Genetics research into complex disorders, including psychiatric disorders, is at an exciting stage. This is not purely because susceptibility genes are beginning to be found, although this often captures most media and public interest, but because genetics is now moving into an era in which it is being integrated with epidemiological and psychosocial research whereby environment and genes are being examined together. Now that susceptibility genes are being identified, genetics is being increasingly embraced by other areas of neuroscience, notably molecular biology, imaging and neurocognitive science as well as mainstream epidemiology. The clinical implications are important and it is crucial not only that genetics research is informed by clinical practice, but equally that findings from these studies are recognized by clinicians and put into practice.

The term “behavioral” or “cognitive” phenotype is used to describe a typical style of behavior or cognition that occurs in association with developmental disorders, in which a genetic anomaly has been demonstrated. Behavioral or cognitive phenotypes reflect the maldevelopment of neural systems that are dysfunctional. Some such characteristics are common to many disorders, such as inattention. Others are found in association with specific genetic substrates. Behavioral phenotypes range from self-injury, hyperphagia and impulsivity to peculiar motor stereotypies. Cognitive deficits can affect visuospatial skills, language, social understanding and mathematical abilities. Occasionally, a particular genetic mutation, or deletion, is associated with a behavioral phenotype that looks like a known disease, such as autism or schizophrenia. The finding does not imply the genetic locus has any direct part to play in idiopathic cases of the syndrome. Major psychiatric disorders have a multigenic etiology; complex mental disorders are not caused by mutations in single genes, but we may get a clue about the neural systems involved in the etiology of idiopathic psychiatric illness by studying “phenocopies” that result from a known genetic etiology.

**Genetic Mechanisms Leading to Behavioral Phenotypes**

**Mutations and Polymorphisms**

Any germ-line alteration in the nucleotide sequence of cells that produce gametes (sperm or eggs) will be inherited by the cells of subsequent generations. Most changes are neutral, with no effect on the phenotype, because the genetic code-reading machinery does not transcribe much of the human genome. Transcribed genes are not all translated into protein products. Nucleotide changes within coding regions may simply substitute one synonymous codon for another. Neutral substitutions lead to DNA polymorphisms, or alternative forms of DNA sequence. Such polymorphisms (which may subtly affect the function of the gene, such as the speed of its translation) are important for tracking down genes in families or populations. The term “mutation” implies that the change in nucleotide sequence leads to an alteration in gene product that affects the phenotype. Evidence for such change will depend on the sensitivity of the measures used to detect it. In complex disorders, such as psychiatric conditions, the phenotype results from the interaction of several polymorphisms, interacting epistatically. One such mutation may be necessary but not sufficient to produce a phenotype. Others may be neither necessary nor sufficient in their own right. The genotype at any given locus may affect the probability of disease, but does not fully determine the outcome. Environmental factors also have a crucial part to play, for example, influencing the timing of onset of the phenotype and its severity.

**Mendelian Inheritance**

The term Mendelian inheritance is used to describe conditions in which single mutant genes are inherited that have a major impact upon the phenotype. Homozygotes have mutant alleles at the same genetic locus, on each of the pair of chromosomes that was inherited, one from mother and one from father. Recessive conditions, in the clinical sense, are seen only in homozygotes. Heterozygotes have two different alleles at the same locus, one of which is mutant. If the mutation is associated with a phenotype, that phenotype is dominant. Even though Mendelian mechanisms are conceptually simple, phenotypic manifestations are variable and multisystemic, because mutations of single genes do not always occur in exactly the same place. We have an excellent model of this mechanism in the Mendelian recessive condition cystic fibrosis. Whereas there is one common genotypic abnormality, more than 1300 mutations have been described in the CGTR gene (Haston & Hudson, 2005). Other anomalies comprise not only single-nucleotide, but also large deletions within the gene. Even among patients who are homozygous for the most common ΔF508 mutation, there is a wide variation in phenotype (e.g., in terms of pulmonary function), and new genetic modifiers are being discovered too (Drumm, Konstan, Schluchter et al., 2005). The degree to which the varying aspects of the phenotype manifest in affected individuals will depend crucially on the rest of their genetic make-up, as well as upon environmental influences. Currently, we know little about the role of genetic modifiers (elsewhere in the genome) in any disease, let alone psychiatric disorders, but they may directly influence the metabolic and cellular pathways involved in the primary pathophysiology of a susceptibility gene (Haston & Hudson, 2005) or they may act in secondary pathways that have a role.
in influencing the course of the disorder, especially one that is neurodevelopmental in origin.

**Chromosomal Anomalies**

Some behavioral phenotypes are brought about by abnormalities in chromosomal structure or in the total complement of material. The expression of several or even many genes is affected. Chromosomal abnormalities can be numerical or structural. **Numerical** abnormalities are associated with either the loss of one of a pair of chromosomes, or with the aberrant formation of more than one copy of a chromosome (as in trisomy 21, 45,X or 47,XXY). **Structural** anomalies are more subtle, and usually involve microdeletions of a few thousand nucleotide bases, or more rarely the loss of a substantial part of a chromosome. Such anomalies may occur during the formation of the sperm or egg, during formation of the zygote at the time the egg and sperm fuse, or after cell division begins in early embryonic development. In the former situation, the abnormality is going to be represented in every somatic cell. If the structural problem occurred later, in just a proportion of developing cells, the individual will be a mosaic for the abnormality. Some cells will show it and others will not. The distribution of the affected cells will be clonal, reflecting the original population of normal or abnormal cells from which they were derived. We should not expect the distribution of those clones to be random. It depends on whether the abnormal cells in question are able to function sufficiently adequately to contribute to the development of the particular tissue. If they are not capable of functioning to a certain minimal degree of efficiency, they could be selected against as the tissue develops over time, and would not then be represented.

**Structural Chromosomal Anomalies**

Small deleted regions, known as microdeletions, comprise just a few megabases (Mb) of DNA, affecting maybe 20 or 30 genes. Examples include 22q11.2 deletion syndrome, Smith–Magenis syndrome and Williams syndrome. Many genes, but not all, are required in two complete copies for normal function. If one copy is missing, there will be haploinsufficiency (insufficiency because the gene is haploid rather than diploid) for that gene product. In the past couple of years, submicroscopic deletions and other rearrangements of large chunks of DNA have been described. These are known collectively as structural variations, and include deletions of DNA (which may occur within a gene), insertions of DNA sequences, inversions and multiple copies of genomic DNA (Redon, Ishikawa, Fitch et al., 2006). Major aberrations in the gene sequences of people who otherwise seem healthy had not been expected, but now we know that each of us is likely to have some such variants in our genome. Their significance is still being determined, and clinical significance may be linked to whether they are inherited or whether they occur de novo. Those that are inherited are more likely to be benign. There is hope that structural variation may shed new light on complex diseases, such as neurodevelopmental psychiatric disorders in which the phenotype is caused by the interaction of many different genes, such as autism (Check, 2005).

**Epigenetic Mechanisms**

The study of epigenetics is relatively recent, and encompasses processes such as methylation or chromatin remodeling which leads to the silencing of genes, on one or other copy, early in development. While strictly speaking heritable, because such modifications occur during the formation of eggs or sperm, they do not change the structure of DNA and can be undone in the germ cells of the next generation. However, we have recently seen evidence that such epigenetically mediated changes in the phenotype could potentially be stable over many generations (Richards, 2006). Concerns have recently been expressed that epigenetic mechanisms could have a role in the disruption of patterns of DNA methylation in the embryo, which may lead to developmental alteration in the offspring with persistent changes in the germ-line (Crews & McLachlan, 2006).

Some hormonally active chemicals can have devastating effects on subsequent generations. For example, treatment with diethylstilbestrol (DES) during pregnancy results in vaginal cancer in the female offspring of humans, and mice. In mice, when mated to control males, female offspring who were not themselves exposed produce females who themselves develop the same rare cancer. There are equivalent transgenerational effects upon males, which have been described in rats treated with certain pesticides. The chemicals responsible for these plausibly epigenetically transmitted changes seem to act by mimicking or blocking endogenous hormones. They behave as biological signals that are misinterpreted by the organism. To date, most affect estrogen activity (and are misinterpreted by the organism as endogenous estrogens), hence they influence sexual reproduction directly or indirectly.

Crews and McLachlan (2006) suggested that the significant gender differences in relative risk of many psychiatric disorders (e.g., ADHD, autism, eating disorders) could imply that phenotypic manifestations are modulated by sex steroids (hormones). Endocrine disruptors could therefore indirectly influence manifestations of psychiatric disease, through this mechanism or even through an influence on maternal care. The work of Szyf, Weaver, Champagne et al. (2005) has shown that the quality of maternal care provided during the early postnatal period (by rats) is influenced by the stress that the mother was exposed to during her pregnancy. Furthermore, the quality of care she provides has an epigenetic effect on specific genes, concerned with neuronal growth in the hippocampus of her offspring. Many genes are potentially regulated by maternal care, and they can influence the behavior of that offspring in adulthood (Weaver, Meaney, & Szyf, 2006). Because the genomic changes are epigenetic, they are also potentially reversible. To date, psychiatrists have not often discussed epigenetic influences on the risk of mental illness, but this is likely to change quite soon as evidence accumulates in human as well as animal models implying specific mechanisms of dysfunction (Persico & Bourgeron, 2006; Rutter, Moffitt, & Caspi, 2006).
Imprinted Genes
A small proportion of genes are systematically different in activity, depending on whether they have been inherited from mother or from father. This phenomenon is known as genomic imprinting. There is expression of the gene in question from only one of the pair of alleles. Imprinting may only be detected in certain tissues, or at certain periods of development. There is no alteration in the underlying DNA sequence. The existence of imprinted genes in a region may be revealed when the only active copy is mutated and ceases to function, or is lost because of a structural abnormality of the chromosome containing it. Occasionally, the chromosome, or a region of the chromosome bearing the gene, undergoes uniparental disomy. Both copies of the gene (and part of the surrounding genome) are inherited from just one parent.

In general, the clinical phenotypes that result from abnormalities involving imprinted loci tend to be severe. To date, most imprinted genes have been described on the autosomes but Skuse, James, Bishop et al. (1997) proposed that imprinting of genes on the X chromosome could be associated with sexually dimorphic characteristics. Although we have yet to demonstrate the mechanism in humans, there is now evidence for imprinting on the mouse X chromosome having an impact upon a sexually dimorphic behavioral characteristic – anxiety in a novel and potentially threatening situation, which affects males to a greater degree than females (Davies, Isles, Smith et al., 2005).

Trinucleotide Expansion Repeats and Anticipation
Some dominant conditions result in phenotypes that become more severe in successive generations. A mechanism associated with this phenomenon is known as “anticipation,” and is exemplified by the Fragile X syndrome and by Huntington disease. Trinucleotide repeat expansions have been proposed as the biological basis of this phenomenon (Pearson, Edamura, & Cleary, 2005). Trinucleotide repeats are triplets of nucleotides, and those associated with anticipation usually comprise some combination of cytosine, guanine and arginine. These are designated CGG, CAG and so on. The repeats may occur within genes, or they may be found in regions of DNA that lie between genes. If they lie actually within genes they may be in transcribed sequences (exons), or within DNA sequences that are excised by the RNA-making machinery (introns). Expansions occur in the course of DNA replication. The repeats grow in length as they are passed from one generation to the next, and indicate germ-line instability. Paternal and maternal expansions could be driven by processes that are specific to sperm or eggs, but we do not know for certain why they occur. For reasons that we do not understand, there are proportionately more neurological than other diseases caused by expansion of CTG, CGG, CAG or GAA repeats. The conditions caused by the expansion are associated with considerable phenotypic heterogeneity, for there is variability in the length of the repeat sequences, and in the degree to which they disrupt transcription and function of the genes with which they are associated. Conditions associated with this phenomenon that have a characteristic cognitive or behavioral phenotype include Fragile X syndrome and Huntington disease.

Fragile X syndrome is caused by disruption to the *FMR1* gene on the X chromosome; within an untranslated region of the gene the fragile site normally has between 6 and 53 copies of CGG but in people with the disorder there are over 230 copies. Expansion of the repeated sequence only occurs when the unstable gene is transmitted by a female (Van Esch, 2006).

The distribution of CAG repeats in the coding region of the Huntington disease gene may be divided into four categories (Myers, 2004). Repeats of 26 or fewer are normal. Repeats between 27 and 35 are rare and are not associated with the expression of the disease, but occasionally fathers with repeats in this range will transmit a repeat to descendants that is expanded to the range for expression of the illness. Repeats between 36 and 39 are associated with reduced penetrance, and some affected individuals will develop the disease but others will not. Repeats of 40 or larger are associated with the phenotypic expression of Huntington disease eventually, although this may be late in adulthood.

Eight of the trinucleotide repeat disorders have the same repeated triplet, CAG, which codes for the amino acid glutamine. Consequently, they are commonly referred to as polyglutamine diseases (e.g., Huntington disease). Another six disorders do not have similar repeats and are classified as non-polyglutamine diseases (e.g., Fragile X syndrome). Polyglutamine (PolyQ) diseases are characterized by a progressive degeneration of nerve cells usually affecting people later in life. Although these diseases share the same repeated codon (CAG) and some symptoms, the repeats for the different polyglutamine diseases occur on different chromosomes. The non-polyglutamine diseases do not share any specific symptoms.

Behavioral Phenotypes Associated with Single-Gene Mutations
Duchenne Muscular Dystrophy
This X-linked recessive condition, the most common neuromuscular disease of childhood, occurs in about 1 in 3500 male births. There is an inexorable course, with proximal muscle weakness increasing through early adulthood, and death usually occurring before the third decade from chronic respiratory insufficiency.

The myopathy manifests fully only in boys. It results from microdeletions (60%), duplications (10%) or point mutations within the *DMD* gene (Xp21.2), which is the largest in the human genome (>2.0 Mb), and produces the protein dystrophin. A specific isoform of dystrophin is expressed in the brain. Becker muscular dystrophy is a milder form with the same underlying etiology, but with a much better prognosis.

The condition is associated with a mild to moderate degree of intellectual disability, affecting verbal skills in particular. Mean IQ is 80 and about one-third of children have IQs below 70. Behavioral characteristics include limited social skills, depression and a remarkably high incidence of autistic behaviors (social and communication deficits) in one-third or more
CHAPTER 24

of individuals (Hinton & Goldstein, 2007). There is a limited verbal working memory (Hinton, De Vivo, Nereo et al., 2001). The intellectual deficits are non-progressive and may even improve over time.

There is no simple correlation between the size or location of the deletion and the severity or prognosis of the muscular disorder (Prior & Bridgeman, 2005); however, mutations located at the 3′ end of the gene are not generally associated with intellectual disability. Inherited cases are invariably associated with maternal carrier status. No study has yet investigated the association with a behavioral-cognitive phenotype in mothers of probands, which would be influenced by random X inactivation. Dystrophin could play an important part in the function of GABA<sub>A</sub> receptors, especially in cerebral cortex, hippocampus and cerebellum (Muntoni, Torelli, & Ferlini, 2003).

Tuberous Sclerosis

Tuberous sclerosis (incidence 1 in 6000 neonates) is both genetically and phenotypically heterogeneous (de Vries, Humphrey, McCartney et al., 2003). Males and females are equally affected; the heritable form is autosomal dominant. There are structural neural abnormalities including cortical tubers, cortical dysplasia, subcortical heterotopias, white matter abnormalities, subependymal nodules and subependymal giant cell astrocytomas (Zaroff & Isaacs, 2005). Affected systems include renal, cardiac, pulmonary and dermatological, as well as the brain. The brain lesions develop in early fetal life. The syndrome has considerable phenotypic heterogeneity, probably partly because of the seemingly random distribution of the areas of abnormal cell proliferation; even monozygotic twins can have quite different phenotypes. Symptoms may take years to become apparent, and the condition often goes unrecognized or misdiagnosed.

Inheritance is autosomal dominant, but two-thirds of cases arise from a spontaneous de novo mutation. Either of two genes is responsible, both of which encode tumor suppressors: TSC1 on chromosome 9 (9q34) and TSC2 on chromosome 16 (16p13). Their protein products are hamartin and tuberin, respectively: intracellularly they form a dimer that prevents transcription and lead to silencing of the gene (Musci & Ferlini, 2003).

Epileptic seizures usually presage other problems, typically infantile spasms. Fewer than 50% of affected individuals have an intellectual disability, but there is probably a bimodal distribution of ability because nearly one-third have severe to profound deficits. Risk factors include the number, size and location of tubers and the type and age of onset of epilepsy, especially uncontrolled infantile spasms.

Cognitive deficits include dyspraxia, speech delay, dyscalculia and visuomotor disturbance. In childhood, behavioral complications include temper tantrums, aggression and attention deficit/hyperactivity disorder (ADHD; 50%). In adulthood, there is an increased incidence of emotional lability, including anxiety (60%) and depression (15–20%). Specific impairments in executive function skills, such as attention switching and planning, are particularly handicapping in adult life.

There is an association between tuberous sclerosis and pervasive developmental disorders (Bolton, Park, Higgins et al., 2002). TSC2 mutations are more likely to be associated with autism spectrum conditions. The risk of clinically significant autistic features is up to 50%, being highest if there is associated intellectual disability, early onset epilepsy and bilateral tubers of the temporal lobes. Chronic uncontrolled epileptiform activity may interfere with the normal development of social reciprocal functions.

Poor attention skills occur in up to 90%, with impaired vigilance, sustained attention, selective attention and response inhibition, even in those whose cognitive abilities are within the normal range. Their severity is correlated with the pattern of tuberous anomalies in the frontal, parietal and subcortical regions of the brain.

Behavioral and cognitive characteristics of tuberous sclerosis do progress. Educational difficulties are more pronounced as children move into secondary school, and demands on attention and other executive skills such as planning and organization become more complex and sustained. Emotional disorders can arise in adolescence, because of increasing self-awareness and the impact of subtle deficits in social reciprocity skills, reflected in limited or maladaptive peer relationships.

Fragile X Syndrome

Fragile X syndrome is the most common cause of inherited intellectual disability, affecting 1 in 4000 males (Pembrey, Barnicoat, Carmichael et al., 2001). A partial phenotype is seen in females, with a prevalence of 1 in 8000. Most mothers of boys with the syndrome have no knowledge of their potential risk for delivering an affected child, and have not been investigated for behavioral anomalies or cognitive deficits. Affected males have fairly distinctive physical features and behavioral characteristics. The most striking deficit is moderate to severe intellectual impairment, with most having IQs under 50.

Fragile X syndrome is caused by the deficiency or absence of the fragile X mental retardation protein 1 (FMR1). In well over 99% of cases, the molecular defect is an expansion of cytosine–guanine–guanine (CGG) repeats in the 5′ untranslated region of the FMR1 gene, which lies on the long arm of the X chromosome at Xq27.3. Large expansions in this region, known as full mutations (more than 200 repeats), inhibit transcription and lead to silencing of the gene (Musci & Caughey, 2005).

Fragile X syndrome is associated with a complex pattern of cognitive disabilities. Despite global intellectual disability, skills that require face and emotion processing, and theory of mind, may be spared (Cornish, Turk, Wilding et al., 2004). There is poor sequential on-line processing, short-term visuospatial memory deficits, impaired motor planning and a repetitive impulsive style of interaction. A characteristic form of repetitive and impulsive speech is found, together with an autistic style of conversation, including concrete understanding and use of language, and turn-taking difficulties. Inattent-
tiveness, restlessness and fidgetiness are more severe than in equivalent intellectual level. Psychiatric problems include anxiety, mood lability, social communication problems and selective mutism (Hagerman, Ono, & Hagerman, 2005).

The association between Fragile X syndrome and autism has intrigued researchers and clinicians for many years. Social anxiety and withdrawal, hyperarousal, peer relationship problems, stereotypic behaviors, gaze aversion and other anomalies of social reciprocity as well as language of an autistic type are found (Hessl, Glaser, Dyer-Friedman et al., 2006). Increased risk could be associated with the premutation as well as the full mutation (Hagerman, Ono, & Hagerman, 2005). It is rare to find the mutation among autistic children of normal range IQ. Just over 2% of autistic children overall will have the FMR1 full mutation (Reddy, 2005).

Rett Syndrome

Rett syndrome is a progressive neurodevelopmental X-linked disorder, occurring in 1 in 10,000–15,000 female neonates. Affected boys usually die soon after birth. Although devastating in its consequences upon normal development, the progression of the disease is variable. Progressive hypotonia, loss of speech and diminished eye contact occur, together with some autistic symptoms. Intellectual disability is almost invariably, together with seizures. Other features, thought to be peculiar to this syndrome, include compulsive hand movements that simulate wringing or washing, and hyperventilation. Following a period of early regression, affected girls may remain in a state where no further deterioration takes place for many years, so affected women can live at least to middle age.

The condition is caused by a mutation in the gene that encodes methyl-CpG-binding protein 2 (MECP2), which has widespread actions within the central nervous system; it lies at Xq28. MECP2 is required for the formation or maintenance of mature neurons and dendrites, and may have a critical role in the development of the monoaminergic system (Segawa & Nomura, 2005). It binds to other genes that play a critical part in brain development such as BDNF. Mutations may lead to erroneous amino acid production (hence an abnormal protein) or to premature truncation of the protein product. There are many different mutations (over 200 have been described), and variants may be sporadic or inherited. Despite having the classic features of the syndrome, up to one-quarter of clinical cases do not seem to have any mutation in MECP2, suggesting another gene may also be involved.

There are several stages in the development of the disorder. The earliest occurs 6–18 months after birth, and is associated with a general slowing of developmental progress. There is less eye contact, and diminished interest in the environment. Gross motor skills are delayed. After a few months there is rapid regression. The second phase, which comes on between 1 and 4 years typically, is associated with loss of spoken language and attempts to communicate, hand-wringing, together with other compulsive movements including clapping or tapping, and moving the hands back and forth to the mouth. Periods of hyperventilation and apnea disappear during sleep. In the third stage there is no further deterioration. Some autistic features can develop during the second stage, including indifference to people and poor eye contact (Mount, Hastings, Reilly et al., 2001) to a degree that is greater than in comparably profoundly retarded girls (Charman, Neilson, Mash et al., 2005). Finally, motor deterioration occurs, characterized by muscle weakness, scoliosis and loss of previously acquired skills such as walking, but no further cognitive deterioration. Sudden death can occur due to cardiac arrhythmias.

Attempts to find mutations within the MECP2 gene that could predispose to autism among males have not been productive. Few autistic girls have the mutation. Despite the theoretical implication that this X-inactivated gene’s pattern of inactivation in females will correlate with the phenotype, there is no clear evidence, although patterns of X inactivation in human brain cannot be determined in vivo (Weaving, Williamson, Bennetts et al., 2003). Some argue that in Rett syndrome and autism there are similar neuropathological changes, with a decrease in neuronal size and increased neuronal packing, together with a reduction in the arborization of dendrites (Segawa & Nomura, 2005; Shibayama, Cook, Feng et al., 2004). Both Rett syndrome and some cases of autism show abnormalities of the sleep–wake cycle, suggesting a possible common underlying pathology, involving abnormalities of brainstem aminergic neurons.

Microdeletion and Duplication Syndromes

Williams Syndrome

Williams syndrome (also known as Williams–Beuren syndrome) is a rare sporadic disorder with an incidence of about 1 in 7500 live births (Stromme, Bjornstad, & Ramstad, 2002). It is associated with a distinctive cognitive and behavioral profile, a superficial facility with language, sociability, good facial recognition and very poor visuospatial skills.

In over 90% of clinically diagnosed cases, there is a submicroscopic deletion on the long arm of chromosome 7 at 7q11.2 (Bayes, Magano, Rivera et al., 2003). This microdeletion contains several genes of possible relevance to the phenotype including:

1 Elastin (ELN), responsible for connective tissue problems including cardiac anomalies;
2 Lim kinase 1 (LIMK1), expressed in the brain, and linked to the visuospatial deficits of the syndrome by several authors (Hoogenraad, Akhmanova, Galjart et al., 2004);
3 General transcription factor II (GTF2I), linked to the intellectual disability associated with Williams syndrome;
4 Syntaxin1A (STX1A), a transcription factor involved in neurotransmitter release;
5 Bromodomain adjacent to leucine zipper 1B (BAZ1B), which may have metabolic influences;
6 Cytoplasmic linker 2 (CYLN2), which is strongly expressed in the brain, and may be associated with cerebellar abnormalities (Hoogenraad et al., 2004);
7 Another transcription factor (GTF2IRD1), which is implicated in the craniofacial and visuospatial anomalies (Tassabehji, Hammond, Karmiloff-Smith et al., 2005); and
**CHAPTER 24**

**8 Neutrophil cystolic factor 1 (NCF1),** associated with hypertension. Up to 20 genes may be deleted; the extent of the deletion is variable but the classic Williams syndrome phenotype is always associated with deletion of ELN, and usually LIMK1. Inversion of the segment of chromosome 7 occurs in about 7% of the general population, and in up to one-third of the parents of probands who transmitted the deleted chromosome 7.

Because of the considerable discrepancy between verbal and non-verbal abilities, the computation of an overall or Full Scale IQ is inappropriate (Meyer-Lindenberg, Mervis, & Faith, 2006). Verbal IQ averages about 70. Visuospatial skills are generally about 2.5 standard deviations below population norms. There is relatively preserved verbal short-term memory and verbal fluency, although it is qualitatively abnormal. Claims about the cognitive strengths of children with Williams syndrome (e.g., their innate musical ability) are based on massive ascertainment bias, a situation that applies equally to many other neurodevelopmental syndromes. Language acquisition in the syndrome is delayed, and the progression of language development may follow an unusual path (Scerif & Karmiloff-Smith, 2005). Grammatical abilities are consonant with verbal IQ. There is no unusual and sophisticated language as was once claimed. In general, pragmatic skills (language used for social communication) are weak.

The social interactions of children with the disease are not unimpaired; they are unusual and lack social reciprocity. Eye contact is sometimes good, and they possess empathic skills from infancy onwards. They are interested in faces – their technique for performing relatively well on tests of face recognition memory shows a cognitive style based on the sum of parts, rather than a gestalt of the face. The children are often uninhibited, and relate indiscriminately to unfamiliar children and adults, which may put them at social risk. They perform poorly on standard tests of attention. Tagger-Flusberg and Sullivan (2000) describe poor social–cognitive skills including theory of mind, and an ability to interpret other people’s facial expressions, especially negative facial expressions.

At this stage, there is no incontestable link between any single gene in the critical region and an aspect of the cognitive or behavioral phenotype. Some progress has been made by studying individuals who are lacking a smaller critical region than is usual (thereby apparently ruling out a few genes) and by the construction of animal models in which putative contributory genes have been knocked out. The greatest interest to date has focused on genes LIMK1 and GT2IRD1, together with CYLN2. All are thought to have some role in the visuonstructional deficits associated with the syndrome. While there is no doubt that ELN has an important role in many features of the syndrome, the gene is not expressed in brain and therefore it is not a candidate for cognitive aspects of the phenotype.

**Prader–Willi Syndrome**

Prader–Willi syndrome is a distinctive disorder, associated with a genetic anomaly on the long arm of chromosome 15, in which hyperphagia, mild to moderate intellectual disability and obesity combine with a typical developmental history. In the great majority of cases there is no inherited predisposition, but a sporadic event leads to the failure to express the paternal copy of the critical region. The estimated prevalence is 1 in 10,000–25,000.

This disorder is associated with structural rearrangements of a critical region about 4 Mb DNA in length, on the long arm of chromosome 15, at 15q11.2–3. The anomalies include deletions, translocations, inversions and supernumerary marker chromosomes, as well as uniparental disomy. Approximately 70% of individuals with the syndrome have a deleted segment of the paternally inherited copy of the chromosome. The critical finding is that the paternally inherited region is absent, and the maternally inherited region is silent (imprinted). In about 25% of cases both copies of chromosome 15 are inherited from the mother.

The most characteristic behavioral feature is hyperphagia (80–90% of cases), with an onset at 2 years (always before 6 years). Food-seeking behavior, hoarding and foraging, pica and consequent obesity occur, associated with elevated levels of ghrelin, a hormone produced by P/D1 cells lining the fundus of the human stomach that stimulate appetite (Butler, Bittel, & Talebizadeh, 2004). Sweet foods are often preferred, small amounts may be used as a reward to shape behavior. Temper tantrums, impulsivity, mood fluctuations, stubbornness and aggression and a variety of other characteristics including skin picking, repetitive speech, obsessive and ritualistic behaviors are reported (Milner, Craig, Thompson et al., 2005).

Children and adults with Prader–Willi syndrome are hypoactive and lethargic, in part because of co-ordination problems, resulting from hypotonia. Obesity following excessive eating will be increased by inactivity (Davies & Joughin, 1992; Nardella, Sulzbacher, & Worthington-Roberts, 1983). Sleep architecture studies show abnormalities too (Helbing-Zwanenburg, Kamphuisen, & Mourtazaev, 1993), with excessive day-time sleepiness. During the night, Prader–Willi syndrome is associated with limited rapid eye movement (REM) and slow wave sleep.

Average IQ is 60 and motor milestones are seriously delayed. Speech difficulties occur in around 80–90% (Cassidy, 1992). Deficits in attention, perceptual–motor integration are found, and sequential processing is weak. Just under half of children with Prader–Willi syndrome attend a mainstream elementary school, fewer attend a mainstream secondary school. There is no relationship between IQ and maladaptive behaviors.

There could be phenotypic differences according to the genetic anomaly, depending on whether chromosome 15 has been deleted, or both chromosomes are intact. Rare instances of point mutations in the imprinting center within the critical region might be different again. Patients with uniparental disomy could be less severely affected than those with deletions, with fewer facial characteristics, obsessive-compulsive symptoms and self-injurious behaviors, plus a higher verbal IQ. Hyperphagia is unaltered.
Within the past few years, interest has developed in the idea that 15q11 constitutes a region that could contain susceptibility genes for autistic disorders (Veenstra-Vanderweele & Cook, 2004). Duplications of the Prader–Willi syndrome critical region have been associated with autistic features of behavior, associated with presumed overexpression of maternally derived genes (Veltman, Craig, & Bolton, 2005). In deletion cases, there are two main classes described depending on the size of the deletion (Butler, Bittel, Kibiryeva et al., 2004). In one variant there are four non-imprinted genes deleted, one of which (NIPA1) is widely expressed in the central nervous system. It is possible that those with the larger breakpoint have a more severe phenotype in terms of performance on multiple psychological and behavioral tests. Adaptive behavior and specific obsessive-compulsive behaviors are worse in those with larger deletions, as are reading, math skills and visuomotor integration skills (Milner et al., 2005).

There is uncertainty about which genes in the Prader–Willi syndrome critical region are associated with the greatest risk of cognitive or behavioral abnormalities. Some assistance has come from the development of animal models, showing, for instance, that the small nuclear ribonucleoprotein N (SNRPN) is a prime candidate. This is expressed from the paternally inherited chromosome only, and is functional in the brain as well as other tissues. Other imprinted genes in the region include MKR3, NDN and MAGL2. The only identified protein products are for the SNRPN and MKRN3 genes, the latter being a zinc finger protein expressed from the paternal chromosome and presumably involved in transcriptional regulation.

Angelman Syndrome

Angelman syndrome is characterized by severe developmental delay, associated communication defects (little speech, non-verbal skills somewhat better) and gait ataxia (Williams, Beaudet, Clayton-Smith et al., 2006). All have excitability, apparent happiness, laughter and smiling with hand flapping, or waving. Most have microcephaly by the age of 2 years, and seizures before 3 years of age. The electroencephalogram (EEG) is characteristic, and associated with seizures. The prevalence is 1 in 15,000 live births.

There are imprinting defects in the same critical region as Prader–Willi syndrome, involving genes that are maternally expressed. Most (70%) have a 4–6 Mb deletion at 15q11.2–3. Uniparental disomy for parental chromosomes is rare (7%). A specific imprinting defect accounts for about 3% of affected individuals; 10–20% are microdeletions and in the other 80–90% there is an epigenetic mutation. Unlike the complex genetic etiology of Prader–Willi syndrome, Angelman syndrome is known to be caused by failure of expression of the gene UBE3A, a maternally expressed gene that is paternally imprinted. Molecular genetic testing identifies UBE3A anomalies in about 90%. It is unknown why the other 10% of phenotypically classic cases have no detectable genetic anomaly.

Abnormal sleep–wake cycles and a diminished need for sleep are common, together with a strange attraction to water and a fascination with plastics and paper that crinkles. The smiling and laughing, which are so characteristic of the syndrome, are dependent on contextual cues, and Horsler and Oliver (2006) warn against the concluding behavioral phenotypes being determined by the underlying genetic anomaly independent of environmental and developmental considerations.

Severe developmental delay is the rule, and a ceiling for psychomotor development occurs at about 24–30 months (Thompson & Bolton, 2003). Very few individuals develop even the simplest language for social communication. Visual skills and a social style based on non-verbal rather than verbal interactions are strengths.

There are differences in phenotype depending on whether the condition is associated with deletion, an imprinting deficit or uniparental disomy. In general, those with the deletion have the most severe phenotype (Williams et al., 2006).

**Smith–Magenis Syndrome**

Smith–Magenis syndrome is usually caused by (in 90% of cases) a microdeletion of the short arm of chromosome 17, at 17p11.2 (Potocki, Shaw, Stankiewicz et al., 2003), including the retinoic acid-induced protein 1 (RAI1) gene, which is probably both necessary and sufficient to cause the condition. Larger deletions may be associated with the deletion of PMP22, which carries with it a risk of a neuropathy in addition to Smith–Magenis syndrome. Virtually all cases are de novo. Incidence is about 1 in 25,000 births. Mutation screening of the gene is not routinely available. The most prominent clinical features of the syndrome are a distinctive facies, short stature, an increased risk of a range of health problems involving cardiac, renal and ophthalmic systems, and cognitive impairments together with a range of severe maladaptive behaviors that persist throughout the lifespan (Madduri, Peters, Voigt et al., 2006; Martin, Wolters, & Smith, 2006).

Infancy is characterized by feeding difficulties, failure to thrive, hypotonia, prolonged napping or need to awaken for feeds, and generalized lethargy. Significant sleep disturbance, stereotypies, and maladaptive and self-injurious behaviors are rarely apparent before 18 months of age. The sleep–wake cycle is inverted, associated with an inverted melatonin circadian rhythm and is a chronic lifelong problem. Individuals are awake at night and sleepy during the day. Whether this can be successfully treated with melatonin or beta-adrenergic blockers is as yet undetermined (Shelley & Robertson, 2005).

Adaptive behavior skills are worse as children grow into adolescence (Martin, Wolters, & Smith, 2006). Social skills are relatively preserved; patients are friendly, sociable and outgoing.

Neurobehavioral features of the syndrome are amongst its most striking features. They are severe, and include hyperactivity, distractibility, temper tantrums and attention-seeking, impulsivity, disobedience, aggression and toileting difficulties. Amongst the most unusual and disturbing behaviors are inserting foreign objects into body orifices including ears, nose, rectum and vagina (polyemoilokomania, up to 50%); pulling out of finger nails and/or toenails (ononychotillomania, 15–30%);
s, independent of cardiac or palatal complications, with motor skills in terms of day-to-day living. This suggests that the phenotype cannot wholly be caused by anomalies in the RAI1 gene. There has been no study of individuals with a point mutation in the gene, compared with those who have a deletion. It is presumed, but has never been assessed systematically, that many of the severe behavioral problems associated with the syndrome are worse than might be expected, given the degree of intellectual disability.

**Velocardiofacial Syndrome, 22q11.2 Deletion Syndrome**

Velocardiofacial syndrome (VCFS; Shprintzen, Goldberg, Young et al., 1981) is characterized by cardiac defects (~75%), cleft palate, intellectual impairment and a characteristic facial appearance, together with a genetic anomaly on chromosome 22 at 22q11.2. The incidence is estimated to be 1 in 3000–5000 live births. Most cases are sporadic but, when inherited, it has an autosomal dominant pattern of transmission. There is an increased risk of severe behavioral problems in children with the condition, and of major psychiatric illness in adulthood including mood disorders and psychosis (Murphy, 2002).

Up to 30% of adults with VCFS will develop a major psychiatric illness, the majority fulfilling diagnostic criteria for schizophrenia (Murphy, Jones, & Owen, 1999). The risk of mental health problems increases with age. ADHD and bipolar affective disorder are the most common diagnoses in childhood, but cognitive and behavioral phenotypes have been poorly described and are largely based on clinical observation rather than systematic assessment.

About four out of five patients with VCFS have a deletion at 22q11.2, with a proximal breakpoint that is similar in most cases (Weksberg, Stachon, Squire et al., 2007). Usually, about 40 genes are affected by the most common deletions.

During infancy there are serious feeding difficulties, independent of cardiac or palatal complications, with motor dysfunction in the oropharynx. Difficulty swallowing and nasopharyngeal reflux can be severe. Gross motor skills are poor, walking is usually not achieved until around 18 months. In a minority, symptoms similar to those of ADHD persist into adulthood.

By adolescence, people with 22q11.2 deletion syndrome express diverse psychiatric symptoms, the most prevalent of which are mood disruptions, attention deficits and psychotic phenomena (Baker & Skuse, 2005). Social and occupational functioning are significantly impaired. Some symptoms (psychotic experiences and frequent angry outbursts) are not found in most equivalently retarded children. Within the syndrome, there is no relationship between psychopathology and IQ. The majority report schizotypal symptoms, correlating with poor social functioning and few interests, and greater functional impairment as the individuals approach early adulthood.

Schizophrenia is a late manifestation in around 30% of cases, on a par with the risk to offspring of two schizophrenic parents (Murphy, Jones, & Owen, 1999). People with schizophrenia have an 80-fold increased prevalence of the microdeletion relative to the general population (Karayiorgou, Morris, Morrow et al., 1995). Individuals with schizophrenia and a 22q11.2 microdeletion are similar in age of onset, symptom profiles or medication responses (Bassett, Chow, AbdelMalik et al., 2003). Linkage and association findings also suggest schizophrenia susceptibility loci at 22q (Harrison & Owen, 2003). Proportionately more young people with the syndrome describe psychotic symptoms than the 25–30% who are predicted to go on to develop a psychotic illness (Baker, Baldeweg, Sivagnanasundaram et al., 2005), implying there is a continuum of psychotic disorder within the 22q11.2 deletion syndrome group from mild to severe, with no clear division between “affected” and “unaffected” categories.

The observed association in 22q11.2 deletion syndrome between older age and poorer functional adjustment reflects a process of intraindividual functional decline. Genetic high-risk studies have not as yet collected sufficiently fine-grained data in an adequate sample to observe such a decline in individuals who develop idiopathic adult-onset psychosis. However, recent clinical research aiming to facilitate early identification and preventive intervention for schizophrenia has identified high-risk groups of young people presenting to psychiatric services with prodromal symptoms. Recent reports from the largest such cohort indicate that, although attenuated psychotic symptoms are moderately predictive of risk of illness within a 12-month period, detection rates are greatly increased when measures of functional capacity and, crucially, recent functional decline are taken into account (Yung, Stanford, Cosgrave et al., 2006).

Psychopathological decline may be mirroring a process of neuropsychological (IQ and memory) and anatomical (medial temporal lobe) deterioration in already at-risk individuals (Pantelis, Yucel, Wood et al., 2003). Longitudinal follow-up of adolescents with 22q11.2 deletion syndrome will determine
whether a similar trajectory characterizes the emergence of debilitating psychotic illness in syndromal cases. Several small randomized controlled trials have now been carried out within clinically high-risk samples, to determine whether it is possible to prevent or delay deterioration in idiopathic schizophrenia by pharmacological or psychotherapeutic intervention. Findings from these trials have been mixed so far, limited by small sample size and short follow-up periods, but ongoing development of detection criteria and treatment protocols may yield results of clinical benefit. We do not know whether such intervention would benefit children with 22q11.2 deletion syndrome. It is also worth noting that autistic symptoms have recently been reported in close association with the syndrome, an observation that appears to have been formerly overlooked (Vorstman, Morcus, Duijff et al., 2006). Their clinical significance is at this juncture uncertain, and it is not known whether the subgroup with autistic spectrum disorders comprises the same children who are at risk of psychosis.

Intellectual impairment is usual, but not invariable. There is no significant difference between impairment of verbal and non-verbal skills in early childhood, but some verbal abilities become relatively poorer over time. Mean IQ is about 75. Standardized neuropsychological tests have identified a specific cognitive profile in 22q11.2 (Zinkstok & van Amelsvoort, 2005) with poor visuospatial memory (Simon, Bish, Bearden et al., 2003; Woodlin, Wang, Aleman et al., 2001) and low arithmetic attainment (Swillen, Devriendt, Legius et al., 1999). Deficits in executive function include poor cognitive flexibility (Woodin et al., 2001) and attentional focus (Bish, Ferrante, Donald-McGinn et al., 2005). By adulthood, verbal comprehension is about two standard deviations below the population mean, but vocabulary and the ability to detect verbal similarities are less severely affected, being on average about the 10th population centile. Non-verbal skills such as picture arrangement and block design are between the 5th and the 10th population centile. Executive function deficits, such as the Wisconsin Card Sort, are also moderately impaired (Chow, Watson, Young et al., 2006).

Children with VCFS have speech and language problems secondary to the cleft palate abnormalities, so speech sounds are hypernasal. Language development is often delayed and impoverished in content, with poor expressive skills, immature grammar, poor syntax and low utterance length. Concept formation is very limited, confined to concrete operations. Sight reading ability may be markedly superior to reading comprehension skills.

At least 40 genes are encoded in the commonly deleted segment in 22q11.2, the region containing a locus that may have a role in idiopathic schizophrenia (Norton, Williams, & Owen, 2006). There are at least three genes of interest (Karayiorgou & Gogos, 2004): PRODH, TBX1 and COMT. Paterlini, Zakharenko, Lai et al. (2005) have recently demonstrated epistatic interaction between the PRODH and COMT genes in mouse models, perhaps providing a basis for understanding the high risk of schizophrenia. Baker, Baldeweg, Sivagnanasundaram et al. (2005) proposed that allelic variants of the COMT gene in 22q11.2 could modulate performance on an evoked response potential task relevant to psychosis risk. The COMT gene contains a variant substitution of A for G at codon 108/158, which results in a triplet coding for either methionine (met) or valine (val). Baker, Baldeweg, Sivagnanasundaram et al. (2005) found that the met allele was associated with reduced fronto-temporal functional connectivity compared to val. In other studies, prepulse inhibition of the startle response was measured. Normally, we do not startle as much to a sudden loud noise if it is preceded by a softer noise within a critical time window, but response is abnormal in schizophrenia and schizotypal personality disorder (Braff, Geyer, Light et al., 2001). In the mouse model of 22q11.2 deletion syndrome, the genes that are critically needed for a normal prepulse inhibition response are TBX1 and GNB1l (Paylor, Glaser, Mupo et al., 2006). There are a few identified human patients with TBX1 mutations, and they may have behavioral phenotypes but their prepulse inhibition is not known. Mutations of TBX1 are associated with some of the physical deficits of the syndrome in humans (Yagi, Furutani, Hamada et al., 2003) as well as in mice.

Chromosomal Aneuploidies

Turner Syndrome

About 50% of clinically identified cases of Turner syndrome are associated with a single X chromosome (X monosomy), and affected females therefore have 45 rather than the usual 46 intact chromosomes (Jacobs, Dalton, James et al., 1997). Most lose the paternal sex chromosome. In 50%, there is tissue mosaicism for a complex variation. The prevalence is 4 per 10,000 live female births, the most common chromosomal aneuploidy.

All affected females will be short relative to their parents in adulthood. They have only one copy of a gene (SHOX) that is important for normal growth in stature and is required in two working copies (Rao, Weiss, Fukami et al., 1997). Turner syndrome is usually associated with degeneration of the ovaries soon after birth ("streak ovaries") so there are absent secondary sexual characteristics without estrogen replacement therapy. Verbal intelligence is normal, but there are associated deficits in non-verbal skills and in arithmetical abilities. Autismic traits, found in over 30%, are mainly in the domains of social reciprocity and communication.

In humans, partial or complete loss of one of the sex chromosomes, either the second X chromosome or the Y chromosome, results in the condition. It is associated with a phenotype because of two main influences. First, because there is insufficient dosage of genes that are normally expressed from both X chromosomes in females (Carrel & Willard, 2005). Second, hormonal factors secondary to degeneration of the ovaries leads to estrogen insufficiency. Genetic influences are probably the more important for cognitive and some aspects of social development.

Because males invariably inherit their single X chromosome from their mother, X-linked imprinted genes could theoretically have sexually dimorphic expression. Expression exclusively from
CHAPTER 24

the paternally inherited X chromosome can only occur in females (Skuse et al., 1997). Recent work with a mouse model of the syndrome has identified a paternally imprinted maternally expressed gene as having a circumscribed impact on a cognitive–behavioral phenotype (Davies, Isles, Smith et al., 2005), but no human equivalent has been found.

Adolescence is a time of difficulty for a number of different reasons: short stature, sexual immaturity and specific deficits in social cognitive competence. As adults, many women experience difficulties with social and partner relationships, and cannot fit into a normal work environment with adults. Consequently, many choose to work primarily with children and a disproportionate number find employment as nursery nurses. Social deficits are more severe among those who inherited their single X chromosome from their mother (Skuse et al., 1997).

Deficits in non-verbal IQ are typical, affecting 80%, and typified by poor ability to copy or recognize complex designs, visuospatial memory defects, and impaired motor task skills that are linked to visuospatial demands (Bishop, Canning, Elgar et al., 2000).

Deficits in socioperceptual processing are usual, affecting memory for faces, facial expressions of emotion (Lawrence, Kuntsi, Coleman et al., 2003b) and interpretation of direction of gaze (Elgar, Campbell, & Skuse, 2002). The risk of autism is increased at least 500-fold (Creswell & Skuse, 1999). “Theory of mind” skills are poor (Baron-Cohen, Wheelwright, Hill et al., 2003a; Lawrence et al., 2003b) to a degree that is more severe than in people with autism. A relatively specific deficit in recognizing “fear” from faces is as profound in women with Turner syndrome as in high functioning people with autism (Lawrence, Campbell, Swettenham et al., 2003a; Lawrence et al., 2003b). These claims of relative difference must, however, be taken as indicative rather than authoritative, because the tasks are sensitive to verbal and non-verbal intelligence, and show age-related differences (Campbell, Lawrence, Mandy et al., 2006).

Many phenotypic features of Turner syndrome are caused by insufficient dosage for a gene, or several genes, that are expressed from both X chromosomes in normal females (i.e., are not subject to X inactivation; Skuse, 2006). With the publication of the genetic sequence of the X chromosome (Ross, Grafham, Coffey et al., 2005) it has become possible to map susceptibility genes more accurately. Using the technique of deletion-mapping, which localized the only “Turner” gene identified to date (SHOX), we searched for a gene that influences social cognitive competence (Good, Lawrence, Thomas et al., 2003). We discovered that EFHC2, a brain-expressed gene important for the modulation of calcium-related neurotransmission mechanisms, is probably responsible for some of the social–cognitive deficits associated with the syndrome (Weiss, Purcell, Waggoner et al., 2007).

Klinefelter Syndrome (XXY Syndrome)

Klinefelter syndrome is a sex chromosome aneuploidy of males, occurring with remarkable frequency, perhaps as many as 1 in 500 male live births. It is associated with an additional X chromosome, which can be either maternal or paternal in origin (each is equally common). The physical phenotype is often not apparent until after puberty, and it is very variable. Tall stature is usual, with long limbs. Testis development is characteristically inadequate, and the majority of affected men are infertile. If the condition is not picked up in childhood, it may go unnoticed until adulthood, when it is revealed by investigations of infertility. However, the majority of cases are never identified clinically (Lanfranco, Kamischke, Zitzmann et al., 2004).

There is considerable variability in the cognitive and behavioral phenotype, but this is not because of tissue mosaicism, which is very unusual in Klinefelter syndrome. There is no clear relationship with parental age. The behavioral phenotype of Klinefelter syndrome may be associated with an increased risk of schizophrenia or affective disorder with psychotic features (Bojesen, Juul, Birkebaek et al., 2006; Delisi, 2005). There is autistic-like behavior in a proportion of 47,XXY males, who find social interactions difficult and who are introverted, anxious, impulsive, quiet, unassertive and socially withdrawn (Geschwind, Boone, Miller et al., 2000). Socially inappropriate and antisocial behaviors were once thought to characterize the syndrome, but this is probably because of an ascertainment bias (Bojesen, Juul, & Gravholt, 2003).

There are often poor verbal skills, particularly those used for reading and language comprehension (Bender, Linden, & Harmon, 2001; Delisi, Maurizio, Svetina et al., 2005). Verbal working memory is impaired (Fales, Knowlton, Holyoak et al., 2003) but non-verbal abilities tend to be unaffected.

As with Turner syndrome, where for years the social problems associated with the syndrome were attributed entirely to short stature and sexual immaturity, social difficulties in Klinefelter syndrome may also arise from deficits in social cognitive processing. Social cognitive deficits probably contribute to some of the behavioral characteristics of the syndrome (van Rijn, Swaab, Aleman et al., 2006). These include disturbances in perception, experience and expression of social cognitive information, executive functions, including response inhibition, but spared concept formation, problem-solving, task-switching and speeded response (Temple & Sanfilippo, 2003). Affected men may have increased emotional arousal in response to emotion-inducing events, they are excessively influenced by their emotions in strategic decision-making and they also find it difficult to perceive their own emotions, a state of mind reminiscent of alexythymia.

The parental origin of the additional X chromosome in Klinefelter syndrome has no obvious effect, but an additional paternal X chromosome might be associated with more impairments of fine and gross motor skills, and speech and language problems (Stemkens, Roza, Verrij et al., 2006). This finding is consistent with the Skuse, James, Bishop et al. (1997) hypothesis concerning X-linked imprinting because males would never normally inherit a paternal X chromosome; the implication is that by so doing one would expect a more severe phenotype. Lopes, Ross, Close et al. (2006) have suggested that the non-imprinted gene PCDH11X could be a candidate
for other symptoms. It has a homolog on the Y chromosome and is strongly expressed in the brain. Because current indications suggest it is likely to escape X inactivation (Ross, Wadekar, Lopes et al., 2006), the gene could be overexpressed in men with the syndrome.

Another contributory influence on the physical, but not necessarily the cognitive or behavioral phenotype, is the X-linked androgen receptor gene. This carries a nucleotide repeat polymorphism, the length of which is inversely associated with the somatic influence of androgens. XXY men with longer repeats within the gene on their active X chromosome have more feminizing traits, such as gynecomastia. Shorter repeats are associated with masculine traits such as greater adult penile length (Zinn, Ramos, Elder et al., 2005).

**XYY syndrome**

XYY syndrome is a sex chromosome aneuploidy of males, occurring in up to 1 in 1000 male live births (Ratcliffe, 1994). It is associated with an additional Y chromosome, which is invariably paternal in origin. The aneuploidy is not selected against before birth, presumably because the Y chromosome contains relatively few expressed genes (Robinson & Jacobs, 1999). Most boys with XYY syndrome are never diagnosed (Abramsky & Chapple, 1997). The physical phenotype is apparent before puberty, because of increased linear growth from around 2 years of age. Tall stature is usual, with a final height of nearly 190 cm, which is above the 95th male adult centile according to current norms (Ogden, Kuczmarski, Flegal et al., 2002). Testicular development is normal, and the majority of affected men are believed to be fertile. Apart from the excessively tall stature, and a possible associated acneiform disorder, there are no characteristic physical features.

There are occasional males who have XYY syndrome with mosaicism for a normal XY cell-line, and in them the physical phenotype is less marked. There is no greater risk of men, with either variant of the syndrome, producing children who have chromosomal anomalies. The various mechanisms by which the extra Y chromosome can be generated are discussed in Robinson and Jacobs (1999).

The behavioral phenotype of XYY syndrome was once thought to be strongly associated with criminality, resulting from observations at the time it was first discovered in the mid-1960s that suggested that an excessive proportion of affected males could be found in prison. Although early reports suggested males with the syndrome were more likely to commit criminal acts against people, there were concerns about ascertainment bias. A follow-up of an unbiased population sample (Gotz, Johnstone, & Ratcliffe, 1999) found a small but significant increase in the overall rate of offences, when compared with controls who had a similar number of years at risk. The causal mechanism could not be ascertained with any certainty, but one possible contributory factor was IQ, which tended to be lower in the XYY than in males from the general population. Interestingly, this group of investigators has reported a consistently higher social class distribution among XYY males’ families of origin than would be expected by chance, indicating that family background is biased against the emergence of criminal behavior. Pooled analysis of three population-based studies (Rutter, Giller, & Hagell, 1998) yielded a much larger unbiased sample and this showed a substantial increase in antisocial behavior (37.5% versus 13.0%) that could not simply be accounted for by lower IQ. In summary, there does appear to be an enhanced risk of antisocial personality traits, coupled with increased antisocial behavior, especially during adolescence.

Autistic-like symptoms have been observed in a proportion of 47,XYY males, but this association has not been investigated in any detail, and may simply be a coincidence (Geerts, Steyaert, & Fryns, 2003; Nicolson, Bhalerao, & Sloman, 1998). Cognitive abilities of males with XYY syndrome are within the normal range, but may be overall about one standard deviation below expected values in terms of both verbal and performance skills (Ratcliffe, 1999). There are reports of delayed onset of language, which may affect up to half (Geerts, Steyaert, & Fryns, 2003; Ratcliffe, 1999). Many have difficulty learning to read, to a degree that is disproportionate with their verbal intelligence, although they do not have comparable difficulties in numerical and arithmetical attainments.

Males with XYY syndrome are likely to be relatively clumsy, with especially poor fine motor skills. Few studies have looked at brain development by means of neuroimaging, but if there is any impact on structural features it must be subtle; to date, none has been reported. There is no evidence of anomalies that are equivalent in magnitude to those found among individuals with aneuploidies of the X chromosome. There is no increased risk of specific psychiatric disorders in childhood or adulthood, apart from a possible influence upon a combined schizophreniform–bipolar phenotype. However, psychiatric difficulties in general may be more common among both children with the disorder (who are reported to be more disruptive at school) and in adults (who are more likely to face marital breakdown, although not unemployment; Ratcliffe, 1999).

**Down syndrome**

The phenotype of Down syndrome (or trisomy 21 syndrome as some would prefer) is caused by a triple copy of the genes on chromosome 21, hence overexpression of genes that are normally tightly regulated. About 130 are expressed in the brain. As this chromosome was the first to be sequenced, it was hoped that genes that are primarily responsible for the phenotypic manifestations of the syndrome would soon be identified. Unfortunately, this has not proved to be the case (Gardiner, Davison, Pritchard et al., 2005; Patterson & Costa, 2005; Roubertoux & Kerdelhue, 2006).

The most striking features of Down syndrome include intellectual impairment. All individuals with the condition have a low IQ, although there is great interindividual variability. In a very small proportion of cases, not more than 2–3%, there is mosaicism for a normal cell-line; such children are likely to be less severely affected. Developmental delay from the outset is the rule, with late acquisition of motor skills – some
CHAPTER 24

children do not walk until 6 years of age. However, the pattern of motor skill acquisition is normal. Intellectual abilities are low, with an average IQ of about 45 and progressive deterioration with age, between early childhood and late adolescence (Vicari, 2006). In adults with the condition there is an increased risk of early onset dementia, which has many features of Alzheimer disease. The ability of children with Down syndrome to use language is very poor, and may be compounded by the hearing loss found in up to 80%. Comprehension of language is rather better, but it has been argued that linguistic skills in the condition follow an abnormal trajectory rather than simply being developmentally retarded. There may be preserved islets of ability (e.g., in terms of spatial processing), although visual perceptual skills are poor (Vicari, 2006).

The behavioral profile of children with Down syndrome varies with age – there is a degree of developmental progression (Capone, Goyal, Ares et al., 2006). During the preschool period, children may have sensory sensitivities (e.g., to sounds), which are associated with anxiety. In most other respects their behavior is unremarkable, but they show little interest in peers and play is rudimentary. By the time they reach school-age, hyperactivity and impulsivity are marked and can lead to management problems, especially if combined with oppositional and defiant behaviors. In recent years, it has become clearer that a substantial proportion of children with the syndrome have an autistic profile, including regression in cognitive, language and social skills (Capone, Goyal, Ares et al., 2006). The associated autistic symptoms include abnormalities in social reciprocity and interest in people, social withdrawal and stereotyped repetitive behaviors with sensory sensitivities. Adolescents and adults are at risk of emotional disorders, including depression and obsessive-compulsive behavior. Occasionally, very severe depressive symptoms are associated with psychotic phenomena.

There has been little progress made in understanding the relationship between abnormal gene expression in the region of trisomy on chromosome 21 and the human characteristics of Down syndrome. An alternative approach to investigating this issue entails using the mouse as a model of the syndrome, and the Ts65Dn mouse seems to be working well (Patterson & Costa, 2005). They have many of the features of Down syndrome in humans, including learning and memory deficits that imply abnormal hippocampal function, deteriorating cognition with age and several neural indicators of abnormal brain development. Aging in Down syndrome is accompanied by amyloid and neurofibrillary pathology, the regional and laminar distribution of which resembles pathological changes seen in Alzheimer disease (Teipel, Schapiro, Alexander et al., 2005). There is atrophy of the corpus callosum and hippocampus in non-demented subjects with age, and corpus callosum size (especially posteriorly) seems to be correlated with cognitive performance deterioration. To date, there has been little progress in discovering the genetic basis of systems that affect the phenotype, because of the immense complexity of those systems and the number of plausible candidates.

Conclusions

A major challenge in developing a truly scientific nosology of child psychopathology for the new millennium is to bring together expertise from multiple complementary disciplines. Such a plea has already been expressed in respect of adult psychiatry. Some years ago, many thought we would soon understand the biological basis of major psychiatric disorders in terms of anomalies in neural circuitry. Andreasen, Nopoulos, O’Leary et al. (1999) suggested that the clinical phenotypes of schizophrenia could be caused by a common pathophysiology (a neurodevelopmental mechanism), associated with misconnections in a cortical–thalamic–cerebellar–cortical circuit. Frith (2004) proposed that schizophrenia, dyslexia and autism, conditions strongly influenced by genetic susceptibility, could all result from functional disconnections between key neural processing centers. Over the past few years, we have seen the publication of the Human Genome Project and an explosion of work on psychiatric genetics. It is arguable that much of what we have learned about the pathophysiology of neurodevelopmental disorders has come from the intensive study of people with anomalous genomes, rather than from genomic linkage studies of affected relative pairs.

If there was any specificity between the genetic basis of the conditions described here and distinctive psychiatric disorders, we might be able to identify candidate genes that have a part to play (albeit perhaps indirectly) in the etiology of otherwise idiopathic conditions. However, we suspect the genes responsible for those idiopathic conditions in the general population are of small effect and individually they increase risk by only a marginal amount. Consequently, we should be cautious in concluding that there is any simple connection between, say, the mutation found in Fragile X syndrome or Rett syndrome and idiopathic autism. Both conditions are associated with gross maldevelopment of neural systems that affect general intelligence, as well as social intelligence. Within the last few years, one of the most striking discoveries in behavioral phenotype research is how many syndromes are associated with some features of autism. This lack of specificity could reflect, in part, the fact that many of them are also associated with moderate to severe intellectual disability.

We have known for many years that certain “single gene” conditions often have distinct autistic-like features, especially Fragile X (Brown, Friedman, Jenkins et al., 1982) and Rett syndrome (Hagberg, Aicardi, Dias et al., 1983), in which their prevalence is 30–40%. Theories have evolved to explain why such associations could lead to a revealing of idiopathic autism’s neural substrate (Belmonte & Bourgeron, 2006; LaSalle, Hogart, & Thatcher, 2005). When only a handful of genetic syndromes had been studied systematically this explanation seemed plausible. Now, given the diversity of conditions with a similar prevalence of autistic traits, the time has come to reappraise earlier optimistic conjectures. Duchenne muscular dystrophy is associated with autistic behaviors (social and communication deficits) in one-third or more of individuals (Hinton, Nereo, Fee et al., 2006). Tuberous sclerosis
Klinefelter syndrome (Geschwind, Boone, Miller chance, including Turner syndrome (Creswell & Skuse, 1999), autistic behavior at a rate far in excess of that expected by Gray
drawn and stereotypies of an autistic nature (Carter, Capone, Down syndrome children frequently display social with-
sion of maternally derived genes are associated with autistic
features in up to 50% (Bolton, 2004). Williams
syndrome but no demonstrable genetic anomaly, or who have
anomaly of the candidate gene but lack the classic symp-
tomatic phenotype. Second, it has proved extraordinarily
difficult to identify a clear relationship between the influence
of a single gene (out of several potential candidates) and any
aspect of the phenotype in conditions such as velocardiofa-
cial syndrome or Williams syndrome, where the “risk region”
of the genome is clearly defined by a microdeletion and every
nucleotide/gene in that region has been mapped. Third, the
intensive study of syndromes described in this review has
revealed a worrying lack of specificity about clusters of symp-
toms that were thought to represent coherent disorders, in the
sense that they were likely to have a common etiology. Most
of the disorders described are to a greater or lesser degree asso-
ciated with a substantially increased risk of autistic spectrum
disorders. In each case, the discovery of what appeared to be
a clue to the etiology of “autism” was greeted with great excite-
ment and sponsored new research efforts. If only we under-
stood why there was such a risk in tuberous sclerosis or Rett
syndrome, we would – so the argument went – gain insights
into the pathophysiology of autism itself. But then we find a
similar risk in Fragile X syndrome, velocardiofacial syndrome,
Prader–Willi syndrome, Turner syndrome, even Duchenne
muscular dystrophy (in each case the proportion affected
seems to be about 30%). These discoveries must call into
question the hypothesis that there is a specific genetic sus-
sceptibility (in each case) in common with idiopathic autistic
disorders. In all the examples given above, formal evaluation
of autistic symptoms using standardized measures demonstrates an enormously increased risk compared with the accepted population prevalence for autistic spectrum disorders of 0.6%.

Cognitive psychology aims to understand the adult mind by dividing it into component domains such as perception, language and executive functions, often employing evidence from lesions to determine localization by observing the absence of function after injury. It is arguable that the very plasticity and flexibility of the developing child’s central nervous system make it less susceptible to study by that approach (Scerif & Karmiloff-Smith, 2005). We hoped to identify genetic mechanisms that influence adaptive behavior by a similar approach to that used by cognitive psychology. Observe individuals with genetic anomalies, identify in what domains they differ from normal, and thereby link genes to processes that are associated with mental disorders. We believed that by so doing we could begin to understand the origins of the cognitive dysfunction that underlies much child psychiatric disorder. In a discipline for which there are few if any clear boundaries between “disease” and “normal” states of mind, a starting point that relies upon categorical disease (or disorder) models may not be appropriate for the investigation of putative genetic etiological mechanisms, even in highly heritable conditions.

Interestingly, since the last edition of this book there has been remarkably little progress made in identifying susceptibility genes for common childhood psychiatric disorders, although some promising findings are emerging with respect to ADHD, at the level of gene variant–symptom relationships (Faraone, Perlis, Doyle et al., 2005) by means of association studies. An alternative approach has also proved successful, albeit in a limited contextual framework. Here, the aim is first to identify plausible candidate genes from intensive studies of people with genetic anomalies (e.g., 22q11.2 microdeletions) and a heightened risk of psychiatric disorder. Second, to discover whether these genes have common variants with different functional activity (e.g., the 108/158 val and met variants of COMT which lie within the deleted region). Third, to genotype individuals from the general population (without psychiatric disorder) in order to investigate the variant’s influence on the neural structure and cognitive–behavioral characteristics of asymptomatic typical individuals. The approach is providing potentially valuable insights into genetic variants that do influence neural functions, and under what circumstances they do so (Meyer-Lindenberg & Weinberger, 2006), although deficiencies in experimental design and the optimistic interpretation of ambiguous results often characterize this line of work. To date, few candidate genes have been studied intensively by these means, and their role in susceptibility to major mental disorder is uncertain.

Arguably, in the search for genes that predispose to the development of symptomatically defined child psychiatric disorders it is both inefficient and conceptually muddled to seek the genetic components of relatively amorphous diseases (still less “comorbid” disorders). As Kendler (2006) reflected, it is highly unlikely that we will discover any direct relationship between gene variation and conventional categories of psychiatric disorder. Rather, we should look for evidence that functional variation in candidate genes influences neural functions that may be common to a number of diseases or disorders. We need to learn how genes control neurobiological development and, in so doing, increasing use will be made of animal studies (Gould & Gottesman, 2006). Creating a heuristic cognitive model of neurodevelopmental disorders will in due course lead to the integration of disciplines, as we seek the biological roots during childhood of psychiatric conditions whose clinical onset is in adulthood. Genetic influences (in the form of quantitative trait loci) on our predisposition to develop psychiatric disorders act throughout the lifespan. The proportion of variance in a trait that is explained by the candidate measured at a particular point in time may be small, just a few percent, yet even genes of such minor effect upon a measured state may be associated with a substantially greater cumulative risk because they have shaped developmental trajectories from embryonic beginnings. It behoves us to remember that stochastic and environmental events often play a critical part in translating a genetic predisposition, measured in terms of cognitive or other vulnerability, into the symptoms and behaviors that are characteristic of a defined syndrome.

To summarize, we agree with Scerif and Karmiloff-Smith (2005) that optimistic statements such as Pinker’s (2001) proclamation that we are now experiencing the “dawn of cognitive genetics” are premature. It is extraordinarily difficult to find any specific links between the functions of individual genes and circumscribed cognitive-level processes, although there are exceptions (Weiss et al., 2007). Reasons to be skeptical include the following issues. When we consider the impact of a genetic anomaly on cognitive or behavioral outcomes, we must first take account of the developmental processes and the possibility that the manifestations of that anomaly may differ along the trajectory from childhood to adulthood. When we choose to study those manifestations will strongly influence our conclusions about their impact. Second, we should be aware that it is very unlikely that the genetic anomaly (whether monogenic or not) affects just one cognitive system, even though that may be the most obvious manifestation. For example, it is notable that the majority of syndromes discussed in the chapter have non-specific effects upon generalized cognitive abilities quite apart from their more characteristic manifestations. To what extent more specific manifestations are a consequence of genetic variation quite remote from the genetic anomaly of interest is not clear, but the difficulty in finding any direct link between the (polygenic) anomaly in 22q11.2 microdeletion and the symptoms of psychosis despite over a decade of research should serve as a cautionary tale.

Although the overt manifestations of these conditions, in terms of their behavioral and cognitive characteristics, superficially imply that the genetic anomaly directly causes them, we need to be aware that there is very unlikely to be developmental independence between the mechanisms leading to the phenotype. Scerif and Karmiloff-Smith (2005) give, as
an example of this interdependence, the difficulty children with Williams syndrome have in understanding spatial language. They also have a fundamental problem with the concept of cardinality, and their verbal abilities predict their competence in that domain (unlike typical children for whom the predictor is visuospatial skills). They propose that a fundamental difficulty in abstracting the relational characteristics of the surrounding perceptual environment could account not only for that language deficit, but also for the problems with number development and configural interpretation of facial characteristics. Genetic anomalies are generally likely to operate at the level of such fundamental impairments, rather than at the refined level of “symptoms” or higher cognitive skills such as language (Marcus & Rabadagliati, 2006).

In practical terms, the knowledge that genetic anomalies such as those described here are often associated with characteristic patterns of behavior and cognitive deficits can be of great significance for the appropriate management of the condition. That knowledge can be reassuring to parents, and can lead to a rational basis for educational support. We must remember not to be seduced by our knowledge of the genotype into a state of genetic determinism—whatever the nature of the anomaly, there are usually potential compensatory mechanisms.

Our role, as clinicians, is to find them, implement them and support the family until they are firmly embedded in the child’s social or educational repertoire.

CHAPTER 24

BEHAVIORAL PHENOTYPES AND CHROMOSOMAL DISORDERS

Human development is the process of individual adaptation to a complex and ever-changing environment. At times the adaptation is smooth; the environment provides support to the individual and the individual is able to use their own skills in a successful adaptation to their circumstance. At other times, however, the adaptation of the individual fails. This may be because the challenges in the environment are too great, the individual’s abilities in adapting to their environment are insufficient or both individual and environmental factors combine together, such that the failure of adaptation can only be explained by understanding the ways in which both sets of processes operate together. This is called the study of risk and resilience. In this chapter we examine the environmental circumstances that pose challenges for children’s development. We also consider why some children seem to manage better than others under similar degrees of environmental stress.

Much of our knowledge about processes of risk and resilience in children come from epidemiology. Population studies carried out from the 1960s onwards (Offord, Boyle, Szatmari et al., 1987; Rutter, Tizard, & Whitmore, 1970) examined the ways in which mental health problems correlate with environmental adversity. Children have been found to show differential levels of aggression and violence as a function of countries, neighborhoods, schools and families (Boyle & Lipman, 2002; Jenkins, Simpson, Dunn et al., 2005; Rutter, Maughan, Mortimore et al., 1979). By studying characteristics of the environment and relating it to rates of disorder we have learned much about which children are likely to show problems. The bulk of the research that we present deals with findings from correlational studies (see chapter 5). Children are observed in their natural environment and patterns of correlation between their mental health and their environment are examined. Understanding patterns of correlation, although an important step in understanding causal process, is not equivalent to it. In order to understand the very specific mechanisms that are likely to explain why some children are more vulnerable than others, we need to draw on results from studies based on other designs.

In illustration of this problem we present the results from a study carried out by the author and colleagues to investigate protective factors of children exposed to marital conflict (Jenkins & Smith, 1990). This was a cross-sectional interview study with children and parents. First, we found that children being raised in high-conflict homes showed more disruptive behavior than children being raised in low-conflict homes. Second, we found that children living in high-conflict homes who had very close relationships with siblings or grandparents showed much lower levels of disturbance than children without a close relationship with a sibling or grandparent. Two conclusions suggested themselves. First, a process in the environment (exposure to parental conflict), either through modeling or some other learning mechanism, caused children to be aggressive. Second, social support from siblings and grandparents helped children in high-risk circumstances to withstand the adverse effects of those circumstances.

However, on the basis of the design it was impossible to rule out other explanations. The association between marital conflict and child adjustment might have been entirely genetically mediated. Biological parents pass on both genes and environments to children. Without some means of disentangling these two sets of influences we cannot conclude that environmental mediation operated.

The interpretation of social support as a protective influence was also questionable. A “child effect” (O’Connor, 2002) may have been operating such that characteristics of the child elicited social support from others. In other words, aspects of children’s personalities may contribute to the environments that they shape around themselves. The critical point is that the mechanism is unclear.

Fortunately, data from different kinds of designs can help disambiguate such findings. Before presenting evidence on psychosocial adversity and resilience we describe the contributions that design innovations have made to this field.

Research Designs that Disambiguate Effects in Risk and Resilience Research

Experimental Design

The essence of experimental design is the random assignment of individuals to conditions. If we could:
CHAPTER 25

1 Randomly assign children to homes in which they either experienced a lot of marital conflict or a little;
2 Ensure that both groups were equivalent on children’s mental health at the start of the study; and
3 Hold all other aspects of the environment constant, then any changes in mental health could only be attributable to their exposure to marital conflict.

Because of the nature of the factors in risk research, however, random assignment to experimental conditions would never be allowed in children. Animal models are extremely valuable in this regard. Both rodents and non-human primates have been exposed to extreme environmental conditions that provide analogs to environmental risk that humans experience. Such studies have shown that environmental stress does change the neurobiology, physiology and behavior of the developing organism (Sanchez, Ladd, & Plotsky, 2001). Experimental paradigms offer the only incontrovertible method for establishing a causal effect. Of course, the problem with these models is one of generalization. Can the meaning of stressors be equated for humans and animals? How do we know whether humans respond in the same way as the species under investigation?

A second source of experimental data, also helpful in showing that environmental stress has a causal role in children’s outcomes, comes from intervention studies that aim to reduce environmental adversity. Children showing disturbance and their families have been randomly assigned to treatment conditions in which the goal is to reduce one of the following environmental adversities: problematic parenting (DeGarmo & Forgatch, 2003; Olds, 1989), marital conflict (Stanley, Amato, Johnson et al., 2006), neighborhood adversity (Leventhal & Brooks-Gunn, 2004); or a combination of high-risk circumstances including negative peer influence and parenting (Chamberlain & Reid, 1998). Results show that reducing environmental adversities does result in reduced psychopathology for children, lending support to the proposition that environmental adversity has a causal influence on behavior.

Disentangling Genetic from Environmental Influence

Genetically sensitive designs have been developed to tease apart genetic and environmental influence. As parents provide children with both genes and the environment in which children are raised, normal epidemiological designs confound these two influences. Details of behavioral genetic designs, including a critique of their strengths and weaknesses, can be found elsewhere (Rutter, 2002; also see chapter 23). Here we briefly describe the logic of the design and its importance for interpreting findings from risk and resilience research. The twin design teases apart genetic and environmental influences by comparing siblings who share 100% of their genes (monozygotic [MZ] twins) with those who share only half of their genes (dizygotic [DZ] twins). Knowing the degree of genetic similarity between the two types of twin and comparing their behavioral similarity allows one to make an inference about the relative importance of genes and the environment. The same estimates can be made utilizing samples of full, half, unrelated siblings and cousins (Guo & Wang, 2002). Results from genetically sensitive designs show that genetic influences are considerable, that siblings are more dissimilar than similar on behavior and personality once genetic effects have been controlled, and that environmental influences are considerable given that genetic influence rarely explains more than half the variance in behavior (Plomin, 1994; Rutter, Silberg, O’Connor et al., 1999).

Three other genetically sensitive designs also provide evidence for environmental effects. The first type of design attempts to explain differences between MZ twins through exposure to adversity in the environment. As MZ twins are genetically identical, any differences in their behavior cannot be attributed to genetic influences. Investigators have found that differences in the child-rearing environment between two siblings have explained differences between the twins in their behavior (Casper, Moffitt, Morgan et al., 2004). A second genetically sensitive design involves an examination of the association between adversity and child outcome when parents and children are not genetically related. An association between parental divorce and disturbed child behavior was found amongst unrelated parents and their children (O’Connor, Caspi, DeFries et al., 2000), suggesting that an environmental mechanism explained the association between divorce and child behavior.

The advent of molecular genetics has allowed for the investigation of gene–environment interaction in behavior: individual children may be more susceptible to the influence of negative environments if they carry specific polymorphisms on specific genes. Recent work in this area has shown evidence for this hypothesis in children (Casper, McClay, Moffitt et al., 2002; Caspi, Sugden, Moffitt et al., 2003). Candidate genes are identified on the basis of animal work as well as case-control studies in humans. Levels of psychopathology amongst individuals in the population are examined as a function of environmental stress, polymorphisms of the gene under investigation and their combined effects that constitute the gene–environment interaction.

Longitudinal Models

Time has an important role in the attribution of causality when correlational data are examined. One criterion for arguing causation is that cause must precede effect. In a cross-sectional design this condition cannot be met. By utilizing longitudinal data we can examine whether an adverse environmental condition existed prior to a behavioral outcome and whether the condition predicts change in the behavioral outcome (see chapter 9). An autoregressive design deals with this issue: effects on behavior at time 2 are predicted by time 1 environmental adversities, while controlling for time 1 behavior. A cross-lagged design enables us to examine reciprocal effects: what effect do two factors have on one another over time? In these designs two processes that covary (e.g., parental harshness and difficult child behavior) are examined over time and the goal is to examine which of the two processes predicts change
in the other more strongly (e.g., marital conflict predicts change in child behavior or child behavior predicts change in marital conflict). Examples of such designs can be seen in Hetherington, Henderson, Reiss et al. (1999) and Jenkins et al. (2005). Examining reciprocal effects is particularly important when family relationships are postulated as the psychosocial adversity. Family members are so proximal to one another, with so many occasions for mutual influence, that we need a design that will help differentiate between influences of different members in order to attribute causality correctly. Autoregressive and cross-lagged analyses investigate general patterns of association between measures in groups of children.

Growth curve modeling (Singer & Willett, 2003) investigates changes for individual children. In this, the behavioral trajectory of individual children can be modeled over time. Circumstances that vary in children’s lives such as moving in and out of poverty, or changes in parents’ marital circumstances (called time-varying predictors), can be used to explain changes in children’s functioning. As we are using changes in the environment to predict changes in the child, the likelihood that associations are spurious is reduced. With such data it is still possible that a third variable, associated with both changes in the environment and changes in the child, is responsible for the correlation, which is why covariates are always entered into such models (see chapter 9).

Natural Experiments

One of the difficulties with correlational designs is that risks co-occur such that we have problems isolating the causal mechanism. Several investigators have capitalized on naturally occurring changes in environments to simulate a “natural experiment.” The goal is to hold everything constant while one thing, the causal mechanism of interest, changes (Rutter, Pickles, Murray et al., 2001). This method has been used to examine the impact of maternal anxiety on the developing fetus (King & Laplante, 2005), as well as the effects of poverty (Costello, Compton, Keeler et al., 2003) and maternal deprivation on children (Rutter & O’Connor, 2004). Experiments are most closely simulated when the “condition effect” occurs randomly. Thus, when maternally deprived and non-deprived children are compared, the assumption is that the children in the two groups would have been indistinguishable before exposure to the stress and none of their characteristics influenced their membership in either group (referred to as a selection effect). When examining results from “natural” experiments it is important to evaluate the extent to which this condition has been met.

Testing Competing Models of Mechanism

In testing causality, the importance of working with competing models, not just disconfirming the null hypothesis, is well documented (Cochran & Chambers, 1965). In this type of study, several causal explanations of behavior are compared on the extent to which the different explanations explain the data. Jenkins, Shapka, & Sorenson (2006) examined the indirect effects, over a 12-year period, of maternal anger on children in a sample of women who had given birth when they were teenagers. Two potential mechanisms through which maternal anger prior to the birth of the child could lead to increased child opposition 12 years later were contrasted: exposure to partner conflict or partner relationship transitions. They found stronger support for the mechanism of partner conflict than relationship transitions.

Effects of Psychosocial Adversity on Children

Conceptual Issues

Before turning to empirical results on psychosocial adversity it is important to consider conceptual issues that must frame our interpretation of existing findings. We do this by considering the role of distal and proximal influences, the extent to which psychosocial adversities are shared by all members of a family or are child-specific, and the mechanisms through which environments affect behavior.

Multilevel Effects: Distal and Proximal Influences

Bronfenbrenner (1979) proposed a model for understanding context effects on children. He suggested that development occurred within embedded “layers” of context. The first layer involves relationships in which the child takes part: relationships with parents, siblings and peers. These interactions are embedded within structures that have a bearing on how the relationships develop. Thus, the pattern of interaction that occurs in a stepfamily is different from that in an intact family (Hetherington, Henderson, Reiss et al., 1999). Bullying in a peer group is a function of the number and proximity of teachers supervising in the playground (Stephens, 1997). More distal influences such as the economics of the community in which school and family structures are embedded will have a further impact on their functioning. Cultures, cultural values, customs and laws represent yet another layer. Such distal influences can be significant, for instance in national differences in homicide (Krug, Powell, & Dahlberg, 1998) related to laws surrounding gun control.

It is necessary to distinguish proximal and distal influences on children. These are relative terms to connote the proximity of the influence on the child. For instance, a friendship with a deviant peer is a more proximal influence than the child being raised in a high-crime neighborhood. Although distal and proximal are simply descriptive terms, they are most commonly used within the framework of mediation. Within this framework, proximal influences have a direct influence on children’s functioning, and distal influences have a direct influence on the proximal process but an indirect influence on the child. Poverty leading to an increase in harsh parenting, which in turn has an influence on children’s antisocial behavior, are examples of distal and proximal risks within a mediation model (Baron & Kenny, 1986). A mediational model requires that a direct effect is established between the distal process and both the mediator (proximal process) and the outcome, when
bivariate correlations are examined. When both the distal and mediator variables are in the model, the mediator should explain some of the variance in the outcome which was initially explained by the distal variable.

Mediation models are often considered to be “causal” models: the mediator is conceptualized as the active agent that is causally responsible for the relationship between two other variables. It is important to note, however, that theories of causation are very discipline-based and influenced by our current scientific knowledge. For example, although “modeling” offers a causal mechanism for behavioral scientists, for neuropsychologists causal mechanisms occur at synapses. For a neuropsychologist, a parent’s aggressive displays towards a child will always be an indirect effect, explained by the more proximal mechanism of the change in neurotransmitters that influences behavior. One of the challenges in developmental science is to link up explanatory mechanisms at different levels of description.

**Family Level and Child-Specific Risks within Families**

One of the most intriguing findings from behavioral genetic research is that children who are raised in the same family and thus share a common environment are more dissimilar than similar after controlling for genetic effects (Plomin & Daniels, 1987). How can environmental influences operate if children develop so differently from one another while exposed to similar influences? We need to distinguish between two aspects of environmental influence: the objective and effective environments (Turkheimer & Waldron, 2000). The **objective environment** refers to the measured environment that children experience: the amount of parental conflict in their home, the parenting that they receive and the income level of parents. The **effective environment** is not directly measured but refers instead to the extent of sibling similarity (given that siblings are raised in a similar environment). The concept comes from behavioral genetics. In this field, inferences about the operation of the environment are made on the basis of the similarity and differences between siblings on behavior and personality (after accounting for genetic effects; see chapter 23). Findings about sibling dissimilarity, once genetic effects have been accounted for (the effective environment), have led environmental researchers to develop more sophisticated ways of thinking about how objective environments affect children.

The objective environment can be divided into the family and the child-specific. Environmental risks that are held in common by all siblings in a family can be thought of as family level risks (e.g., parental divorce). Experiences such as the way that a parent relates to a child, or the child’s peer relationships, will vary across children in the same family and are therefore child-specific. Risks that we might think of as family level, such as parental conflict, depending on the way in which the construct is measured and the way that it is expressed in a family, may be child-specific. Jenkins et al. (2005) found that siblings had more similar experiences of exposure to parental conflict than they had about the amount that parents argued about them. Thus, exposure to parental conflict is more of a family level risk than amount of parental argument about children.

As siblings are more dissimilar than similar once genetic effects have been taken into account, some have argued that family level environmental influences cannot have a large causal role in disturbance (Harris, 1998). This is not the case. It may be that family level risks are important influences on behavior but they operate by increasing dissimilarity between siblings. Jenkins et al. (2005) found that marital conflict at time 1 increased the dissimilarity between siblings on disruptive behavior from time 1 to time 2. This is likely to be because of endogenous factors already operating within children at the time of the stress. One sibling may react to parental conflict with increased aggression, but in a child without such a behavioral tendency, increased aggression will not occur.

A second source of sibling difference is the set of risk factors unique to individual children (e.g., hostile parenting and negative peer relationships). Although child-specific experiences are certainly important in understanding sibling differences, they have not been found to explain as much variance (1–5%) in sibling differences as was once hoped (Turkheimer & Waldron, 2000). By differentiating between family level and child-specific risks and utilizing research designs that allow us to look at both the objective and effective environments, we can gain some clarity on the ways in which adverse environments influence children.

**Mechanisms Involved in Stress Causing Emotional and Behavioral Disturbance in Children**

Probably the best way to think about the adverse effects of stress on humans is to think about the way in which environmental adversity affects the emotion system. Emotions involve many component processes with manifestations that can be biological, behavioral, cognitive or relational. The emotion system refers to all these component parts that make up emotional experience. Thus, the experience of anger is associated with characteristic muscle movements of the face, cognitions about the intent of other people in their actions towards the self, as well as behaviors such as raising the voice and aggression towards others. There are also characteristic interpersonal consequences from the expression of anger (for a review of all of these areas see Oatley, Keltner, & Jenkins, 2006). Although connections across components of the emotion system have been established (Oatley, Keltner, & Jenkins, 2006; Panksepp, 1998), there is enormous complexity in how experiences in one part of the system affect another. Thus, associations have been shown between biology and behavior; cognitions and behavior; behavior, cognition and relationships. However, the direction of causality is not well understood, and bidirectional influences are likely. Thus, depression is thought to involve a perturbation of the neurotransmitter serotonin. Cognitive therapy, shown to be effective in the treatment of depression, involves changing cognitions with a consequent change in behavior and mood. Have cognitions changed neurotransmitters?
Stressful environments have been shown to affect all levels of the emotion system. Experiments with rodents and non-human primates show that multiple biological systems are affected including the hypothalamic-pituitary-adrenal (HPA) axis, neurotransmitter systems and brain cytoarchitecture (Fleming, 2006; Kraemer, 1992; Repetti, Taylor, & Seeman, 2002; Sanchez, Ladd, & Plotsky, 2001). In humans, environmental stressors have been shown to influence the functioning of the HPA axis, patterns of cognitive appraisal, emotion understanding, perception of others’ emotions and psychopathology (Bugenthal, Martorell, & Barraza, 2003; Cole, Teti, & Zahn-Waxler, 2003; Dodge, Bates, & Pettit, 1990; Fries & Pollak, 2004).

Empirical Findings on Distal Risk Factors
Distal risk factors are those associated with behavioral problems in children, which increase the risk of proximal stresses and play an indirect part in children’s disturbance.

Deprived Neighborhoods
Deprived neighborhoods have impoverished conditions characterized by high unemployment rates, predominate minority populations, dense public housing, crime and violence, as well as social isolation (e.g., Massey & Kanaiaupuni, 1993). Effects of deprived neighborhoods account for 5–10% of the variance observed in developmental outcomes (Leventhal & Brooks-Gunn, 2000).

Boyle and Lipman (2002), in a Canadian sample, found that 4–5% of the variance in teacher reported emotional and conduct problems was attributable to neighborhood. Xue, Leventhal, Brooks-Gunn et al. (2005), in Chicago, found that 11% of the variance in emotional disturbance was attributable to the neighborhood. Further, using an autoregressive design, they showed that characteristics of neighborhoods predicted a change in emotional disturbance over 2 years. This provides more compelling evidence than a cross-sectional study for a causal effect. However, methodological problems of a correlational design remain. Although many individual and family level characteristics are included in models examining the effect of neighborhoods on children, it remains possible that uncontrolled effects at the individual and family levels contribute to the neighborhood effect (poor families end up in poor neighborhoods; Duncan, Connell, & Klebanov, 1997).

Results from an experimental study (Leventhal & Brooks-Gunn, 2004), the Move to Opportunity (MTO) program, provide more compelling causal data. Families recruited from high-poverty neighborhoods in the USA were randomly assigned to the experimental or control condition. The experimental group was given vouchers to move to a low-poverty area. Control families were not offered the option of moving. Children’s achievement was tested on standardized reading and math tests 2.5 years after their families had entered into the program. Approximately 40% of families in the experimental condition took up the option of moving and effects were calculated for all families (intention to treat). Positive effects were most evident for adolescent boys, who showed significantly higher scores on reading and math than boys in the control group. Children who moved to low-poverty neighborhoods were found to engage in more homework, which was identified as a partial mediator of the program effect. Some caution must be exercised about the long-term benefits, as a subsequent follow-up (Leventhal, Fauth, & Brooks-Gunn, 2005) did not reveal significant program effects (thought to be the result of selective attrition in the control group).

One component of the neighborhood effect may be exposure to violence, with most relevant studies sampling in deprived US cities. Gorman-Smith and Tolan (1998) interviewed African-American and Latino adolescents in public high schools in deprived neighborhoods in the Chicago area, with the majority of the sample living in poverty. They found that 16.5% reported that a family member had been robbed or attacked and 15.6% had seen someone shot or killed in the previous year. These rates are consistent with those reported by others working with samples drawn from deprived US neighborhoods (Aisenberg & Ell, 2005). With respect to possible causal effects on emotional and behavioral problems, Gorman-Smith and Tolan (1998) found that exposure to violence in the community at time 1 predicted an increase in adolescents’ disruptive behavior over a 1-year period. The use of the autoregressive design strengthened the conclusion that violence exposure was causally related to the development of disturbance rather than simply an association.

Deprived neighborhoods have negative effects on parents. In poor neighborhoods parents show higher levels of depression, less positive parenting and more negative parenting (Klebanov, Brooks-Gunn, & Duncan, 1994; Finderhughes, Nix, Foster et al., 2001). Effects on parents partially mediate the negative influence of poor neighborhoods on negative child outcomes (Gutman, McLoyd, & Tokoyawa, 2005).

Exposure to War
Children in war-torn countries can be exposed to extremely high levels of violence. Three thousand and thirty children 8–19 years old living in 11 prefectures were interviewed in the year following the Rwandan genocide (Dyregrov, Gupta, Gjestad et al., 2000). Seventy-eight percent of those interviewed experienced a death in the family, while 70% saw someone being killed or injured and 15% reported hiding under a dead body to escape detection during the massacre. Rates of disturbance among refugee children are substantially higher than amongst non-refugee populations (Hodes, 2000). Rates vary as a function of direct exposure to violence and trauma (Sack, McSharry, Clarke et al., 1994). The most common form of psychopathology found in children and youth exposed to war violence is post-traumatic stress disorder (PTSD), but the full range of childhood disorder is also seen (Howard & Hodes, 2000; see chapters 31 & 42). In a random sample of 209 youth who were living in Cambodia during the Pol Pot regime who subsequently emigrated to the USA, the prevalence of PTSD was 18%. Fifty-three percent of their mothers had PTSD. It is important to note that there is marked heterogeneity in
levels of disturbance amongst children exposed to violence. Factors that account for such heterogeneity are discussed on p. 386 (see also chapter 31).

Poverty
Many studies have shown that living in poverty is associated with increased risk of mental health problems in children. Here we describe four studies that use methodologies that suggest a causal influence of poverty on children's behavior. Costello et al. (2003) took advantage of a natural experiment in order to investigate the impact on children of an acute infusion of money into a previously poor community. Fortuitously, a longitudinal study was ongoing on a Native American reserve that later housed a new casino. The casino provided every Native American family with an income supplement. Children's behavior was compared pre- and post-casino. When children were able to move out of poverty, a reduction in conduct problems was observed. Emotional problems did not, however, show a similar reduction.

Two other studies use longitudinal data and growth curve modeling to examine changes in children's well-being as a function of changes in their environment. Macmillan, McMorris, & Kruttschnitt (2004) examined whether changes in mothers' lives on poverty, marital status, education and employment predicted antisocial behavior of children using four waves of child data from the 1979 National Longitudinal Survey of Youth (NLSY79). Investigators coded families for changes in poverty, and formed groups who had experienced poverty for varying lengths of time and at different times in the children's lives. Years living in poverty had a large effect on initial levels of antisocial behavior. Further, children exposed to persistent poverty, those who only moved out of poverty for a short time and those who moved into poverty showed faster rates of change on antisocial behavior than children who had never lived in poverty. One methodological advantage of this study was that many other time-varying demographic predictors such as periods of unemployment, changes in marital status and changes in maternal education were included in the models. Effects of poverty were stronger than any other demographic factors and persisted after all such effects were accounted for. The NICHD Early Child Care Research Network (2005) reported similar findings.

Similar to the research on neighborhoods, parenting has been found to have a mediating role in the relationship between poverty and children's well-being. Several researchers have shown that the psychological stress associated with poverty increases parents' use of harsh and unsupportive parenting, which subsequently leads to adverse mental health outcomes in children and adolescents (Grant, Compa, Stuhlmacher et al., 2003).

In addition to harsh inconsistent parenting, poverty also affects parental abilities to monitor their children. In the natural experiment described above (Costello et al., 2003), when parents moved out of poverty their supervision of children increased. This in turn explained the relationship between poverty and children's antisocial behavior. Differential parenting refers to the extent of difference in parental behavior to different children in the family. Higher levels of differential parenting predict more negative outcomes in children (Dunn, Stocker, & Plomin, 1991). Jenkins, Rashbash, & O'Connor (2003) found that differential parenting was greater in families experiencing socioeconomic deprivation.

There are experimental data from animal work on foraging that may have some relevance for the effects of poverty on parenting. Champoux, Zanker, & Levine (1993) randomly assigned squirrel monkeys to conditions that varied on how easy it was to find food. When it took more effort to find food, monkeys showed more inactivity and chronically elevated cortisol than when food was more easily available. Extending this design, Lyons, Kim, Schatzberg et al. (1998) looked at the effect on mothers and their offspring. They found that when it was harder to find food, parenting became less optimal: mothers pushed their offspring towards less contact, while infants demanded more contact. As in the Champoux, Zanker, & Levine (1993) study, there was a negative impact of the experimental condition on maternal physiology (elevated cortisol) although the same effect on the infants' physiology was not seen. Results suggest that exposing mothers to scarce resources may have a negative effect on their own stress reactivity as well as their parental behavior. Although we cannot directly equate foraging for food in squirrel monkeys with exposure to poverty in humans, it may be that there is commonality in the experience of not having ready access to the basics that support existence and the effect on physiological systems in animals and humans.

Empirical Findings on Proximal Risk Factors
Parenting
Failures of parenting represent the best-documented proximal risks in childhood. We deal with two types of parenting risk: attachment failures and parenting quality.

Parenting in early infancy centers on attachment processes. Bowlby (1971) proposed that the attachment system is a biobehavioral system developed for the protection of young. He suggested that the parent provides the infant with a secure base from which to explore the world. When the infant experiences fear he or she signals distress to the parent and the parent responds by providing protection. The core mechanism of this theory relates to parental responsivity to distress (Goldberg, Grusec, & Jenkins, 1999). As the infant enters the second year of life, and representational abilities including linguistic skills become more advanced, physical proximity is no longer necessary to provide this sense of protection to the infant. It has been suggested that mental representations, based on the infant’s experiences with the caregivers at times of distress, form the basis for the development of subsequent close relationships built on trust.

The best evidence that failures of the attachment system affect infants comes from a series of studies beginning in the 1950s examining the outcomes of children who were raised without primary attachment figures (see chapter 55). Deficits in cognitive and socioemotional development have been noted...
This experience is associated with relationship anomalies in childhood, such as indiscriminate friendliness and poor peer relationships (Chisholm, 1999). In adulthood, women institutionalized as children are more likely to have difficulties parenting their infants and likely to experience more relationship transitions with partners. Depression and other mental health problems are more likely (Quinton & Rutter, 1988). Similarly detrimental outcomes have been noted for children who are raised in the family home but experience high levels of parental neglect (Trickett & McBride-Chang, 1995). It is notable that there is enormous heterogeneity amongst individuals who have been exposed to institutional care, with some showing no adverse outcomes and others showing very compromised development, an issue that we return to later.

Results from experimental studies in animals support the findings for humans and suggest some of the physiological systems that are involved in the relationship between psychosocial adversities and negative outcomes. Rodent models involve offspring being raised without their mothers. These separations lead to marked behavioral abnormalities in adulthood. Maternally deprived rats show reduced consumption of sweetened solution (perhaps indicative of anhedonia), as well as increased freezing, decreased exploration in an open field test and of novel environments, increased acoustic startle response as well as increased hyperactivity and inattention (Caldji, Francis, Sharma et al., 2000; Fleming, 2006; Fleming & Li, 2002; Ladd, Huot, Thrivikraman et al., 2000).

These behavioral changes are accompanied by a myriad of physiological and neurobiological alterations that last into adulthood. Maternally separated rats exhibit differences in HPA axis response to stressors, such as increased adrenocorticotropic hormone (ACTH) and corticosterone (Ladd et al., 2000), alterations in corticosterone releasing factor system (CRF; Ladd et al., 2000; Plotsky & Meaney, 1993) and serotonergic and GABA dysfunction (Caldji et al., 2000). These studies suggest that maternal separation during critical periods of development produce enduring neurobiological changes.

Similar studies have been carried out with non-human primates raised without mothers. In one study, infant rhesus monkeys were separated from their mothers within 2 days of birth, and were either mother-deprived or raised with a terry-cloth surrogate mother for the first 30 days of life (Kraemer, Ebert, Schmidt et al., 1991). Both groups of maternally separated monkeys developed depression symptoms and lower CNS concentrations of norepinephrine (Kraemer et al., 1991). Other studies have found increased pituitary–adrenal and behavioral responses to stress in adulthood in monkeys that were maternally deprived during infancy (Suomi, 1991). This evidence across humans and animals, both correlational and experimental, suggests that deprivation in care for infants has a causal role in the development of disturbance.

Non-attachment-based aspects of parenting become important beyond infancy. The study of parenting quality is extensive and diverse (Bornstein, 1995). Here we concentrate only on those aspects of parenting that have been shown to increase the risk of psychopathology in children. The aspect of parenting most consistently linked to psychopathology is parental harshness. Harsh parenting can be viewed dimensionally with physical abuse as the endpoint. Effects, however, are evident all along the continuum and long before physical abuse is an issue. Harsh parenting involves verbal aggression, hostility and criticism towards children. It has been shown to predict change in child behavior using a longitudinal design that controls for previous behavior, lending support to the idea that harsh parenting has a causal role in childhood disturbance (Ge, Conger, Cadoret et al., 1996; Kim, Conger, Lorenz et al., 2001). Physical abuse is associated with an increased risk of both disruptive and emotional psychopathology in children (Cicchetti & Toth, 2005), as well as antisocial personality disorder (Casp et al., 2002), depression and anxiety in adulthood (Brown, Harris, & Eales, 1996).

It should be remembered that aversive interactions between parents and children are partially child-driven effects. Children who are hyperactive, impulsive and negative in their mood (Bates, Pettit, Dodge et al., 1998; Shaw, Owens, Giovannelli et al., 2001) are harder for parents to manage. Patterson, Capaldi, & Bank (1991) have proposed a social learning mechanism to explain how ineffective parenting of temperamentally difficult children can result in later disruptive behavior problems for children, based on longitudinal observations of parent–child behavior.

Differential parenting is another aspect of parenting found to increase the risk of psychopathology. Caspi et al. (2004) investigated the longitudinal effects of differential parenting on MZ twins. They found that differential harsh parenting did predict increased disruptive behavior in the twin who was treated more negatively. It is also interesting to note that higher average differential parenting in a family is associated with more negative adjustment amongst all children, after accounting for individual level effects (Boyle, Jenkins, Geogiades et al., 2004). This suggests that not only is differential parenting more negative for the individual who experiences most harshness, but there is also a spillover element such that all siblings are worse off when treatment across children is more differential.

Another dimension of parenting that is associated with psychopathology, particularly disruptive behavior and particularly in adolescence, is lack of parental monitoring. Parental knowledge about where children are, who they are with and what they are doing, has been found to be a strong predictor of youth crime; interventions that increase parental monitoring by tracking children and doing random checks on their whereabouts have reduced antisocial behavior (Dishion & Kavanagh, 2003). However, see Kerr and Stattin (2000) for evidence that, at least in part, this reflects what children choose to tell parents about their activities.

**Sibling**

Another proximal process shown to affect the development of disorder in children is aggression in the sibling relationship.
CHAPTER 25

Patterson (1984) has suggested that siblings train one another towards higher levels of aggression through escalating coercive behavior that results in the other sibling backing down. Sibling interactions in the home have been observed over time. Using an autoregressive design, the aggression of one child has been shown to predict a change in the aggression of the other child for preschool (Garcia, Shaw, Winslow et al., 2000) and adolescent boys (Bank, Burraston, & Snyder, 2004).

Peers
A similar risk mechanism to that described for siblings is likely to operate for peers. Several studies, including one involving an experimental design, have shown that peers may train one another to increased levels of deviant disruptive behavior. The most convincing demonstration of the negative impact of deviant peers comes from a group treatment study (Dishion, McCord, & Poulin, 1999). The experimental group was offered treatment for their delinquency in a group setting. The treatment for the comparison group was individually administered. Boys were randomly assigned to treatments and the two groups were indistinguishable at the start of treatment. The investigators were surprised to find on follow-up that adolescents who were treated in group settings showed a major rise in delinquency over time. Through group treatment the investigators had inadvertently facilitated introductions to other delinquent youth. The boys formed groups outside of the sessions. They reinforced one another, exchanged techniques and encouraged further delinquent activities. Other studies have produced somewhat inconsistent findings on peer group deviancy amplifying effects (Dodge, Dishion & Lansford, 2006). That they can occur is not in doubt, but uncertainties remain on their generality.

Exposure to deviant peers is not only a problem in adolescence. Boys in grade 1 were assessed and followed up into their early adolescence (Kellam, Ling, Merisca et al., 1998). After taking account of the boys’ own aggression in grade 1, the average level of aggression in the classroom predicted an increase in target boys’ aggression over the next 7 years. Howes (2000) assessed levels of aggression in preschool classes in childcare settings. When the proportion of aggressive children was higher in the preschool daycare, this resulted in children being more aggressive themselves when they entered grade 2, after taking account of children’s own aggression in preschool.

Marital Conflict
The following three risks – marital conflict, separation and parental depression – show both distal (indirect) and proximal (direct) properties with respect to children’s outcomes.

Marital conflict has been found to be associated with a wide range of emotional and disruptive behavior outcomes, with the association between the latter and marital conflict being particularly robust. A number of studies provide convincing longitudinal evidence that marital conflict influences child behavior, in designs whereby marital conflict at time 1 predicted child behavior at time 2, controlling for child behavior at time 1 (Davies, Harold, Goike-Morey et al., 2002; Grych, Harold, & Miles, 2003; Jenkins et al., 2005).

The aspect of marital conflict found to be most harmful for children is openly expressed, interparental hostility or aggression. Silence, ignoring or other unexpressed modes of unhappiness in marriage do not have the same negative impact on children, at least in the short term (Jenkins & Smith, 1991). Children rate themselves as feeling more upset by conflict that remains unresolved between parents than conflict that is resolved (Cummings & Davies, 1994). Conflict that is about children has been found to be more distressing than conflict that is about non-child-related issues (Grych & Fincham, 1993).

There is enormous variability in the extent to which children are negatively affected by marital conflict. Children’s attributional processes concerning the conflict explain some of this variability. Those who perceive the conflict as threatening to family well-being (Davies, Harold, Goike-Morey et al., 2002) or who blame themselves for it are more adversely affected (Grych, Harold, & Miles, 2003). Attributional processes change as children mature cognitively. When children are around 5 years of age their understanding of parental conflict tends to be more self-focused, behavioral and unidimensional. By 9 years old they show a more complex understanding that involves understanding how two parents can have different goals and the implication of triangulation for family relationships (Jenkins & Buccioni, 2000). The quality of the parent–child relationship has been found to be a partial mediator of the relationship between marital conflict and children’s well-being (Buehler & Gerard, 2002).

Separation and Divorce
Parental divorce is associated with an increased risk of psychopathology (Amato, 2001; Cherlin, Furstenberg, Chase-Landale et al., 1991) which continues into adulthood (Amato & Sobolewski, 2001). Several reasons for this association including father absence, decreased access to financial resources for the custodial parent and undermined parenting have been examined. The strongest factors, however, appear to be the presence of interparental conflict (Amato, 2001) and disruptions to parenting (Amato & Sobolewski, 2001). These usually precede and follow separation. There is also some evidence to suggest that marital quality prior to divorce affects how divorce is experienced: children react more adversely when there has been low parental conflict prior to divorce. When conflict is high it may be that divorce is more welcome (Morrison & Coiro, 1999).

Parental Mental Illness
Children are at risk who have a parent with depression (Dowdney & Coyne, 1990), schizophrenia (Niemi, Survaisaar & Huakka, 2004), alcoholism (Lewis, 2000) or personality disorder (Jaffee, Moffitt, Caspi et al., 2003; see chapter 25). The transmission of the risk is both genetic and environmental. Significant genetic influence has been described for the most common emotional and disruptive behavior disorders
for children (Rutter et al., 1999). The environmental effect is explained by a disturbance in parenting as well as concomitant exposure to other risks such as parental conflict (Dowdney & Coyne, 1990). Risks have been shown to potentiate one another (Rutter, 1979) such that children exposed to multiple family adversities are more likely to demonstrate disturbance than children exposed to single risks. Parental depression has been shown to be associated with more problematic attachment processes (Lyons-Ruth, Connell, Grunebaum et al., 1990), lower levels of warmth, monitoring and discipline (Cummings, Keller, & Davies, 2005) and less verbalization to children with later effects on vocabulary (Pan, Rowe, Singer et al., 2005). Maternal depression and anxiety during pregnancy may have negative effects on the developing fetus (Van den Bergh & Marcoen, 2004), as prenatal exposure has been shown to predict disturbance in later childhood after accounting for any periods of postnatal exposure.

Summary of Effects of Psychosocial Adversity on Children
In summary, the evidence suggests that exposure to a range of environmental adversities increases the risk of disorder in children. However, there is enormous heterogeneity in children’s response to stressful environments. Although some children react to stress with the development of psychopathology, other children show no adverse behavioral reaction. One type of environmental adversity does not cause one type of disturbance; most of the risks outlined above have been shown to result in an increase in both emotional and disruptive behavior disturbances. The relationship between the type of risk to which a child is exposed and the outcome that results is non-specific. One reason for heterogeneity in response to stress relates to individual vulnerability, both genetic and non-genetic, as well as the complex ways that factors across different levels of children’s environments operate together. These issues are discussed next.

Resilience
Conceptual Issues
Resilience is the study of individual differences in response to stress. The interest in resilience research lies in understanding why certain children are more vulnerable to the adverse effects of negative environments than other children. The study of this issue should not be confused with the study of why some children show better functioning than other children. When children across the population are compared with one another there are large differences in adjustment that can be accounted for simply by the presence and severity of risks in their lives. This difference in functioning amongst children is sometimes referred to by researchers as resilience (Luthar, Cicchetti, & Becker, 2000; Masten, Hubbard, Gest et al., 1999). However, this is not how the term is used in this chapter. Here we use it to refer only to children who do well despite the fact that they are exposed to high levels of environmental adversity. We want to know that the same factor does not operate to confer advantage to all children (both children exposed and not exposed to adversity), but rather that it operates specifically to confer protection on children that need protection. Demonstrating that a factor operates differently for children in high- and low-risk circumstances requires the investigation of contingencies, an issue that we return to shortly. The study of resilience is explicitly inferential (Riley & Masten, 2005). Judgments are made regarding the exposure of individuals to experiences that have the potential to disrupt normative functioning, but this potential is not realized in a minority of individuals, who are resilient.

Resilience is best understood from the perspective of developmental processes and transactional models. Individuals are in continual interaction with other social and physical systems (Sameroff & Mackenzie, 2003). Accordingly, resilience is a dynamic process that involves adaptations that occur prior to, during and after stress exposure (Rutter, 1999). Individual adaptation arises from many dynamic processes occurring within the organism at the biological (e.g., genetic, hormonal) and behavioral levels (e.g., attention, capacity for learning) as well as between the organism and the various levels of the different systems in which the individual is embedded (close relationships with caregivers and peers, influences from school and community). This complex process of adaptation can function to alter the impact of adverse events on the organism, increasing or decreasing individual susceptibility (Masten & Powell, 2003).

Contingencies occur within and across developmental periods. Most of the literature on resilience deals with contingencies that involve predictors moderating one another within a developmental period. But contingencies are also evident across time that depend on the way in which events are sequenced or when they occur. Connor, Morrison, & Petrella (2004) have shown that certain types of reading instruction only benefit the child when preceded by other types of instruction. The formation of good peer relationships in middle childhood is in part dependent on attachment relationships during infancy (Sroufe, Egeland, & Carlson, 1999). Events at one point in a life can have more of an impact than at another point. Elder and Clipp (1988) found that friendships developed during war combat were experienced as more significant (and presumably more protective) than those developed under less traumatic circumstances.

The demonstration of contingent effects in human research is somewhat crude as it relies on statistical interactions between two influences. These can be hard to identify (McClelland & Judd, 1993; Rutter & Pickles, 1991), even when contingent influences are almost certainly occurring. In order to demonstrate contingent relationships the design needs to include children in high- and low-stress environments. If a significant interaction is present, a second factor has a different effect on the outcome in high- and low-risk circumstances. When referring to beneficial outcomes under high-risk circumstances this second factor is called protective, when referring to negative outcomes it is called a vulnerability
CHAPTER 25

factor. These are simply two ways of discussing the same contingent effect. Different kinds of contingencies, with slightly different meanings, have been outlined (Luthar, Cicchetti, & Becker, 2000). Examining contingent relationships gives us unique insight into the ways in which factors combine to moderate the influence of one another.

Empirical Findings on Child-Specific Attributes: Biological, Cognitive and Behavioral as Moderators of Stress

We begin by considering child-specific characteristics at the biological, behavioral and cognitive levels that have been shown to moderate the impact of psychosocial adversity. These factors describe vulnerabilities about individual children that result in certain children being more susceptible to the adverse effects of stress. The results we describe are based on single-child-per-family designs; there have been few sibling studies of resilience. The factors to be discussed, however, as assessed at the child-specific level, should also explain within-family differences in development. Future research will examine whether these child-specific factors explain why siblings react to family level environmental adversities so differently.

Biological Moderators

Biological vulnerabilities may be endogenous (e.g., genetic effects) or they may arise from environmental adversities that affect the developing brain (Repetti, Taylor, & Seeman, 2002). Thus, smoking (Fergusson, 1999) during pregnancy has been found to be associated with an increased risk of emotional and behavioral problems later in child development, as is poor nutrition in early childhood (Liu, Raine, Venables et al., 2004). These biological vulnerabilities may in turn alter the individual's susceptibility to subsequent stressors. This process is referred to as the diathesis-stress model: the vulnerabilities of some individuals (diatheses) increase susceptibility to the adverse effects of stress (Davidson & Neale, 2001). Here we review a range of individual diatheses that demonstrate such patterns.

Polymorphisms of genes that affect neurotransmitters have been found to increase vulnerability to stress for certain types of disturbance. The MAOA enzyme is involved in the metabolism of mono-amine neurotransmitters, and one form of a MAOA gene has been found in animal and human studies to be associated with increased aggression. Following this research, Caspi et al. (2002) found that males with this form of the MAOA gene were at very high risk for conduct disorder when they had also been exposed to maltreatment during childhood. The presence of either risk – this particular form of the gene or exposure to maltreatment – did not raise the risk of disorder if present on its own. In a second study on the same sample, Caspi et al. (2003) found that individuals exposed to life events were more likely to develop depression if they had a short, rather than a long form of a gene involved in the production of serotonin. Experimental work with rhesus monkeys gives a further indication of mechanism (Kraemer, 1992; Suomi, 2005). Bennett, Lesch, Heils et al. (2002) found lower concentrations of a serotonin metabolite in the cerebrospinal fluid of monkeys who were peer reared (stress condition) and had the short rather than the long form variant of the serotonin gene. The gene was not associated with concentrations of the serotonin metabolite in mother-reared animals. These studies show first that genetic diatheses exist that increase individual vulnerability to disorders in the presence of particular kinds of life stresses and, second, that neurotransmitters are likely to be important mediators in this process.

Vagal tone is another biological factor that has been shown to moderate the effects of stressful environments. It represents a measure of emotion regulation as it represents an individual's ability to maintain homeostasis and regulate physiologically (Porges, 1995). Low vagal tone has been found to be associated with behavioral problems. El-Sheikh (2005) found that for children with high vagal tone, exposure to parental alcohol abuse did not predict an increase in externalizing or internalizing problems. For children with low vagal tone, however, exposure to parental alcohol abuse was a predictor of an increase in both types of symptomatology over time.

Cognitive Moderators

Masten, Hubbard, Gest et al. (1999) predicted change in positive behavioral functioning from childhood to adolescence as a function of life events and children's IQ in a 10-year longitudinal study. They found that IQ protected children from developing conduct problems when they were exposed to significant life events. When children experienced few life events, IQ was a weaker predictor of change in conduct problems. The use of the autoregressive design made for a stronger argument with respect to causal processes.

The ways that children and adults appraise or give meaning to events in their world have also been found to be important contingencies in how individuals react to stress. Negative appraisals of the self (Hammen, 1988) and events in the world (Mazur, Wolchik, Virdin et al., 1999) have been shown to increase individual vulnerability to adverse environments. A similar moderating effect has been shown for children's social problem-solving skills (Dubow & Tisak, 1989).

Coping Moderators

Individuals differ in their sense of personal agency and the repertoire of coping mechanisms they can utilize when faced with adversity (Rutter, 2006). Although research evidence is lacking to show that such factors moderate the relationship between risk and adjustment, such factors have been shown to differentiate between the outcomes of high-risk children. Hauser, Allen, & Golden (2006) interviewed adults admitted to a psychiatric institution as adolescents. They found that adolescents with a sense of personal agency, a self-reflective style and a commitment to relationships experienced far better outcomes than adolescents who did not possess these characteristics.

Temperament Moderators

Temperament refers to stable individual differences in emotionality and self-regulation that are thought to have a biological
Psychosocial Adversity and Resilience

Further, more physically attractive babies elicit more positivity and attachment behaviors than less attractive infants (Langlois, Ritter, Casey et al., 1995). Such findings suggest that characteristics of children contribute to the supportiveness of the environment that surrounds them. This is referred to as an evocative gene–environment correlation.

Future Directions

We have shown that understanding the effects of adversity and the processes of resilience depends on an integration of findings from different methods in developmental science. As we move forward, certain kinds of studies hold particular promise. First, for researchers examining the effects of stress on children, animal models are extremely important. They will provide an understanding of the way in which stress affects brain development as well as providing an understanding of the reversibility of such effects, once therapeutic interventions are applied. Second, within-family designs will be central to the next decade of research on risk and resilience. Such designs will allow us to differentiate between child-specific and family-wide risks, to distinguish between the objective and the effective environment and to understand why siblings exposed to similar environments develop so differently. It is important that such studies collect high-quality observational longitudinal data that allow us to examine reciprocal influences of parents, children and siblings. Third, studies that combine molecular genetic data with measures of environmental risk will allow for the examination of gene–environment interaction. This will be a key focus of research over the next decade. Fourth, emotion processes in humans occur within biological, cognitive, behavioral and relational levels of analysis. It is important that we understand the ways in which these different levels of experience operate together. Finally, limiting the definition of resilience to factors that operate differentially in high- and low-risk environments will enable us to gain a better understanding of compensatory processes in development.

CHAPTER 25

Acute Life Stresses
Seija Sandberg and Michael Rutter

Historical Background

It has long been generally recognized that stressful life experiences may have an adverse effect on health and predispose to physical and psychiatric illness (Haavet & Grünfeld, 1997; Rutter, 2005). Through experimental and clinical studies, Cannon (1929) laid the groundwork for psychophysiological research by demonstrating that external stimuli associated with emotional arousal caused changes in basic physiological processes. Some three decades later, a bridge to psychiatry was firmly laid out. Meyer (1957), a physician and psychiatrist, argued that to be pathogenic, life events need not be catastrophic or particularly unusual. He advocated the value of life charts to bring out temporal links between happenings such as change of habitat, school entrance, graduation, marriage, divorce and bereavement, and the onset of psychiatric disorder.

This proposition was further developed in the 1960s by Holmes and Rahe (1967) through their production of questionnaires to provide overall scores of degree of life change in adults – the assumption then being that it was the extent of life change that was stressful and not necessarily the unpleasant nature of the experiences. In addition, there were numerous studies of specific life events affecting all age groups – such as family break-up, bereavement, and disasters such as floods, earthquakes or hijacking. The realization that it was necessary to take into account the social context of life events in order to assess their meaning and hence their stressful quality constituted perhaps the most significant conceptual advance that followed (Brown & Harris, 1978).

Two main approaches have been applied in the assessment of life events in children. First, questionnaires have been used to ask about the occurrence of specified life events during a particular time period (Allen & Rapee, 2006; Johnson, 1982), most commonly the previous year. The main advantage of questionnaires is their low cost and ease of administration to a large number of individuals, making them readily applicable for large-scale epidemiological enquiries (Silberg, Pickles, Rutter et al., 1999). However, they have the considerable disadvantage that they cannot readily deal with the personal meaning or social context of events and they are limited in their ability to obtain accurate timing. As a result, there is substantial variability in what broad categories of “events” (e.g., divorce or illness) actually reflect in terms of personal experiences (Dohrenwend, 2006).

Second, interviews have been employed to obtain detailed descriptions of life events, and of their surrounding circumstances, during a defined time period (Goodyer, 1990; Monck & Dobbs, 1985; Sandberg, Rutter, Giles et al., 1993; Sandberg, Paton, Ahola et al., 2000; Williamson, Birmaher, Ryan et al., 2003). Accurate timing is facilitated by using personalized time points such as birthdays, family holidays, school terms and the like. The notion of contextual threat (i.e., psychological threat to the individual as viewed in the light of that person’s personal social context), first introduced by Brown and Harris (1978), has been incorporated as a cornerstone measure in all these interview-based life event assessments with children. The level of contextual threat is commonly assessed in terms of enduring effects. In the Psychosocial Assessment of Childhood Experiences (PACE; Glen, Simpson, Drinnan et al., 1993; Sandberg & Zimmer, 2002; Sandberg et al., 1993) the threats include the following:

- Loss of an attachment figure (e.g., parent or close friend);
- Threat of loss of an attachment figure (e.g., parent threatening to abandon child);
- Loss of a valued idea (major disappointment/humiliation);
- Physical jeopardy (e.g., being in physical danger because of an accident);
- Trauma as witness (being witness to a frightening incident involving someone else); and
- Psychological challenge (taking on a new role or new responsibilities).

Brown & Harris (1978) were also the first to emphasize the need to differentiate between independent and dependent life events (i.e., those that could and could not have been brought about by the person’s own behavior) – a distinction included similarly in the interview-based assessments with children. Thus, bereavement would fall in the former category and rejection by a close friend in the latter (with it probably being to some extent related to the child’s own behavior). In addition, in the PACE (Sandberg & Zimmer, 2002; Sandberg et al., 1993) there is the further distinction between independence from the child’s behavior and independence from the behavior of the parent(s). Parental divorce and abuse of the child are examples of life events dependent on the parents’ behavior.
Some life events rate high on contextual threat because they cause a major alteration in life circumstances (e.g., death of a parent). In other events the threat is primarily cognitive. That is, the event drastically changes the child’s perception of an aspect of themselves, or of other people or things in a way that presents a threat to the child’s self-esteem (e.g., severe humiliation) or reduces his or her perceived sense of security (e.g., parent threatening to abandon the child). Life events may also involve a combination of real life change and cognitively mediated threat (e.g., the parents’ marital separation).

Most life events occurring to children involve important social relationships, whereas far fewer can be seen as being largely unpredictable “acts of fate.” The latter mainly include major traumatic experiences such as being kidnapped or sudden losses of close persons.

**Risk Effects of Life Events**

Life events may carry risk either because they tend to provoke the onset of psychiatric disorder, or because they increase the overall liability to recurrent or chronic disorders. The former risk has mainly been studied through case–control studies focusing on the timing of the life events, and the latter risk through population studies measuring the overall burden of life stresses over time.

The causal effect on the onset of disorder has mainly been tested through showing that, in comparison with controls, there is a major provoking life event in the 2 months preceding onset, whereas this occurs less often in other time periods, life events in controls being distributed in a more random fashion. Alternatively, a few longitudinal studies have shown an increased likelihood of onset of disorder in the weeks or months immediately following a major life event. Most of this research has concerned adults (Brown & Harris, 1978, 1986; Brown, Harris, & Eales, 1996). The findings in children have been much less consistent. Only one study (Goodyer, Herbert, Tamplin et al., 2000) has shown a strong timing effect, with a significant increase of negative life events shortly before onset. Others have tended to show an increase in negative events over a more extended period of time (Jensen, Richters, Ussery et al., 1991; Olsson, Nordström, Arinell et al., 1999; Sandberg et al., 1993; Williamson, Birmaher, Ryan et al., 2003). Even in the Goodyer et al. (2000) study, only half of the adolescents with an onset of depressive disorder during the 12-month prospective follow-up period had experienced a high-threat life event in the month preceding the onset. Furthermore, in many cases the life event (“personal disappointment”) was not classified as independent of the individual’s behavior and hence, could conceivably have been related to symptoms of depression.

Although case–control comparison on timing constitutes the standard life events method, it involves several important methodological limitations with respect to the causal inference (Goodyer, Herbert, Tamplin et al., 2000; Sandberg, Rutter, Pickles et al., 2001). First, the case–control comparison for a specific time period will be affected by any general (non-time-specific) difference in life events as brought about by either genetic liability or other environmental factors (e.g., chronic psychosocial adversity). A more rigorous test is provided by within-individual comparisons of the pre-onset time period with other time periods. The only study so far to use this method gave rise to weak inconclusive time effects, although showing the usual case–control difference (Sandberg et al., 2001). Second, with very few exceptions (Sandberg et al., 2001; Silberg, Rutter, Neale et al., 2001), studies with both adults and children have used the same informant for data on life events and data on the onset of disorder. The possibility of reporting bias is clear. Third, the timing method presupposes that each episode of disorder has a simple unambiguous time point when it began. The available evidence suggests that this is an exception rather than the rule. Some onsets are gradual, some symptoms begin before others, and often there is a different point when symptoms lead to social impairment (Rutter & Sandberg, 1992; Sandberg et al., 2001). Moreover, inter-informant and retest reliability on the timing of children’s psychiatric onsets is weak (Angold, Erkanlis, Costello et al., 1996). Fourth, many psychiatric disorders are recurrent or chronic; this is so in both childhood and adult life. Accordingly, a more basic question with respect to the causal role of life events is whether they affect liability to psychopathology over time, rather than just having a provoking role with respect to the timing of onset.

The causal effect of life events in relation to the overall liability to disorder has been most rigorously tested through twin designs, which can take account of possible genetic mediation (Kendler, Karkowski, & Prescott, 1999). Studies with adults show a clear environmentally mediated risk effect. Findings in children show the same (Rutter, 2005). It should be noted, however, that the risk is only indexed by the life events. It could be that the main risk derives from chronic psychosocial adversities associated with the acute stresses, rather than from the acute stresses themselves. There is abundant evidence that, in psychiatric samples, acute life events are very frequently associated with chronic adversities and that it is the longer-lasting psychosocial hazards that constitute the greater risk (Rojo, Conesa, Bermudez et al., 2006; Sandberg et al., 1993; Sandberg, McGuinness, Hilary et al., 1998). Nevertheless, acute stressful life events, especially those carrying long-term threat to the psychological security of the child, may add to the risk provided by chronic adversities and, in some circumstances, constitute a sufficient risk in their own right (Sandberg et al., 2001).

The distinction between independent and dependent life events constituted an important methodological innovation that helped in testing the causal connection with psychopathology. Nevertheless, the fact that a person brought about a particular experience through their own behavior does not mean that the experience cannot then influence his or her later behavior or predispose to disorder (Rutter, Silberg, & Simonoff, 1993). Thus, for example, people choose whether or not to smoke cigarettes but that does not mean that smoking cannot have
CHAPTER 26

a carcinogenic risk effect on lung cancer. Similarly, the fact that a person behaves in a way that leads to rebuffs or rejections from peers, or predisposes them to being scapegoated in the family, does not mean that the rejection or scapegoating will not constitute a significant stress experience for them. It is essential to use research designs and data analyses that can provide a rigorous test of the postulated stress effect, but at the same time it is important to appreciate that the implication is for the choice of research strategy and not for an automatic ruling out of a stress effect. That is pertinent to the findings that children and adolescents with psychiatric disorder differ from community controls in their exposure to both independent and dependent life events, as well as chronic adversities (Allen & Rapee, 2006; Allen, Rapee, & Sandberg, unpublished data; Olsson et al., 1999; Sandberg et al., 1993; Williamson, Birmaher, Anderson et al., 1995; Williamson et al., 2003). They have also been shown to experience more of such acute and chronic stresses than children with physical illnesses such as asthma (Sandberg et al., 1998).

Some life events carry both a negative and positive affective valence. The contextually positive features usually refer to hedonic qualities, enhancement of self-esteem or favorable effect on life circumstances. So far, research on positive aspects of life events has been limited, and the findings with respect to psychiatric disorder have been inconclusive (Brown, Lemyre, Bífülco, 1992; Jensen et al., 1991; Leenstra, Ormel, & Giel, 1995; Sandberg et al., 1993). The only study to have demonstrated a protective function of positive life events against the increased risk relating to negative life events is that by Sandberg, McCann, Ahola et al. (2002). In a prospective study of children with asthma, positive life events, provided they occurred in close proximity to the negative ones, significantly reduced the risk of a new asthma attack following a severely negative life event. However, this protective function was not observed among those children who lived in conditions characterized by high chronic stress. Once again, the significant role of chronic psychosocial adversities was highlighted.

Individual Differences in Exposure to Stressful Life Events

Children, like adults, vary enormously in the extent to which they experience stressful life events. Accordingly, it is necessary to consider the origin of these individual differences. First, a few stressful life events represent chance or an act of fate. That applies to natural and man-made disasters such as war, floods, earthquakes and shipping accidents. Second, stressful life events may reflect structural factors in society that make negative experiences much more likely as a result of racial (or other) discrimination, poverty, social disorganization or dangerous life circumstances (such as in areas of high violence). Third, dependent life events may come about because a person's own behavior shapes their experiences to a considerable extent (Sandberg et al., 1993, 1998). The recognition of the importance of individual differences in exposure to risk experiences, together with an appreciation of the multiplicity of influences on this individual variation led to an increase in the study of the possible causal processes involved (Adams & Adams, 1993, 1996; King, Schwab-Stone, Flisher et al., 2001; Rutter, Champion, Quinton et al., 1995; Wals, Hillegers, Reichart et al., 2005; Williamson et al., 1995; Williamson, Birmaher, Frank et al., 1998).

Longitudinal studies have shown the important extent to which a person’s own behavior predicts their later experiences. Thus, Robins' (1966) classic follow-up of child guidance clinic attendees into mid-adult life found that antisocial behavior in childhood was associated with a major increase in negative life experiences many years later. These included multiple divorces, unemployment, frequent job changes, lack of friends and lack of social support. Similarly, Champion, Goodall, & Rutter's (1995) 20-year follow-up of London school children demonstrated that psychopathology at age 10 years (especially conduct problems but, to a lesser extent, emotional disturbance) was associated with a more than doubling in the risk of both acute negative life events and chronic stressful experiences in adult life. Both studies suggested that the sequelae frequently depended on chain events that involved links reflecting separate psychological processes – including learned maladaptive emotional responses, self-perpetuating behavior patterns or habits, lowered self-esteem influencing the ability to deal with future experiences, and getting into situations that generated severely negative life events.

The Christchurch longitudinal study (Fergusson, Woodward, & Horwood, 2000) confirmed these cumulative chain effects and indicated that stressful life events in the 15–21-year age period were associated with a several-fold increase in suicidal ideation and suicidal acts, with the effects of childhood risk factors largely mediated through mental health problems in the intervening years. Somewhat similarly, in their prospective study of children of parents with a bipolar disorder, Wals et al. (2005) found that sub-threshold anxiety and depressive symptoms both increased the rate of behavior-dependent stressful life events and the onset and/or recurrence of a mood disorder.

Similarly, Daley, Hammen, Burge et al.'s (1997) 2-year longitudinal study of late adolescent women found that depression that was comorbid with other problems was associated with more stress experiences later, even after controlling for chronic adversity. They concluded that stresses arose, not just from individual behavior, but also from their broader social world, in turn shaped by interpersonal and intrapersonal factors.

Through gene–environment correlations (see chapter 23), genetically influenced child and parent behaviors have a role in the shaping and selecting of environments, and in the responses evoked in other people. For these reasons, twin studies have shown significant genetic effects on people’s likelihood of experiencing negative life events (Kendler, Neale, Kessler et al., 1993; Silberg et al., 1999; Thapar, Harold, & McGuffin, 1998). It is important to note, however, that the effect of children’s genetically influenced behavior in eliciting negative reactions from other people to some extent depends
on social context. Thus, Riggins-Caspers, Cadoret, Knutson et al. (2003) found that the effect of children’s disruptive behavior in eliciting negative reactions from their adoptive parents mainly applied when the parents themselves were distressed or impaired in some way.

To an important extent, parents who pass on risky genes are more likely also to create risky rearing environments. Thus, Rutter and Quinton (1984) found that parental personality disorder was associated with a much higher rate of marital discord and of hostility focused on the children than in a comparable general population sample. Parental mental disorders of varied types have been found to be associated with adverse rearing features in a range of other studies (Adrian & Hammen, 1993; Minde, Eakins, Hechtman et al., 2003; Murray & Cooper, 1997; Rutter, 1989).

**Acute Life Stresses and Chronic Adversity**

Much research has shown that negative life events are more common in individuals who also have chronic psychosocial adversities (Brown & Harris, 1986; Rojo, Conesa, Bermudez et al., 2006; Sandberg et al., 1993, 2000). That raises several rather different issues. It highlights the fact that many of the stressful life events impinging on children are influenced in one way or another by their parents’ behavior. This is the case, for example, with divorce, abuse, domestic violence, crime, substance abuse and neglect.

It is not just parental mental disorder that predisposes to the generation of stressors; personality features may do the same. Ellenbogen & Hodgins (2004) in a cross-sectional study of children whose parents had a bipolar disorder, major depression or no disorder found that high parental neuroticism was associated with less good psychosocial functioning, more poor parenting, more dependent stressful life events and less good coping than other parents. The implication (with the caveat that the association was cross-sectional) was that a substantial part of the risk effects on the children derived from the neuroticism-generated stresses and adversities.

Societal influences outside the family can also generate stress. Thus, in the case of sexual abuse it is not just the acts of abuse that are traumatic, but also repeatedly having to testify in court is associated with an increased risk of long-term sequelae, especially if there is a lack of maternal support and a lack of corroborating evidence so that doubt is cast on the child’s account (Goodman, Bateman-Fraunce, & Kenny, 1992; Quas, Goodman, Ghetti et al., 2005; see also chapters 28 & 29).

Broader living conditions are also influential. Geographical areas characterized by social disorganization not only predispose to crime (Brooks-Gunn, Duncan, & Aber, 1997; Sampson, Raudenbush, & Earls, 1997), but also provide environments in which young people are more likely to be the targets of violence and the witnesses of the shootings of friends and family. Similarly, poverty and poor life circumstances are likely to predispose to family ill health and interparental conflicts, which in turn increase the likelihood of acute negative events (Sandberg et al., 1993, 2000), as well as make harmonious effective parenting more difficult (Beck & Shaw, 2005; Brody, Murray, Gerrard et al., 2004; Conger, Ge, Elder et al., 1994).

The well-documented association between acute negative life events and chronic adversity raises the question of the extent to which the psychopathological risks derive from the event itself or from the chronic adversities with which it is associated. One of the crucial advances was the appreciation by Brown and Harris (1978) that the main risk in adults was provided by the long-term contextual threat, and not by the acute unpleasantness of the event or the degree of life change involved. The same seems to apply in childhood. By long-term threat, what is meant is not just the practical consequences such as the effects on parenting or on intimate relationships, but also the possible long-term effects on self-esteem and self-image. Because of this, public humiliation is usually more of a stressor than, say, being bitten by a dog. In adults, especially in the case of depression, a single high-threat event in the 6–9 weeks preceding onset was sufficient to provoke a major affective disorder (Brown & Harris, 1978; Surtees & Wainwright, 1999). As noted, this clear-cut timing effect has been less evident in most studies of children.

That does not necessarily mean that a single high-threat event cannot provoke the onset of disorder. That it can has, perhaps, been most clearly shown in the case of sexual or physical abuse (see chapters 28 & 29). Nevertheless, even in these cases, the sequelae are most striking when the abuse has been recurrent, as well as severe, and when it has implications that involve a breach of trust. What is important, however, is that the sequelae can persist for many years after the abuse came to an end (see chapter 13).

Three issues need to be considered. First, can acute life stresses create an increased ongoing liability to disorder that extends beyond any on-set-provoking effect? Second, is any such increased liability a function of the multiplicity of acute events, rather than the overwhelming effect of a single stress event carrying a long-term threat? Third, is any overall increase in liability really a function of chronic adversity, rather than acute stress, with the latter no more than an index of the long-lasting life difficulties or hazards? No clear-cut answers to these questions are available. Nevertheless, it is evident that life events carrying long-term psychological threat to children nearly always involve social interaction, and derive from, or lead to, chronic psychosocial adversities ranging from being the victim of bullying to illness and discordant relationships within the family (Essex, Klein, Cho et al., 2003; Goodyer, Wright, Altham, 1988; Goodyer, Herbert, Tamplin et al., 1997; Jensen et al., 1991; Sandberg et al., 1993, 1998, 2000; Tiet, Bird, Davies et al., 1998). Also, it is evident from epidemiological and clinical studies that the main psychopathological risk associated with family break-up derives from the associated family conflict rather than from family separations or changes (Cuffe, McKeown, Addy et al., 2005; Fergusson, Horwood, & Lynskey, 1992; McMahon, Grant, Compas et al., 2003). It is for this reason that, on the whole, parental divorce
carries a greater psychopathological risk than the loss of a parent through death (Rutter, 1971).

Sandberg et al. (1993, 1998) showed that the main risk for children derived from the acute stresses that stemmed from, or were otherwise associated with, chronic adversity. It may be concluded that, although single severe stress events may carry risk, it is multiple events and events associated with chronic adversity that carry the greatest risk.

**Specificity of Stress Effects**

It is conceivable that specific associations between particular stressors and particular outcomes could be mediated by psychological, biological or social processes, and the specific nature of the stressor. In adults, some findings have suggested a degree of specificity, with “loss” events more important in the provocation of depression, and “danger” events in the onset of anxiety disorders (Brown, Harris, & Eales, 1996; Finlay-Jones & Brown, 1981; Miller & Ingham, 1985). In contrast, little evidence that this is so in children exists so far, and even this is inconsistent (Allen, Rapee, Sandberg, unpublished data, Eley & Stevenson, 2000; Goodyer, Wright, & Altham, 1990a,b; Williamson, Birmaher, Dahl et al., 2005). This may be because, up to now, very few studies testing full specificity designs (i.e., specific stressors linked to specific outcomes, via specific mediators, in the context of specific moderators) have been carried out in children.

The general lack of specificity (for review see McMahon et al., 2003) may have several explanations. Particular claims have been made with respect to possibly specific effects of sexual abuse (with respect to later sexual difficulties) but non-specific effects of both physical and sexual abuse outweigh specific sequelae (see chapters 28 & 29). The one relatively specific stress effect (applying to overwhelming unusual stresses) concerns post-traumatic stress disorder (PTSD) but it should be noted that PTSD is by no means the only response to overwhelming stress (see chapter 42).

Most crucially, many stressors include several rather different components involving loss, conflict, humiliation and danger. It is possible – although not yet demonstrated – that these components when they occur separately do have more specific effects. In addition, most studies have failed to differentiate between acute stresses occurring outside the context of chronic adversity and those occurring in association with ongoing lasting hazards of various kinds.

**Individual Differences in Response to Stressful Life Events**

Some of the earlier clinical reports on the effects of stress tended to assume that negative life events necessarily increased psychopathological risk. However, both human and animal studies have been consistent in showing that, in some circumstances, stress experiences may be protective, exerting “steeling” effects (Rutter, 1983). For example, prospective studies by Parker, Buckmaster, Schatzberg et al. (2004) and Parker, Buckmaster, Sundlass et al. (2006) in non-human primates have demonstrated that moderately stressful early experiences strengthened socioemotional and neuroendocrine resistance to subsequent stressors. Brief separations from mother, at an age when biologically but not socially independent, led to diminished anxiety and enhanced exploratory and play behavior backed up by neurohormonal evidence indicating less biological stress response. It was also established that stress inoculation, rather than increased levels of maternal care following stress exposure, was the important factor. These results therefore suggest that a combination of mild stress causing acute anxiety and hypothalamic–pituitary–adrenal (HPA) axis activation is necessary for the development of subsequent stress resistance. The possible neural mediation of “steeling” effects has been investigated by Maier and colleagues in a series of rat studies (Amat, Paul, Zarza et al., 2006). Earlier experiments had shown that controllable stress provided some form of “immunizing” protection against later stress. Amat et al. found that behavioral immunization was blocked by inactivation of the ventral medial prefrontal cortex (mPFCv) by the administration of muscimol. The same effect was produced by anisomycin at the time of the initial controllable stress, but this was not found if it was only given later at the time of uncontrollable stress. The implication seems to be that the mPFCv is needed both to process information about the controllability of stress and to use this information to regulate responses to subsequent stressors. Replication is awaited.

“Steeling” effects reflect the fact that negative experiences, as well as challenges and transitions, are a normal part of life that all people have to learn to cope with. Successful physiological and/or psychological coping may be strengthening rather than weakening. This recognition has led to the concept of resilience, meaning the phenomenon that, whereas some individuals succumb following stress, others survive relatively unscathed, or even strengthened, following severely adverse experiences (Rutter, 2005, 2006c).

**Resilience**

Traditionally, clinicians and researchers have tended to view this marked individual variation in people’s responses to stressful life experiences in terms of the overall balance between risk and protective factors. This has meant a focus on variables – asking, for example, whether the risks are mitigated, or compensated for, by compensatory positive experiences. That does indeed constitute an important consideration. However, Rutter (2006b,c) has argued for the need to go beyond the concepts of risk and protection that carry the implicit assumption that effects will apply similarly to everyone (see chapter 25). Instead, he suggested the value of examining the mechanisms and processes involved in individual differences in response. It is implicit in this concept of resilience that it does not refer to an individual trait, and it does not assume that the same processes will apply to all individuals, all stresses and all outcomes, or indeed to all phases in a person’s life. The focus, therefore, is not on fixed variables but rather on coping processes – coping incorporating both physiological and psychological
mechanisms. This means that resilience cannot be measured directly as an observed trait, for it is not a single quality.

Several different implications follow from what is known as resilience. First, there is good evidence of the importance of gene–environment interactions (Kramer, 2005; Rutter, 2006a; Rutter, Moffitt, & Caspi, 2006b; see chapter 23). Thus, Caspi, McLay, Moffitt et al. (2002) and Caspi, Sugden, Moffitt et al. (2003) showed that allelic variants of the MAOA gene and the serotonin transporter promoter gene moderated the effects of child abuse and recurrent negative life events on the liability to antisocial disorder and to depression. There was no main effect of the genetic variant on the psychopathological outcome as such, but there was a substantial and significant effect in influencing the susceptibility to the environmental stressors. Structural and functioning imaging studies in human adult volunteers without psychopathology showed that the allelic variation was associated with a substantial measurable neural response to fearful stimuli or challenging situations (Hariri, Mattay, Tessitore et al., 2002; Hariri, Drabant, Munoz et al., 2005; Meyer-Lindenberg, Buckholtz, Kolachana et al., 2006; Pezawas, Meyer-Lindenberg, Drabant et al., 2005).

The importance of these (and other related findings) is that it provides pointers to the biological basis of the stress response, it suggests that the causal chain for the genetic effects and the stress effects may be the same and it indicates that the processes apply not just to people with a disorder but also to those without psychopathology.

A second resilience consideration derives from the evidence (albeit still limited) that protection may be fostered by controlled exposure to risk rather than by avoidance of risk. The parallel here is the protection against infectious disease afforded by either naturally acquired immunity or immunization. The psychological parallel, perhaps, is the evidence that the elimination of phobias is better achieved through controlled exposure than by avoidance.

A third consideration is the recognition that protection may be afforded by features or circumstances that are neutral (or even risky) in the absence of stress. For example, Quinton and Rutter (1988) found that a planning tendency (fostered by good school experiences) was protective for girls reared in institutions but not for girls in the general population. The point was that the latter did not need to plan because their environments were generally benign and supportive whereas that was far from the case with the girls returning to discordant dysfunctional families on discharge from institutions.

A fourth consideration is that it matters how people deal with the stresses and challenges they face. Adverse sequelae are much more likely if maladaptive responses (such as reliance on drugs or alcohol) are employed than if more adaptive practical or emotional coping strategies are used. Finally, it is clear that resilience may come about by experiences both preceding and following the stress events or chronic adversities (Laub & Sampson, 2003; Rutter, 1996).

Brown, Lemyre, & Bifulco (1992) have suggested that, in adults, positive experiences that directly counter the negative effects of the stressful event may be protective. Thus, a happy occasion is not likely to help much but a new loving relationship may do much to make up for a lost relationship. Whether or not the same applies in childhood is not known. On the whole, little effect (apart from one study of new asthma exacerbations; Sandberg et al., 2002) has been found for hedonically positive events. However, there is evidence that a good close confiding relationship may partially mitigate the effect of family discord and conflict (Jenkins & Smith, 1990), and that a lack of such a relationship may increase the adverse effects of severely negative life events (Sandberg et al., 1993).

Sensitizing Effects
Clinicians have long recognized the possibility of sensitizing effects of stress experiences. Thus, experience suggests that someone who has experienced the death of a much-loved person (either within the family or a close friend) may be more vulnerable to the psychopathological effects of a later second bereavement. Likewise, studies in adults have highlighted the role of early loss events (especially if leading to lack of care) in sensitizing to later stressors (life events involving loss, in particular), and thus paving the way to depression (Brown & Harris 1986; Hammen, Henry, & Daley, 2000). Similarly, one major humiliation may increase sensitization to further humiliations, or even predispose the person to interpret minor rebuffs as humiliating rejection. Abuse (physical or sexual) in the context of a trusting or dependent relationship may also give rise to a more pervasive reluctance to trust people even when they give no indication that a lack of trust is warranted. This was evidenced, for example, in a Canadian study of high school students (Wolfe, Scott, Wekerle et al., 2001). Boys with a childhood history of maltreatment were three times more likely to engage in violence towards their dating partners compared with youngsters who had not been abused. So far, however, little sound empirical research in children exists that could document the strength or importance of sensitizing effects, or indicate when such effects are likely to arise.

An exception here is a longitudinal study by Essex, Klein, Cho et al. (2002) starting with an unselected sample of expectant mothers recruited from antenatal clinics. When assessed at 4.5 years, the children whose mothers had experienced high levels of stress both during the child’s infancy (three assessments in the first year of life) and at the time of assessment, had significantly higher cortisol levels compared with the rest of the sample. Furthermore, exposure to maternal depression beginning in infancy was the strongest predictor of the children’s high cortisol level. The same study also showed that the children with high cortisol levels exhibited significantly more problems in their emotional and behavioral adjustment.

Research on adults has also clarified the biological basis of the sensitization phenomenon by showing that trauma experience can interact with a pre-existing biological abnormality. This was demonstrated by a twin study of adult trauma patients by Gilbertson, Shenton, Ciszewski et al. (2002), who showed that smaller hippocampal volumes in those with PTSD represent a preexisting familial vulnerability factor rather than
being a neurotoxic product of trauma per se. The design, however, did not allow any assessment of whether the vulnerability factor was in any way related to earlier stresses.

Anniversary reactions in which there is the recurrence of psychopathology on the anniversary of some major stress event or loss represent another example of past experience sensitizing to a later one. In adults, the majority of evidence on this stems from studies of war veterans (Morgan, Hill, Fox et al., 1999), but attention has also been drawn to anniversary reactions possibly constituting a subgroup of seasonal mood disorders and bipolar disorder (Beratis, Gourzis, & Gabriel, 1996). Once more, as far as children are concerned there is clinical evidence of the reality of the phenomenon but a paucity of research that might be informative on its frequency or importance. In the psychoanalytic literature, however, the topic of anniversary reactions has been more extensively dealt with regarding both children (Azarian, Miller, Palumbo et al., 1997) and adults (Taylor, 2002).

A cognitive vulnerability–transactional stress theory proposed by Hankin and Abrahamson (2001) to explain the development of gender differences in depression in adolescence is worth noting here. This transactional model involving bidirectional effects among biological changes, negative affect, pubertal timing and “social” life events posits a causal chain leading to a higher rate of depression in girls. It argues that in girls, negative affect resulting from a negative life event is more likely to be perpetuated by their negative cognitive style (possibly related to pre-existing vulnerability resulting from early abuse, for example), thus leading to clinical depression, which once established promotes self-generated negative interpersonal life events, and these in turn help to keep the chain going.

The concept of sensitization can also be utilized in the context of treatment. Thus, there is evidence that cognitive–behavioral treatment programs involving desensitization, in the form of careful graded exposure to traumatic memories, are helpful for children with PTSD (Stein, Jaycox, Kataoka et al., 2003).

## The Concept of Adjustment Disorder

For many years, the diagnosis of “adjustment disorder” was extremely popular in child and adolescent psychiatry (for a systematic review see Hill, 2002). Its prime use seems to have been the apparent value of avoiding stigmatizing diagnostic terms that implied a poor prognosis. At that time, many clinicians assumed a substantial discontinuity between child and adult psychopathology, with the former more benign and more normative. The relationship with a putative stressor constituted the “peg” on which to hang this diagnostic notion.

Research findings have cast doubt on virtually all of these assumptions. Acute stress experiences are associated with a wide range of psychopathological disorders and there is nothing particularly distinctive about those provoked by stress. Moreover, although some stress reactions are quite brief in duration, others are long-lasting. Moreover, mild disorders that fall short of the symptom criteria specified for other diagnoses may not be associated with stress events and may nevertheless involve significant social impairment (Angold, Costello, Farmer et al., 1999). Finally, the continuities between child and adult psychopathology are strong rather than weak (Rutter, 2005; Rutter, Maughan, & Kim-Cohen, 2006a; see also chapter 13).

Both the major classification schemes – ICD-10 (World Health Organization, 1996) and DSM-IV (American Psychiatric Association, 2000) – still include the diagnostic category of adjustment disorder, but it is noteworthy in being the only diagnosis without a characteristic clinical picture. Rules are specified to indicate when the diagnosis may be made but they are essentially arbitrary and lacking empirical research support. The category probably retains some utility in providing a means of recording mild non-specific disorders that do not meet the criteria for other specific diagnostic categories and yet involve significantly impaired social functioning, but its use should not be misleadingly tied to the association with a life stressor. Accordingly, the concept is best regarded as an historical anachronism rather than a solid diagnostic category and it will not be considered further here (for a review of the evidence see Hill, 2002).

### Bereavement as a Specific Kind of Life Stress

Traditionally, bereavement has been given special attention as a stress reaction. DSM-IV excludes bereavement reactions lasting less than 3 months from psychiatric disorders on the grounds that these are normal expected reactions. However, pathological grief reactions are considered disorders if they last longer than 3 months and if they include specified symptoms (the symptoms being ones that are more appropriate for adults than for children). ICD–10, on the other hand, does not have a specific pathological grief diagnosis and does not exclude bereavement reactions just because they last less than 3 months, provided that they are associated with significant social impairment. Unlike DSM-IV, it also recognizes that the disorders that follow bereavement may take many different forms. The literature on bereavement was well reviewed by Black (2002) and only the key findings are noted here.

First, the notion that, in the general population, normal grief reactions do not last longer than 3 months is simply wrong. To the contrary, most follow-up studies indicate that sequelae often last up to 2 years (perhaps more clearly shown in adults than in children). For example, in a longitudinal study of parent-bereaved children and adolescents (Cerel, Fristad, Verducci et al., 2006) an increased rate of impairing psychiatric symptoms, especially depression, was still present at the 2-year follow-up.

Second, with children, the long-term sequelae depend more on the consequences of the bereavement than the parental loss as such. Thus, the long-term risks are particularly influenced by the effects on the quality of parental care and on the psychopathology of the surviving parent, as well as by the child’s own psychiatric problems predating the bereavement (Cerel et al., 2006; Dowdney, 2000; Harris, Brown, & Bifulco, 1986). Accordingly, childhood bereavement as such is not a major risk factor for later psychopathology (Harrington & Harrison,
1999) with the risks substantially less than those associated with parental divorce or family break-up (Rutter, 1971).

Third, this conclusion applies to bereavements arising from illness or accidents. The sequelae of bereavements deriving from sudden, unexpected, violent or mutilating deaths, particularly if witnessed by the child – especially those of family members – produce more serious psychopathology. Children can get caught up in war and civil conflict, and may witness the murder of parents, siblings and other familiar people (Newman, Black, & Harris-Hendriks, 1997; Osofsky, 1997). Of the children who experience death of a loved one, those who witness a sudden, horrific and unexpected death and those who perceive a threat to their own life are more likely to develop PTSD (Harris-Hendriks, Black, & Kaplan, 1993; Pynoos, Frederick, Nader et al., 1987; Stoppelbein & Greening, 2000). Family survivors of homicide are at high risk of developing dysfunctional symptoms such as PTSD that tend to persist longer than in other bereavements (Amick-McMullan, Kilpatrick, & Resnick, 1991; Masters, Friedman, & Getzel, 1988). These features are considered more fully in chapter 31.

Fourth, it is important to recognize that children’s responses to bereavement are not identical to those seen in adults. Young children are more likely than older ones to have difficulty comprehending death and in enduring feelings of grief and mourning. For example, according to the review of children’s reactions to death (Cuddy-Casey & Orvaschel, 1997) the concepts of irreversibility and universality were found to be understood before causality, and external events, such as moving and speaking, were believed by children to cease before internal ones, such as thinking and feeling. Children younger than 5 years generally appear unable to give a narrative account of the sequence of events around bereavement. Likewise, children’s capacity to sustain sad affects increases gradually with age and maturity. Thus, young children do not sustain affects for long periods and their apparent lack of sadness may deceive their caregivers into believing that they are unaffected by the loss.

The reactions of young children often take an immature form and therefore appear different. It is also not unusual for young children to develop pathological mourning reactions (Goodyer, 1990). At a preverbal age, for example, children react to loss with bodily responses. They may lose their recently acquired control over urination or defecation, lose their appetites, fail to settle to sleep or become restless. Motility or speech may be temporarily lost. Lowered resistance to infections and other illnesses has also been noted in young children following the loss of a parent (for a broader review of the effects of stress and adversity on immunological responses see Institute of Medicine of the National Academies, 2006). As children may not understand the source of emotions of grief they often suffer alone without seeking support from carers or other adults. The misconstruing of emotions can lead to hypochondriasis or other psychosomatic symptoms and these in turn may bind the surviving parent to the child, thus reinforcing the symptoms. Children may also hide their own grief in order to protect their parent and avoid upsetting them. Disruption of attachment because of the death of a caregiver – usually a mother – during early childhood increases the risk of an attachment disorder, a separation anxiety disorder, anxiety, depression or other emotional disorder during childhood or adolescence. Adolescents in the process of separating from parents may either take a step back by becoming more involved with the family, especially if they are the eldest or the same sex as the deceased parent, or react by rejecting the family and moving into a premature adult role.

The effects on children of a sibling death have been less well studied than that of a parent. The available studies indicate a mixed picture, with some (Pettle Michael & Lansdown, 1986) reporting high levels of both emotional and behavioral disturbance up to 3 years following sibling bereavement, while others (Brent, Moritz, Bridge et al., 1997), although detecting a several-fold increase of major depression in the first 6 months, found the risk disappearing by the 3-year follow-up.

According to Black (2002), the assessment of children and adolescents who have been bereaved, especially by a traumatic death, must involve not only evaluation for the presence of psychiatric disorders, but also their attachment needs, where they should live (if it is not possible or desirable to live with the parents) and what contact they should have with a perpetrator parent (if the death has been brought about by homicide). The assessment must also include an evaluation of the effect of the bereavement on their carers’ parenting capabilities. Likewise, it is essential to interview each affected child (and adult) individually. The specific assessment of post-traumatic reactions is necessary in traumatic bereavements, and is desirable in the case of all bereaved children.

The majority of bereaved children will not require psychiatric treatment, but most will benefit from contact with a concerned adult outside the family to help the child understand and come to terms with their loss. Such help may be provided by a school counselor, health visitor or counselor attached to a GP’s surgery, or volunteer bereavement counseling services. Child and adolescent mental health services can provide useful support, training and consultation to such services. Black (2002) recommended that in an effort to prevent morbidity and focus resources, psychiatric assessment should be made available to the following high-risk groups: children under 10 years; those with learning difficulties; those who have suffered previous losses; where there is a family or personal history of psychiatric disorder; where the death is sudden or otherwise traumatic; children caught up in witnessing violent deaths of those known to them (homicide, accident, suicide); where there is perceived threat to their own life; those with multiple psychosocial adversities; and those where the surviving parent(s) are failing in their care of the child.

Mechanisms Moderating and Mediating Stress Responses

In so far as negative life experiences have enduring effects on mental health, it is necessary to consider the mediating...
mechanisms by which the sequelae are carried forward in time, and what factors have a moderating role in this process (Rutter, 2000a,b). First, persistence may come about because the initial adverse experiences led to altered patterns of interpersonal interaction (Moss, Cyr, & Dubois-Comtois, 2004) which, in turn, brought about further negative experiences (Rutter et al., 1995; Rutter, Giller, & Hagell, 1998). Alternatively, as suggested by the findings relating to physical abuse, the experience may result in altered cognitive sets or styles of emotional and cognitive processing (Dodge, Pettit, Bates et al., 1995; Overmier & Murison, 2005). A third possibility is that the stress affects neurobiological structure and function, as suggested first by animal studies and subsequently by a growing body of research on humans (for reviews see Dickerson & Kemeny 2004; Grossman, Churchill, McKinney et al., 2003; Levine, 2005; Shea, Walsh, MacMillan et al., 2004). In their meta-analytic review of 208 laboratory studies with adults, Dickerson and Kemeny (2004) concluded that it is particularly tasks containing both uncontrollable and social-evaluative elements that are associated with the largest cortisol and adrenocorticotropin hormone changes and with the longest times for recovery. The implication (as yet untested) is that it is these elements that may be most important in more naturally occurring stress events in childhood, as well as adulthood.

The mechanism with respect to severe and lasting early adversities could also lie in the developmental programming of the brain (for reviews see Bremner & Vermetten, 2001; Granger, Hood, Dreschel et al., 2001; Kaufman, Plotsky, Nemeroff et al., 2000; Ladd, Huot, Thrivikraman et al., 2000; LeDoux, 2002; Pine, 2003). Evidence from preclinical studies has been most consistent in demonstrating the effects of early adverse experiences on brain structure and function. Thus, it has been established that stress effects on the development of hippocampus are mediated by at least three forms of structural plasticity: neuronal atrophy, neurotoxicity and neurogenesis. Of these, neuronal atrophy can be caused by exposure to stress leading to a cascade of glucocorticoids; however, it is a reversible effect. Prolonged stress, on the other hand, leads to a neurotoxic effect with a permanent effect. Stress may also inhibit the normal neurogenesis leading to reduced hippocampal volume. Studies of maternal depression and postnatal handling have highlighted the importance of early experience on the development of the brain and the multiple neurotransmitter systems (Kaufman et al., 2000).

Similarly, research in rodents and non-human primates has led to greater understanding of the brain areas and brain functions, including neurochemical responses, involved in threat perception (Pine, 2003). Thus, stress during key stages of development has been shown to produce long-term alterations in the threat response. These comprise a neuroanatomical circuit involving two major cortical pathways (pre-frontal cortex and components of temporal lobes), two key subcortical structures (amygdala and hippocampus) and a neurochemical pathway consisting of ascending brainstem monoamine neurons. Regulation of this circuit can be shaped through experiences during development.

There is also evidence of experience-related developmental plasticity (Pine, 2003; Yehuda & McEwen, 2004), with experience having a direct role in organizing stress regulatory systems during development. Here, the key factors are the level and nature of early maternal care, which can affect behavior, as well as the hormonal and neural systems related to stress regulation. These maternal influences, beginning soon after birth and appearing to operate within a critical window in the early postpartum phase, can also permanently alter the HPA axis in adulthood (Yehuda & McEwen, 2004).

Animal studies have also shown that the subsequent caregiving environment can moderate the adverse effects of early stress on neurobiological systems (Kaufman et al., 2000), and “adoption with optimal parenting” (“cross-fostering”) has been found to reverse maladaptive HPA axis alterations. Furthermore, there is evidence to suggest that comparable effects could occur in humans and therefore have therapeutic implications.

Clinical studies of adults with a childhood history of abuse have implicated long-term dysfunction of the stress response systems (HPA axis, noradrenergic and hippocampal systems) and it has been proposed that these effects underlie the symptoms of PTSD and other stress-related disorders (Delahanty, Nugent, Christopher et al., 2005; McEwen, 2000; Oliff, Langeland, & Gersons, 2005). Likewise, dysregulation of the HPA axis has been suggested as the possible link between exposure to major traumatic events such as sexual abuse and subsequent psychiatric disorder in children (Carrión, Weems, Ray et al., 2002). An association between abnormal cortisol levels and emotional problems accompanied by extreme behavioral inhibition, social wariness and withdrawal has also been reported in studies with children (Ashman, Dawson, Panagiotides et al., 2002; Essex et al., 2002; Smider, Essex, Kalin et al., 2002). The findings have, however, by no means been consistent with regard to the nature of the dysregulation and the patterns of association (for review see Gunnar & Donzella, 2002; Gunnar & Vazquez, 2006).

A more consistent, but complex, picture has emerged from neurochemical studies in adults (Yehuda & McEwen, 2004). These have established with some certainty that stress should no longer be defined by glucocorticoid excess any more than glucocorticoid excess be taken as evidence of stress. Here, a study by Yehuda, Halligan, Golier et al. (2004) on the effects of trauma exposure on cortisol response to dexamethasone administration has been especially informative. It has helped to clarify the likely reasons for previous conflicting findings regarding cortisol levels in major depressive disorder (MDD). The study was able to establish the important role of major traumatic experiences in enhancing cortisol suppression (i.e., lower cortisol levels in PTSD patients), in contrast to higher cortisol levels in persons with MDD. However, in individuals with both PTSD and MDD, those with a trauma experience predating that causing PTSD, cortisol levels resembled those found in PTSD. Heim, Newport, Bonsall et al. (2001) reported similar findings and concluded that a history of early
abuse may explain why only about half of MDD patients show reduced suppression, thus indicating that neurobiological sensitization of HPA axis is a prominent neuroendocrine response in MDD in the presence of PTSD.

There is also evidence that vulnerability to later emotional and behavioral dysregulation extends to include prenatal stress in both animals (Coe & Lubach, 2000; Kofman, 2002; Schneider, Moore, Roberts et al., 2001; Yehuda & McEwen, 2004) and humans (Gutteling, de Werth, & Buitelaar, 2005; Kraemer & Clarke, 1996; Phillips & Jones, 2006; Wadhwa, 2005). A neurobiological model of prenatal stress proposes that maternal stress exerts a negative influence on fetal developmental outcome that is mediated by the HPA system. Central to an understanding of how high levels of glucocorticoids in maternal circulation may alter fetal development is the knowledge that maternal–fetal communication during gestation is endocrine rather than neural, and cortisol levels in the fetus correlate with those in the maternal circulation. This has important implications, because excess levels of cortisol inhibit intrauterine growth, may accelerate the onset of parturition indirectly and may alter the regulation of glucocorticoid receptors in the brain of the developing fetus. It has been suggested that intrauterine exposure to high levels of cortisol could permanently increase the “set point” for HPA axis deactivation in relevant brain areas, resulting in stress responses and behavioral alterations consistent with depressive illness. Glucocorticoid exposure in the third trimester appears to be the critical period for stress programming.

Primate research has also presented evidence that chronic unpredictable stress during pregnancy may have long-lasting effects on brain activity and behavior of the offspring (Coe & Lubach, 2000; Schneider et al., 2001). Prenatal stress appears to affect the neurobiology of the neonate so that its responses to common events and stimuli are markedly altered. These effects on brain mechanisms are more likely to be diffuse, rather than specific. As a consequence, the neonate may, for example, be more fussy and difficult, affecting how the caregiver is able to cope. Thus, prenatal stress appears to set the infant’s neurobiology into a state in which vital attachments are hard to achieve and adverse experiences more likely. The adverse experiences can in turn result in further neurobiological deflection of development. Prenatal effects on fetal neurobiological development may also be easily confused with genetic predisposition. Prospective studies of prenatal maternal stress on children’s neuroendocrine and behavioral functioning have shown significant associations with both (Gutteling, de Werth, & Buitelaar, 2005; Phillips & Jones, 2006; Wadhwa, 2005). The effects are best demonstrated in relation to birth weight but they extend more widely. Up to now the inferences about mediation are limited by a lack of tests of genetic mediation and by limited contrasts with postnatal stresses. Nevertheless, some prenatal effects seem probable.

In children and in adults, not only have negative life events been associated with a wide range of psychopathology (Gowers, North, & Byram, 1996; Sandberg et al., 1993), but they have also been shown to precede the onset of many somatic illnesses and to relate to their reoccurrence (Haavet & Grunfeld, 1997). The role of stress in viral infections has been the focus of research in more recent years. Thus, it has been shown that stressful experiences have adverse effects on the body’s immunological responses (for review see Segerstrom & Miller, 2004), this possibly providing the mediating factor in relation to the demonstrated effects of adverse life events in increasing susceptibility to infections. It is also well acknowledged that the immune system and the central nervous system form a bidirectional communication network. In this network pro-inflammatory cytokines have a critical role (see chapter 57).

Implications for Clinical Practice

Most children presenting with the common forms of psychopathology have experienced, and may continue to be experiencing, acute life events carrying long-term threat. Such events are clinically important for a variety of different reasons and it is necessary that any adequate diagnostic assessment includes enquiring about them. Thus, they may have had a role in precipitating the sudden onset or exacerbation of acute emotional disorders or of suicidal acts or ideation. The key events might include bullying at school, humiliating experiences, rejection by friends, unexpected or supposedly unwarranted punishment at school or home, or episodes of physical or sexual abuse. Clearly, a key consideration in all instances is whether the events are ongoing, whether they should be preventable, and how the child (and family) are coping with them.

The events may also serve as an important index of ongoing chronic adversities – at home, at school, or in the family. In that connection, a key question is whether parents or teachers are responding to the child’s behavior in ways that create stress. Are misdemeanors being dealt with through humiliating or stigmatizing the child or by outbursts of uncontrolled anger? The main point here lies in the identification of the coping responses used by the child and the child’s family (or teachers). The focus in this instance is less on the causal impact of the life events than on the ways in which patterns of interpersonal interactions may be working in positive or negative ways.

In that connection, equal attention needs to be paid to how the child is responding to stresses and challenges. That is where resilience concepts come into their own. What are the ways in which the child is coping effectively and how may they be used in planning effective therapeutic interventions? A particular issue concerns comparisons among siblings. If, apparently, other children in the family are coping successfully with comparable stresses, but the child-patient is not, what are the factors that seem to be making a difference? Do the differences among siblings reflect variations in the ways parents are treating the children or do they reflect differences
in the children’s coping strategies? In other words, the main importance of stressful life events does not lie in the causal attributes given to particular events but rather to the implications for coping strategies. By the same token, the focus needs to be as much on the mechanisms involved in the creation of negative life events as in their effects.

Looking into the Future

A major growth area in stress research concerns the mediating mechanisms that underlie both the development of psychopathology and the development of resilience. Much of the research has focused on the HPA axis but we lack a good understanding of whether the neuroendocrine changes mediate (i.e., account for) the psychopathological sequelae. Evidence is beginning to accumulate on the differences in response to acute negative events and to chronic adversities but the findings so far are rather inconclusive. We know even less about what it is that leads to “steeling” rather than “sensitizing” effects. It is evident that both occur but why and how? The findings on gene–environment interaction (G × E) are particularly promising in providing leads on both the genetic and environmental causal pathways and, most especially, on the ways in which they come together. However, it would be a mistake to focus exclusively on neuroendocrine effects. Negative life events may have effects on self-esteem, cognitive sets and internal working models. There is a general acceptance that they are likely to be important in mediating both positive and negative consequences but research into their role is in its infancy. What is particularly needed is research that seeks to contrast competing alternative mediating mechanisms in G × E, neuroendocrine responses, cognitive mechanisms, coping responses and effects on interpersonal interactions, to mention but a few possibilities. These issues apply as much to anniversary reactions as to sensitizing effects. Do these reflect the same or different phenomena?

Although there is now evidence that the mother’s anxiety during the pregnancy can have effects on the fetus, little is known about the psychopathological consequences after birth. There have been speculative suggestions about biological programming effects but, so far, these remain as just one possibility. Systematic research into mechanisms (using animal models as well as human studies) is required and this will have to examine competing possible processes, including the mediators for the psychopathological consequences when they occur.

Finally, we need to turn to a topic not considered in this chapter. Our focus has been on definable negative life events. As we have shown, they are important. In addition, however, we need to draw attention to the fact that many of the more common psychopathological disorders in young people (but not in older age groups) have tended to rise over the last 50 years (Collishaw, Maughan, Goodman et al., 2004; Rutter & Smith, 1995). Why? Could this be because there have been changes in the pattern of life challenges as they face young people? That remains an almost wholly under-researched topic, but clearly it is one of huge policy and practical importance.

Acute Life Stresses

Impact of Parental Psychiatric Disorder and Physical Illness

Alan Stein, Paul Ramchandani and Lynne Murray

Brief Review of Main Disorders Considered

There is now a substantial body of evidence that psychiatric and physical disorders in parents are associated with an increase in a range of psychological disturbances in children. For many parental psychiatric disorders the rates of transmission to the child are substantial. This is particularly important because, even after remission of the disorder in the parents, disturbance in children may persist. There is therefore a need for clinical measures to reduce risk to the offspring, and for the introduction of policies to prevent difficulties arising. In addition, the elucidation of the processes involved in inter-generational transmission of disorder is scientifically important in that it will provide insight into the understanding of the pathways involved in both disturbances in child development and the evolution of disorders, as well as healthy development and resilience.

What is the Scale of the Problem?

The issue of the effects of parental disorder on children applies both to mothers and fathers; most of this chapter will concentrate on parental psychiatric disorders, as that is where most research has been carried out. However, we also provide a brief review of the evidence in relation to physical disorders. Some disorders are especially common in the child-bearing years, such as depression, anxiety, eating disorders and alcoholism. In the following section we primarily focus on the psychiatric or psychosocial outcomes for children. Alongside these, other difficulties, such as the impact on normal family functioning, must also be considered. These are summarized in the section on clinical implications.

Parental Psychiatric Disorders

Depression is the most common psychiatric condition amongst women of childbearing age and has a point prevalence of over 8% (Weissman, Leaf, Tischler et al., 1988). A significant proportion of the research conducted on parental depression has focused on the postnatal period, and this is considered separately below (see p. 408). However, depression affecting parents of older children has also revealed consistent associations with difficulties in their children. These include an increased risk of insecure attachment to the depressed parent (Martins & Gaffan, 2000), an increased risk of behavioral problems, such as conduct disorder in school-aged children, and, in adolescence, an increased risk of psychiatric disorder. This is most noticeable for depression, but also includes an increased risk of anxiety disorders (Beardslee, Versage, & Gladstone, 1998). An increased risk of psychiatric disorder persists into adulthood. In a 20-year longitudinal study, Weissman, Pilowsky, Wickramaratne et al. (2006) found that the offspring of depressed parents had a three-fold increase in major depressive disorder, anxiety disorders and substance dependence, as well as an increased risk of physical health problems and greater social impairment. There is evidence that the more severe and chronic the parental depression, the greater the impact on risk for offspring disorder (Hammen & Brennan, 2003).

Anxiety disorders in parents are also common, the lifetime rate for the most prevalent of the anxiety disorders, social phobia, being 13% (Kessler, McGonagle, Zhao et al., 1994). Studies of children of parents with anxiety disorders show them to be at high risk for anxiety themselves (Biederman, Petty, Faraone et al., 2006). In one study, children of parents with anxiety disorders were seven times more likely to be diagnosed with an anxiety disorder compared with normal control groups, and twice as likely as children of parents with dysthymia (Turner, Beidel, & Costello, 1987). One well-controlled study found that there was a two-fold increased risk of anxiety disorders among offspring of anxious parent probands, compared with offspring of substance abusing parents or controls (Merikangas, Dierker, & Szatmari, 1998). Social phobia has been reported in almost one-quarter of the children of patients with social phobia (Mancini, Van-Ameringen, Szatmari et al., 1996).

In a 5-year prospective study of the adolescent children of parents with bipolar disorder (Hillegers, Reichart, Wals et al., 2005), lifetime prevalence was found to be 10% for bipolar disorder, with prevalence for mood disorders of 40% and psychopathology in general of 59%. Seven percent of offspring showed current mood disorder, with 28% displaying current psychopathology. Other studies have found even higher rates of disorder, with much higher risks for both bipolar disorder (morbidity risk 33.0 versus 2.8) and earlier onset depression (by age 12 years, morbidity risk 34.2 versus 7.5) in children of parents with bipolar disorder compared to children of adults without mood disorder (Henin, Biederman, Mick et al., 2005).
Eating disorders have also been shown to occur commonly among women of childbearing age (Fairburn & Harrison, 2003), and the prevalence may be rising. Most affected women with eating disorders have bulimia nervosa or eating disorder not otherwise specified (EDNOS; see chapter 41). A small minority have anorexia nervosa and their low weight (and the fact that they are not ovulating) means that this last group are less likely to conceive. Underweight women required an average of 29 months to conceive, compared to 6.8 months in normal weight women (Hassan & Killick, 2004). Nonetheless, potential eating disorders involve psychopathological risks for the offspring, particularly during infancy and adolescence (Patel, Wheatcroft, Park et al., 2002). A large Scandinavian study (Brinch, Isager, & Tolstrup, 1988), using retrospective reports, found that 17% of children of women with a history of anorexia nervosa failed to thrive in the first year of life. Two longitudinal studies have shown some adverse outcomes for children of mothers with eating psychopathy in the postnatal year. Stein, Woolley, Cooper et al. (2006) showed that, compared with controls, children whose mothers had experienced an eating disorder in the postnatal year were more likely to have conflictual mealtimes at 5 years of age. At 10 years they were more likely to have concerns about body shape and weight and to use dietary restraint. Stice, Agras, & Hammer (1999) found that childhood eating disturbance at 5 years of age was predicted by a range of maternal variables such as body dissatisfaction and the internalization of the thin ideal. Furthermore, at 8 years of age, higher maternal restraint scores predicted worries about being too fat in girls but not in boys, while maternal disinhibition scores predicted weight control behaviors in daughters (Jacobi, Agras, & Hammer, 2001).

Alcoholism and substance abuse are conditions that are easily overlooked. However, they are not uncommon amongst adults of childbearing age, and are certainly associated with higher risks amongst the children (Lieberman, 2000). For example, a large Dutch study (Cuipers, Langendoen, & Bijl, 1999) found that adult children of alcoholics had a significantly higher 1-month, 12-month and lifetime prevalence of mood, anxiety and abuse and/or dependence disorders than offspring of non-alcoholic parents (lifetime risk for any disorder 57.7% versus 39.5%). Sons of problem drinkers had a higher occurrence of eating disorders (2.0% versus 0.1%) and schizophrenia (1.6% versus 0.3%). Rates were especially high for the children of fathers with drinking problems. The authors concluded that, relative to other parental problem behaviors, parental problem drinking is a strong predictor of psychiatric disorders, especially abuse and/or dependence disorders. One particular hazard of alcoholism is drinking during pregnancy, which has been shown to be associated with fetal alcohol syndrome (FAS). For example, Von Knorring (1991) reported that FAS appears in 5.9% of births of alcoholic women, compared to a rate of 0.01–0.03% in the general population (but see chapter 30 for a discussion of uncertainties about the boundaries of FAS).

Some severe psychiatric disorders such as schizophrenia are associated with lowered birth rates, but a good proportion of affected adults do have children. Similarly, those with personality disorders, while having difficulties in forming intimate relationships, are still likely to have children. Compared with the general population, parents with a diagnosis of schizophrenia have a greatly increased risk of having a child who later develops schizophrenia themselves (Gottesman & Shields, 1976). In addition, although most of the study samples have been relatively small, they do suggest that children of affected parents have a raised risk of a range of other mental disorders, including attention deficit/hyperactivity disorder, anxiety disorders and depressive disorder.

Postnatal Psychiatric Disorders

The postnatal period has been much studied in recent years. This is in part because of the relative vulnerability of the developing infant at this time, who is entirely dependent on carers for his or her health and successful development. There has also been a recognition of the significant morbidity and distress caused by postnatal psychiatric disorder, in particular postnatal depression. Other important psychiatric disorders can occur in the postnatal period and have significant effects on the mother and her family, including anxiety, schizophrenia, substance abuse and some eating disorders. However, in this section we focus on depression and, to a lesser degree, affective psychosis, as mood disorders are the most prevalent and the most studied.

Estimates of depression occurring specifically in the postnatal period appear to be somewhat higher than at other times, at 13% (O’Hara & Swain, 1996). Most research has been conducted in the developed world; more recent studies of developing world populations have often shown rates to be substantially higher, although there is significant variability (Halbreich & Karkun, 2006). The symptoms of depression occurring at this time are largely the same as at other times, with low mood and loss of interest and enjoyment usually prominent. Those at particular risk of developing postnatal depression include women with a past history of depression and those without good confiding relationships. Other factors can include relative socioeconomic deprivation and social isolation (Boycie, 2003).

An increasing number of longitudinal studies have identified associations between maternal postnatal depression and adverse child outcomes. The potential mechanisms by which any risk may be transmitted from parents to children are considered on p. 411, but the difficulties reported include more difficulties managing the babies’ crying (Seeley, Murray, & Cooper, 1996); characteristic impairments in mother–infant interaction (Murray, Fiori-Cowley, Hooper et al., 1996a); and higher rates of emotional (Lyons-Ruth, Alpern, & Repacholi, 1993) and behavioral problems as the children approach school age (Sinclair & Murray, 1998). A number of studies have also found an association between postnatal depression and poorer cognitive development (Hay, Pawlby, Sharp et al., 2001; Murray, Kempton, Woolgar et al., 1993; Murray et al., 1996a) although this has not been confirmed by all studies (e.g., Murray, Hipwell, Hooper et al., 1996b). There are few longer-
term studies that have followed up children into adolescence, but one identified a higher risk of both mood and anxiety disorders for the offspring of mothers who were postnatally depressed (Halligan, Murray, Martins et al., 2007).

Postpartum psychosis is far less common, affecting 1–2 women per 1000. Episodes are frequently affective in nature and the most notable risk factor is a past or family history of affective psychosis. These disorders can have a devastating effect on the mother, infant and family. The impact on an infant can be manifest both in terms of a mother’s ability to care for herself and her infant (poorer quality caregiving), and by the infant becoming the focus of a mother’s delusional beliefs. Fortunately, this latter problem is a relatively rare occurrence; nevertheless, when it does occur, provision of a high level of treatment, supervision and support becomes necessary. This will often require in-patient care, ideally in a specialist mother and baby unit, where the baby can remain with the mother in all but the most extreme of presentations, and where experienced skilled staff can provide the level of care and supervision necessary. It is in these circumstances in particular where the clinician also has to be aware of potential danger to the child’s well-being, either through direct risk from a mother with delusional beliefs and/or hallucinations, or through neglect of the child. The need to balance the risk (to mother and child) with the desire to keep parent and child together to promote the development of a positive relationship and facilitate the mother’s recovery requires experienced clinical judgment. These concerns regarding the protection of the child’s well-being are not confined to the occurrence of psychotic illness in the mother, although they are more often to the fore here. These should also be considerations when severe parental depression may lead to neglect of their infant’s care.

Similar issues also arise with other disorders. There has been little study of the longer-term outcome of children whose mothers suffered a postnatal psychotic episode. The few small studies that there have been (McNeil & Kajj, 1987) tend to suggest an absence of ill effects, possibly because episodes are of limited duration, and recovery is generally good. For a fuller discussion of how to assess a range of psychiatric disorders and the risk of infanticide in the immediate perinatal, and the role of mother and baby psychiatric units, see Marks, Hipwell, & Kumar (2002).

Alcohol and drug problems can often coexist with depressive disorder. Some of the risks and potential effects of these disorders are considered elsewhere (see chapter 36), but of particular relevance to the early postpartum period is the problem of the withdrawal syndrome. Newborn babies of mothers who are drug-dependent are already at higher risk than non-exposed infants for perinatal complications such as prematurity and low birth weight. A withdrawal syndrome can develop in some cases, particularly where the mother has been using opiates, but this can also occur with other drugs such as benzodiazepines. The symptoms and signs seen in the infant depend on the drug used, and the risk and severity of these symptoms are diminished significantly if the mother has been abstinent from drug use for more than a few days (American Academy of Pediatrics: Committee on Drugs, 1998). In circumstances where a child exhibits a withdrawal reaction, the issue of child protection will also require careful consideration and, where parents have a continuing substance addiction, child protection will be a continuing concern for the professionals involved.

Parental Physical Disorders

The association between physical illnesses and child disturbance and development has been less-well studied than that with parental psychiatric disorder. Nonetheless, some physical illnesses are relatively common in adults of parenting age, and a number of chronic conditions have been shown to affect women of childbearing age; indeed, almost 10% of women aged 18–44 years report some restriction of activity caused by chronic disease (Misra, Grason, & Weisman, 2000). In this relatively limited research field, much of the work has focused on cancers that affect parents. Breast cancer alone affects 1 in 9 women in the Western world. Over one-quarter of those affected have children living with them and, consequently, this has tended to be the most frequently studied condition. Reviews of the effects of parental cancer on children’s development have, unsurprisingly, revealed a relatively complex story (Visser, Huizinga, van der Graaf et al., 2004). There is a relatively consistent increase in emotional problems seen in adolescent offspring of parents with cancer. However, there is less evidence regarding emotional problems in younger children, and it is inconsistent. That is not to say that they are unaffected, as qualitative interview studies have highlighted common feelings of guilt and distress, but these may not always translate to changes in measured scores on psychological questionnaires. The effects on children appear to be moderated by a number of the same factors that moderate the effects of parental psychiatric illness on children (see p. 411). These include the degree to which the cancer affects parental, family and marital functioning, and the pre-existing relationship between parent and child. Pre-existing family structure has been shown to significantly predict child outcome, with children from single-parent families more at risk (Visser, Huizinga, Hoekstra et al., 2006).

HIV/AIDS has become the largest pandemic ever, and in sub-Saharan Africa in particular it has reached catastrophic proportions. Young people of childbearing age, particularly women, are most affected with, for example, 10 million people in sub-Saharan Africa aged 15–24 being infected – the next generation of parents. There is now substantial evidence that the offspring of mothers with HIV are at increased risk in terms of their development, growth and survival (Stein, Krebs, Richter et al., 2005). In parts of sub-Saharan Africa, up to 40% of women attending antenatal clinics are HIV-positive. Untreated, transmission to the infant (during pregnancy, labor, delivery, or through breastfeeding) can occur in up to 40% of cases. However, this can be dramatically reduced to 10% by the provision of a single dose of nevirapine to the mother as she goes into labor and to the infant within the first few days of birth. The transmission can be reduced to well...
below 10% with the addition of Cesarean section and formula feeding. However, both infected and uninfected children show increased levels of developmental problems. Surprisingly, relatively little research has been carried out into this. Nonetheless, the research that has been carried out suggests that uninfected children born to mothers with HIV are at increased risk of a range of problems including attentional difficulties, behavioral problems, difficulties with social adjustment and language development (see chapter 38). One of the most important mechanisms is likely to be through compromised maternal care, especially in the context of maternal depression. Maternal depression has been shown to be relatively common amongst women following the diagnosis of HIV/AIDS during pregnancy (Rochat, Richter, Doll et al., 2006), which is when most women in Africa receive their diagnosis.

Studies of parents with other illnesses have used diverse groups of physical health problems, including diabetes and multiple sclerosis (Korneluk & Lee, 1998). Some studies have compared children of these parents with children from “healthy” families, and some with families where a parent has a psychiatric disorder. Overall, children in families where a parent has a physical illness have higher rates of anxiety and depression than children in “healthy” families, but broadly similar rates to those seen in families where a parent has a psychiatric disorder. It should be stressed that most of the studies were relatively small, and had limited scope to investigate the mechanisms by which any increased risk may occur. Similar moderating influences, such as those apparent in the literature on parental cancer outlined above, are likely to operate (Pederson & Revenson, 2005), although there is a lack of research addressing this at present. Given the high prevalence of chronic physical illnesses in adults of parenting age, further research to understand the way in which increased risk to the child occurs is important, particularly as it may point the way towards the development of effective interventions. Anxiety and depression are clearly only two areas of child functioning that may be affected by parental ill-health. They are the most studied, but some studies of functional disorders (e.g., irritable bowel syndrome) have also examined responses to illness in the children themselves. This research has shown the way in which the adult’s disorder is linked to a change in parental behavior in seeking medical help when their young child exhibits common symptoms of illness (Crane & Martin, 2004). These studies suggest that a lower parental threshold for seeking help may potentially affect children’s interpretations of symptoms as they grow up to take increasing responsibility for their own health.

**Studies of the Parents of Children with Disorders**

Another way in which researchers have attempted to illuminate some of the associations between disorders in children and parents is to conduct “bottom-up” studies. In these studies, the psychiatric states of parents of children who are known to have disorders are examined in an attempt to illuminate the nature of the risk. These types of study complement those that begin with parents as the index, and are of particular use when a relatively rare child disorder is being studied. They can also provide additional information in relation to more common child disorders such as anxiety. For example, Martin, Cabrol, Bouvard et al. (1999) found an increased prevalence of both anxiety and depressive disorders in mothers and fathers of anxious school-refusing children. Increased prevalences of simple phobia and/or social phobia were found among the fathers and mothers of phobic disordered school refusers, and increased prevalences of panic disorder and/or agoraphobia were found among the parents of separation anxiety disordered school refusers. Similarly, Cooper and Eke (1999), in a community sample, found raised rates of social phobia among the parents of shy children. A recent study, using a clinic sample, found that social phobia and separation anxiety in the child were each associated with an increase in these same disorders in their mothers (Cooper, Fearn, Willetts et al., 2006). Similar patterns have been seen in eating disorders, where raised rates of eating psychopathology have been found among the mothers of children with feeding problems (Cooper, Whelan, Woolgar et al., 2004; Stein, Stein, Walters et al., 1995).

Such patterns of association suggest a degree of specificity in some of the links between the disorders in parents and offspring, particularly for social phobia and separation anxiety, and possibly eating disorders, while other parental disorders (e.g., depression and general anxiety disorder) appear to be more general in their intergenerational association.

**Summary of Findings**

In summary, although the evidence is relatively limited, there do appear to be increased risks of anxiety and depression in children when a parent has a chronic physical illness. The exact extent of these risks is clearly dependent on a number of family factors such as the family’s structure and current social situation, functioning, and also the developmental stage of the child.

It can be seen from the above that a wide range of common disorders that affect parents are associated with an increased risk of adverse outcomes for their children. Parents can, of course, be affected by more than one illness, and the risks to children’s development associated with multiple disorders can be greater than those associated with a single disorder. In the following section we consider some of the mechanisms by which this increased risk might operate; of particular note is the fact that the symptoms of many of these disorders will impact on parents’ psychosocial functioning and interfere with the demands of parenting (i.e., positive, sensitive and responsive parenting to facilitate child development). Examples of such symptoms include:

1. **Depression** – sadness, withdrawal and focus on negative aspects of life;
2. **Anxiety** – focus on the perception of threat in the environment;
3. **Schizophrenia and other psychotic disorders** – delusions, abnormal beliefs about a range of issues especially paranoid ones; and
4 Alcoholism – unpredictability and the potential impact as well on socioeconomic circumstances.

It is not difficult to see how some of these patterns of behavior can interfere with optimal parenting. The recurrent hospital admissions and separations associated with severe illness further affect normal parenting functioning. However, it is worth stressing two further points. First, many children manage well in the face of these adversities and so there is also need to consider this in any model of mechanisms and risk indicators. Second, there are other mechanisms by which these disorders exert their influence through the generations. We move now to consider these.

Overview and Introduction to Mechanisms

The previous section has outlined the increased risks (of psychopathology and other social, cognitive, emotional and behavioral disturbances) experienced by the children of parents with a range of psychiatric and physical disorders. The nature of transmission of this increased risk is clearly complex and multifactorial. The fact that many children of parents with disorders do not develop problems themselves is testimony to the fact that the associations seen are not deterministic, but rely on a number of risk factors coming together. There is strong evidence that as the number of risk factors accumulate for children, the likelihood that they will develop psychological disturbance dramatically increases. Rutter (1999) has shown the synergistic effects of multiple risk factors on adverse child outcome. Nonetheless, it is important, both clinically and scientifically, to elucidate as precisely as we are able the exact mechanisms underlying intergenerational transmission of risk. This allows us to better identify potential points of intervention, as well as increasing our understanding of the disorders themselves. Recent years have seen significant advances in our understanding of how genetic risks operate in different circumstances and interact with environmental factors (Rutter, Moffitt, & Caspi, 2006) and also in our understanding of how important environmental factors such as disturbances in parenting and marital conflict mediate the pathway between parental mental illness and child developmental disturbance (Cummings, Keller, & Davies, 2005).

The following sections attempt to disentangle a number of these potential mechanisms while recognizing that, in reality, they frequently co-occur and interact with one another (Rutter, 1989). Although genetic mechanisms are referred to first, the focus is predominantly on environmental mechanisms as, although they may not always be the strongest influence in absolute terms (depending on the condition in question and the developmental stage of the child or adolescent), they are the factors that are more amenable to intervention in the current clinical context.

Genetic Mechanisms

Decades of research have shown that children of parents with severe psychiatric disorders such as schizophrenia, bipolar disorder and depression are at increased risk for those disorders. This is not unique to psychiatric disorders, as many physical illnesses such as asthma and heart disease also show familial transmission. Twin studies and adoption studies have consistently demonstrated this increased risk and pointed to a significant genetic component, but have also shown that the risk is variable. For example, not all children with a parent with schizophrenia will develop schizophrenia. Recent developments in research have begun to explain why some of this variability occurs, including research on epigenetic effects, whereby other factors, both genetic and environmental, moderate the expression of genes (for a fuller description see chapter 23). In addition, the variability is different for different disorders. For example, bipolar disorder has a relatively high genetic risk for the offspring of affected parents (Henin et al., 2005), while anxiety disorders carry a smaller genetic risk (Gordon & Hen, 2004). Earlier attempts to identify individual genes for psychiatric disorder, and thereby account for the apparent increased genetic risk to children of parents with psychiatric disorder, proved disappointing, with the realization that effects of multiple genes are likely to be involved in the majority of cases. In recent years there has also been an increased recognition of the complex interplay of genetic and environmental effects. These facets of gene–environment interplay are addressed later in this chapter (see p. 413).

Environmental Mechanisms

Many of the environmental mechanisms of transmission of risk from parents with disorder to their children have been most clearly elucidated in the field of mood and anxiety disorders, and so examples will be used from this field of research. However, many of the same mechanisms may operate in other conditions, and while these will not be exhaustively referred to here, other studies are available (Patel, Wheatcroft, Park et al., 2002; Rutter, 1989). Here, antenatal effects are considered first, followed by the associations of parental psychiatric disorder with parent–child interaction, and with marital functioning. The direct involvement of children in the symptoms of the parent’s psychopathology is considered, followed by some of the methodological complexities of elucidating these mechanisms. Finally, both gender-specific and age-dependent associations are briefly considered.

Antenatal Effects

It has been apparent for many years that alcohol and drugs (including some prescribed drugs) can have a dramatic and enduring effect on fetal development. High levels of alcohol consumption by pregnant women are associated with an outcome for a newborn child characterized as fetal alcohol syndrome (Mukherjee, Hollins, & Turk, 2006). It has been more difficult to demonstrate whether lower levels of alcohol consumption lead to increased risks for the developing fetus. Other drugs, such as opiates and cocaine, can also have a significant effect on fetal development in the short and longer
CHAPTER 27

term (Bennett, Bendersky, & Lewis, 2002). Exposure in the form of maternal smoking is also associated with adverse outcomes, including low birth weight. These risk factors are likely to exert their influence by a variety of mechanisms. Animal research suggests that this may include direct brain effects of the substance and other effects; for example, fetal hypoxia in the case of smoking (Chiriboga, 2003).

Over a decade ago the Barker hypothesis (that a substantial proportion of the risk for adult disorders such as coronary heart disease was determined by the in utero environment and antenatal development) had a dramatic effect on the way in which risk for these disorders, and their etiology, was considered (Barker, Osmond, Rodin et al., 1995). This did not have a major impact on thinking about psychiatric disorders at the time, although animal models began to demonstrate that stress in pregnancy had potentially lasting effects on the developing infant. More recently, epidemiological evidence has demonstrated an association between high levels of anxiety in pregnancy and an increased risk of behavioral problems in children (O’Connor, Heron, Golding et al., 2003). It seems likely that the mechanism of risk operates through an effect in pregnancy on the hypothalamic–pituitary–adrenal (HPA) axis of the developing fetus. The finding of high levels of cortisol in these children at older ages lends some support to this notion (O’Connor, Ben-Shlomo, Heron et al., 2005), although other mechanisms, such as reduced placental blood flow in response to stress, are also possible. This had led to some enthusiastic calls for antenatal intervention although, given the relatively small size of the associations, it is probably too early to be advocating widespread interventions aimed at reducing anxiety in pregnant women. It may be that the identification of women with particularly high levels of anxiety in pregnancy becomes warranted, especially given that this is also a clear risk marker for postnatal depression. It is less clear whether depression occurring in the antenatal period is also associated with increased risks for the developing child. One study found that, while maternal depression occurring antenatally was associated with an increased risk of conduct disorder in children, depression in the antenatal period was not (Kim-Cohen, Moffitt, Taylor et al., 2005). Further studies using similar designs are likely to prove informative.

Postnatal Psychiatric Disorder and Parent–Child Interaction
Depression in mothers occurring in the postnatal period has become one of the most studied psychiatric phenomena in recent years, and a substantial body of work has now examined the links between postnatal depression and child development (see for example Murray & Cooper, 2003). It should come as no surprise that the cardinal features of depression (i.e., low mood, low energy and loss of interest or enjoyment in activities) have the potential to have an important impact on a mother’s parenting abilities. Postnatal depression is associated with significant changes in the patterns of interaction between mothers and their infants. Most notable are a decrease in positive parenting behaviors by mothers, and an increase in negative and intrusive interactions (Field, Healy, Goldstein et al., 1988; Murray et al., 1996a; Stein, Gath, Bucher et al., 1991). These alterations in maternal sensitivity and responsiveness are associated with adverse subsequent cognitive development in the children (Murray et al., 1996a). The exact mechanisms remain somewhat uncertain, but it seems likely that the decrease in parental stimulation and appropriate contingent response decreases learning opportunities for the infant at a crucial stage of development early in life. A lack of appropriate emotional responsiveness, and particularly the occurrence of negative or hostile interactions, may similarly interfere with the development of child emotion regulation, and affect subsequent peer interactions and other emotional development, including vulnerability to depression (Murray, Woolgar, Cooper et al., 2001).

Although other psychiatric disorders affecting mothers in the postnatal period have been less extensively studied, the links between eating disorders and mothers’ interactions with their infants at mealtimes have been characterized (Stein, Woolley, & McPherson, 1999). Mothers with eating disorders have been shown to be less facilitating and more intrusive than control mothers when interacting with their infants at mealtimes. Finally, research is emerging on the links between maternal anxiety disorder and potentially adverse mother–infant interactions; for example, mothers with social phobia show particular difficulties in supporting their infant’s interactions with other people, partly by “modeling” their fearful responses to unfamiliar people, and also by being less actively facilitating of the infant’s contact with them. Such responses in turn affect the development of infant social responsiveness (Murray, Cooper, Creswell et al., 2007). In a community sample, mothers with higher anxiety were found to be less responsive to their infants during interaction than mothers with lower anxiety (Nicol-Harper, Harvey, & Stein, 2007).

There has been far less research examining the associations between psychiatric disorder in fathers and their children’s early development (Ramchandani, Stein, Evans et al., 2005), and less still on any effects of disorder on their interactions with their infants (Field, Hossain, & Malphurs, 1999). Most of these studies have been small and so it is difficult to draw any firm conclusions. The wider literature on paternal influences suggests that there may be specific differences between the effects of psychiatric disorder in mothers and fathers, both in terms of the areas of functioning affected and relative gender specificity. However, the precise nature of the operation of these effects has yet to be elucidated.

Psychiatric Disorder and Parental Relationships
The effects of psychiatric disorder on a parent’s functioning are pervasive, so it is no surprise that parents’ own relationships are affected by disorders such as depression occurring in either parent. Indeed, depression is clearly associated with an increased risk of marital problems (Cummings, Keller, & Davies, 2005), and can have a direct effect on the mood and functioning of the other parent. This has importance as a mechanism by which parental disorder impacts upon children in
two ways. First, where one parent is depressed, having a second parent who is well can have a protective effect upon the child. In contrast, having a second depressed parent can have a double-dosing effect on a child, as well as depriving them of a potentially “protective” well parent (Goodman & Gotlib, 1999). Second, exposure to marital conflict is a clear risk factor for an increased risk of behavioral problems in children (perhaps particularly in boys), and so this is another pathway by which the effects of parental depression can affect children’s development. Although less well studied, the effects of parental alcohol and drug misuse, as well as antisocial personality traits, may also operate strongly through a deleterious effect on the marital relationship. In addition, many psychiatric disorders are associated with an increased risk of marital breakdown, leading in many cases to dislocated relationships for the child, and exposure to other risk factors such as increased socioeconomic adversity.

**Direct Involvement of the Child in the Parental Psychopathology**

This refers to the situation where a child becomes a role-player in the parent’s own psychopathology. At its most extreme, it might mean the child becoming involuntarily involved in a homicide/suicide where a severely depressed parent includes the child in their own death because of extreme hopelessness about the future. Children can also become the focus of other parental delusional beliefs, or incorporated into other parental psychopathology such as obsessions.

**Bidirectional Effects and Confounding Effects**

All of the mechanisms outlined above assume a single direction of causality. That is, the parental psychiatric disorder leads to the marital dysfunction or the eventual disturbance in the child. In reality, of course, the picture is more complex than this. Clearly, just as parents can influence their children, so children can also affect their parents (Yarrow, Campbell, & Burton, 1968). For example, children with severe disabilities place greater demands upon the parenting capacity of any parent, and so higher rates of some disorders such as depression might be expected in parents in these circumstances. A second example is that more difficult temperamental characteristics in infants are associated with a higher risk of depression for their mothers (Murray, Stanley, Hooper et al., 1996c). So, these effects can be bidirectional. In addition, other factors, such as socioeconomic deprivation, may confound the relationships seen between parental illness and child development problems, as both the parental and the child problems may be more common in situations of socioeconomic stress. These confounding factors may be very important to consider; nonetheless, there remains a substantial body of research pointing to a very real influence of parental illness on the various domains of child development, as outlined above.

**Gene–Environment Interplay**

The complex area of gene–environment interplay has become one of the most exciting areas of developmental science and, while there are few implications of direct clinical relevance from this work at present, it is likely to be influential in the thinking about the development of psychiatric disorder in children and adolescents in the years ahead (see chapter 23). Rutter, Moffitt, & Caspi (2006) have provided an extensive review of the current state of the research area. There are three mechanisms of interplay between genetic and environmental factors that seem particularly promising.

The first is the process whereby genes can affect the types of environments in which children (and adults) find themselves. This is known as gene–environment *correlation*, and can refer to both child and parental genes. For example, twin studies have shown that genes are implicated in individual differences in exposure to a wide range of environments having important associations with psychopathology (Rutter, 2007; Rutter, Moffitt, & Caspi, 2006).

The second mechanism is what is called gene–environment *interactions* (see chapter 23). Recent examples of this include the finding of an interaction between a polymorphism of the serotonin transporter gene and stressful life events, leading to increased risk of depression. Carriers of the shorter alleles of the serotonin transporter gene (conferring increased risk) are only at higher risk of subsequent depression in the presence of stressful life events (Caspi, Sugden, Moffitt et al., 2003). These findings have been confirmed in some, but not all, subsequent studies to examine this question. Gene–environment interactions have been described in other areas of psychopathology. The gene encoding for higher levels of monoamine oxidase A (MAOA) is found to moderate the strong association between exposure to maltreatment as a child and subsequent antisocial behavior (Caspi, McClay, Moffitt et al., 2002). In addition, a variant of the catechol-O-methyltransferase (COMT) gene is found to interact with low birth weight to predict conduct problems in a high-risk group of children (Thapar, Langley, Fowler et al., 2005).

The third area of gene–environmental interplay is that of *epigenetic* effects, which is where environmental factors exert a clear influence on the expression of genes. So, without altering the DNA itself, they nonetheless affect how genes then code for specific proteins, and so effectively alter the function of the genes. The mechanisms are described in chapter 23. Most of the current research of relevance to child psychosocial development is occurring with animals, with Canadian researchers identifying early maternal nurturing (licking and grooming behavior) in rodents as having a direct impact on the genetic expression of genes related to the HPA axis (Weaver, Cervoni, Champagne et al., 2004). Although it is not yet clear how directly applicable to early nurturant behavior in humans this research is, it does point the way to potentially promising avenues of research in understanding the effects of adverse early experience in increasing the risk of mood disorders in developing children and adolescents. Our understanding of these important areas of interplay between genes and environmental risk factors is likely to grow hugely in the years ahead.
CHAPTER 27

Gender

There are three types of gender effects to consider here, at a parental level (mother versus father), at a child level (boy versus girl vulnerability) and the interaction between the two (e.g., mother–daughter versus mother–son associations, or similar father–child associations). There is an increasing literature on the role of the father in normative child development (Tamis-LeMonda, Shannon, Cabrera et al., 2004); however, the quantity of research addressing the role of paternal psychopathology is far more limited. The range of psychopathology experienced by fathers differs from that of mothers (the higher rates of alcohol and antisocial disorders in fathers compare with the higher rates of anxiety and depression in mothers). It follows that the types of psychopathology that a child is exposed to in different parents will thus differ at the population level. This may account for some of the difference in associations seen with maternal versus paternal psychopathology. But what of exposure to the same disorder in mothers or fathers? Limited work suggests that this may result in differing effects for the child. For example, depression in fathers is more specifically linked with behavioral problems in children, whereas exposure to maternal depression has more diffuse associations with child psychopathology (Ramchandani, Stein, Evans et al., 2005). This raises the question of potentially differing mechanisms by which maternal and paternal psychopathology might impact on children. Two particular candidates are direct parent–child interaction and the effects of psychopathology on the parents’ own relationship. Mothers and fathers have different amounts and types of direct interaction with their children (with fathers typically less involved, but spending more of their limited time with their children in play; Tamis-LeMonda et al., 2004). This may moderate the exposure that children have to psychopathology. Work on antisocial behavior in fathers suggests that this may well be the case (Jaffee, Moffitt, Caspi et al., 2003). In addition to these direct links with parent–child interaction, less direct mechanisms may operate. For example, depression is strongly associated with an increase in marital conflict, and exposure to this conflict is linked, in turn, to increased rates of child behavioral problems.

There are conflicting results regarding the differences seen in boys and girls. Some, but by no means all, research on postnatal depression in mothers has shown an increased risk for boys compared with girls, in terms of their cognitive performance (Hay et al., 2001; Murray et al., 1993). Whether this is because of the increased vulnerability of boys to a range of risks for their neurocognitive development, or whether there is a degree of specificity in the risk from factors like parental depression is as yet unclear. Although there is little research comparing specific risk pathways from mothers to daughters versus mothers to sons and father–son versus father–daughter risks, there are suggestions that boys may be more particularly at risk to paternal depression and other paternal psychopathology (Ramchandani et al., 2005).

Developmental or Age-Specific Effects

There is an assumption that children and adolescents will be more vulnerable to the potential impact of parental depression at two particular points in their life: the postnatal period and adolescence. During the immediate postnatal period, infants are rapidly developing, with enormous brain growth (Gale, O’Callaghan, Godfrey et al., 2004), and, in spite of their immaturity, young infants are highly sensitive to the quality of other people’s interactions with them. Infants are therefore extremely vulnerable to the effects of any factor, such as depression, that impairs the ability of their caregiver to give optimum care. During adolescence, a large number of crucial developmental changes occur, both physiological and psychosocial. This is also the time when the common emotional disorders, such as depression, begin to significantly increase in prevalence. Research has confirmed the association between parental depression and increased risk to children and adolescents in both the postnatal period (Murray & Cooper, 2003) and adolescence (Beardslee, Versage, & Gladstone, 1998; Halligan, Murray, Martins et al., 2007). It is apparent that children present with different symptoms and disorders at different ages, despite exposure to the same parental disorder (Radke-Yarrow, 1998). It remains somewhat unclear whether this is a result of the naturally changing patterns of psychopathology seen as children develop, or whether there are different effects because the exposure to a similar parental psychopathology has a differential impact itself at different ages.

Clinical Implications

There is a substantial research literature on the treatment of children who are themselves diagnosed with a disorder. However, the question of treatment in the case of offspring who may be at risk for developmental problems by virtue of psychiatric disorder in their parents has received relatively little attention. Nevertheless, this is an important topic for research, not only because of the clinical implications, but also because treatment research can help scientifically in elucidating the factors that explain the process of development in these populations.

The few studies there are have principally addressed the question in relation to parental depression. One study of 7- to 17-year-old children whose mothers were simply treated with antidepressant medication found that maternal remission within 3 months (occurring in approximately one-third of women) was associated with a significant decrease in child and adolescent disorder and symptoms, particularly of the emotional variety (Weissman, Pilowsky, Wickramaratne et al., 2006). A similar association of symptom reduction in the parent with better child outcome in this age group was found in a study conducted by Beardslee and colleagues (Beardslee & Gladstone, 2001; Beardslee, Gladstone, Wright et al., 2003), where psycho-educational support was directed to the whole family. An intervention with somewhat older children (13- to
18-year-olds) found, by contrast, that the involvement of parents in a psycho-educational group program that was principally directed at the adolescents themselves was of no additional benefit (Clarke, Hornbrook, Lynch et al., 2002). Together these studies suggest that involvement of the affected parent in treatment might be more important when children are younger, and become less critical as they reach later adolescence.

With regard to infants and toddlers of depressed mothers, some benefits of treatment in terms of maternal reports of problem behavior in the children have been found. In one trial, maternal reports of child attachment security improved with an attachment-oriented toddler–parent psychotherapy delivered over a 1-year period (Cicchetti, Toth, & Rogosch, 1999). Similarly, brief (2 month) psychological treatments for postnatally depressed mothers, whether counseling, cognitive–behavioral therapy (CBT) or a dynamic therapy, were associated with maternal reports of a reduction of problems in the relationship with the infant immediately after treatment, and at 18-month follow-up there were benefits in terms of reported infant behavior problems (Murray, Cooper, Wilson et al., 2003a). Nevertheless, other outcomes in this study showed no benefit of the interventions, and there was no long-term benefit (5 year) on any measure, including the recurrence of maternal depression.

A number of imaginative interventions have been designed by Field and colleagues to target infants of depressed mothers in high-risk groups; these have included infant massage (Field, 1995), giving support to mothers in observing infant responses (Hart, Field, & Nearing, 1998), and coaching in relation to specific aspects of problematic mother–infant interactions (Malphurs, Field, Larraine et al., 1996). While all appeared to result in improvements at the time they were delivered, whether they can bring about longer-term benefits is still unclear. Infant massage has subsequently been shown to be associated with improved mother–child interaction and infant sleeping in studies of non-depressed parents (Underdown, Barlow, Chung et al., 2006). Long-term monitoring and treatment may be necessary, however, because postnatal depression is associated with recurrent episodes (Cooper & Murray, 1995; Halligan, Murray, Martins et al., 2007), even if successfully treated at the time (Cooper, Murray, Wilson et al., 2003), and because chronicity is an important predictor of several child outcomes.

Treatment aimed at reducing risk to offspring in the context of maternal eating disorder has been examined in only one study. Stein et al. (2006) evaluated a treatment delivered over 13 sessions which used video feedback to help mothers with an eating disorder become more aware of, and responsive to, their infant’s behavior during feeding. Post-treatment assessments showed benefits in terms of reduced rates of mother–child conflict, enhanced maternal facilitation of infant behavior and increased infant autonomy compared to a counseling control group. Both groups maintained good infant weight with no differences between them.

With regard to parental anxiety disorder, no direct evidence is available concerning the implications for the children of treatment. The facts that risk for disorder in the offspring of affected parents is substantial, and that a number of parenting dimensions are implicated in intergenerational transmission of disorder, make it important to conduct treatment research in this area.

A considerable practical challenge when considering treatment from the point of view of the offspring of parents affected by psychiatric disorder is that secondary adult clinical services are often not sufficiently well co-ordinated with child and adolescent mental health teams to take on board the issue of risk to offspring. With regard to community, as opposed to clinic, populations, somewhat different problems are posed, the most notable being that depressed parents may not be motivated to seek treatment, either for themselves or their children. With regard to treatment in the postpartum period, although good tools have been developed for primary health care workers to screen for depression, such as the Edinburgh Postnatal Depression Scale (Cox, Holden, & Sagovsky, 1987), the detection and identification of the disorder have been quite poor, especially in the early postpartum weeks. Furthermore, those who are likely to be at greatest risk for parenting difficulties associated with depression may be the least willing to take up interventions (Murray, Woolgar, Murray et al., 2003b).

A helpful overall framework for assessing the potential risks to children where a parent has a psychiatric disorder is provided by Rutter (1989). It is wise not to assume risk to children purely because their parent has a psychiatric disorder. Careful assessment should include the areas most likely to be affected by the parental disorder. These are outlined above, but include specific deficits in parental interaction with their children, the quality and type of care the parent is able to provide, and the presence of family and marital discord. The specific feelings that an affected parent has towards their child (or children) can be discussed. Review of these factors over the past history, as well as at the present time, can give useful insight into any potential areas of difficulty that may exist. A thorough and individualized assessment of this kind will be the best guide to the areas where intervention (if required) is most likely to be of benefit.

Clinicians can also have a practical, positive role in providing support, information and, if necessary, treatment to parents affected by psychiatric disorder. The establishment of close collaborative links with adult psychiatric services is likely to lead to the most positive outcomes for families where a parent has chronic severe psychiatric difficulties, but this is not always possible, either because such services are not readily available, or because of differences in thresholds for accepting referrals. Nevertheless, there is sufficient clinical knowledge, and an evidence base (Cobham, Dadds, & Spence, 1998; Sonuga-Barke, Daley, & Thompson, 2002; Weissman et al., 2006) to suggest that treating parental psychiatric difficulties will, in many cases, lead to better outcomes for the child and family, even when it is a child in the family who is presenting to health services. This is now being recognized in treatment guidelines; for example, the UK guidelines for the
treatment of depression in children and young people specifically identify the assessment of parental mood as part of the clinical assessment (NICE, 2005). Indeed, in some circumstances, this is a critical part of case management and, without it, children’s recovery may be hampered (Cooper, Fearn, Willetts et al., 2006). What then to do in terms of treatment is sometimes a difficult clinical judgment. When the ideal circumstance of close joint management with adult services is not available, a clinician might be able to liaise with the parent’s general practitioner, but in some circumstances provision of treatment directly to the parent within the child and adolescent mental health setting may be the best course of action. The crucial point is to remember to assess, recognize and arrange appropriate management of parental difficulties, as well as the child’s presenting problem.
